displays the contribution to the total chi-square test statistic for each cell. See also the descriptions of the DEVIATION, EXPECTED, and OBSERVED options.
COLUMN=B | BD | DB | DBD | DBD1/2 | DBID1/2
COL=B | BD | DB | DBD | DBD1/2 | DBID1/2

provides other standardizations of the column coordinates. The COLUMN= option is rarely needed. Typically, you should use the PROFILE= option instead (see the section “The PROFILE=, ROW=, and COLUMN= Options” on page 1099). By default, COLUMN=DBD.

CP
displays the column profile matrix. Column profiles contain the observed conditional probabilities of row membership given column membership. See also the RP option.

CROSS=BOTH | COLUMN | NONE | ROW
CRO=BOT | COL | NON | ROW

specifies the method of crossing (factorially combining) the levels of the TABLES variables. The default is CROSS=NONE.

- CROSS=NONE causes each level of every row variable to become a row label and each level of every column variable to become a column label.
- CROSS=ROW causes each combination of levels for all row variables to become a row label, whereas each level of every column variable becomes a column label.
- CROSS=COLUMN causes each combination of levels for all column variables to become a column label, whereas each level of every row variable becomes a row label.
- CROSS=BOTH causes each combination of levels for all row variables to become a row label and each combination of levels for all column variables to become a column label.

The “TABLES Statement” section on page 1081 provides a more detailed description of this option.

DATA=SAS-data-set
specifies the SAS data set to be used by PROC CORRESP. If you do not specify the DATA= option, PROC CORRESP uses the most recently created SAS data set.

DEVIAITION | DEV
displays the matrix of deviations between the observed frequency matrix and the product of its row marginals and column marginals divided by its grand frequency. For ordinary two-way contingency tables, these are the observed minus expected frequencies under the hypothesis of row and column independence and are components of the chi-square test statistic. See also the CELLCHI2, EXPECTED, and OBSERVED options.

DIMENS=n
DIM=n

specifies the number of dimensions or axes to use. The default is DIMENS=2. The maximum value of the DIMENS= option in an \((n_r \times n_c)\) table is \(n_r - 1\) or \(n_c - 1\), whichever is smaller. For example, in a table with 4 rows and 5 columns, the
maximum specification is DIMENS=3. If your table has 2 rows or 2 columns, specify DIMENS=1.

**EXPECTED | EXP**

displays the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence and are components of the chi-square test statistic. In other situations, this interpretation is not strictly valid. See also the CELLCHI2, DEVIATION, and OBSERVED options.

**FREQOUT | FRE**

indicates that the PROC CORRESP input data set has the same form as an output data set from the FREQ procedure, even if it was not directly produced by PROC FREQ. The FREQOUT option enables PROC CORRESP to take shortcuts in constructing the contingency table.

When you specify the FREQOUT option, you must also specify a WEIGHT statement. The cell frequencies in a PROC FREQ output data set are contained in a variable called COUNT, so specify COUNT in a WEIGHT statement with PROC CORRESP. The FREQOUT option may produce unexpected results if the DATA= data set is structured incorrectly. Each of the two variable lists specified in the TABLES statement must consist of a single variable, and observations must be grouped by the levels of the row variable and then by the levels of the column variable. It is not required that the observations be sorted by the row variable and column variable, but they must be grouped consistently. There must be as many observations in the input data set (or BY group) as there are cells in the completed contingency table. Zero cells must be specified with zero weights. When you use PROC FREQ to create the PROC CORRESP input data set, you must specify the SPARSE option in the FREQ procedure’s TABLES statement so that the zero cells are written to the output data set.

**GREENACRE | GRE**

displays adjusted inertias when performing multiple correspondence analysis. By default, unadjusted inertias, the usual inertias from multiple correspondence analysis, are displayed. However, adjusted inertias using a method proposed by Greenacre (1994, p. 156) can be displayed by specifying the GREENACRE option. Specify the UNADJUSTED option to output the usual table of unadjusted inertias as well. See the section “MCA Adjusted Inertias” on page 1102 for more information.

**MCA**

requests a multiple correspondence analysis. This option requires that the input table be a Burt table, which is a symmetric matrix of crosstabulations among several categorical variables. If you specify the MCA option and a VAR statement, you must also specify the NVARS= option, which gives the number of categorical variables that were used to create the table. With raw categorical data, if you want results for the individuals as well as the categories, use the BINARY option instead.
**MININERTIA=n**

MIN=n

specifies the minimum inertia \((0 \leq n \leq 1)\) used to create the “best” tables—the indicator of which points best explain the inertia of each dimension. By default, MININERTIA=0.8. See the “Algorithm and Notation” section on page 1097 for more information.

**MISSING | MIS**

specifies that observations with missing values for the TABLES statement variables are included in the analysis. Missing values are treated as a distinct level of each categorical variable. By default, observations with missing values are excluded from the analysis.

**NOCOLUMN <= BOTH | DATA | PRINT >**

NOC < = BOT | DAT | PRI >

suppresses the display of the column coordinates and statistics and omits them from the output coordinate data set.

- BOTH suppresses all column information from both the SAS listing and the output data set. The NOCOLUMN option is equivalent to the option NOCOLUMN=BOTH.
- DATA suppresses all column information from the output data set.
- PRINT suppresses all column information from the SAS listing.

**NOPRINT | NOP**

suppresses the display of all output. This option is useful when you need only an output data set. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

**NOROW <= BOTH | DATA | PRINT >**

NOR <= BOT | DAT | PRI >

suppresses the display of the row coordinates and statistics and omits them from the output coordinate data set.

- BOTH suppresses all row information from both the SAS listing and the output data set. The NOROW option is equivalent to the option NOROW=BOTH.
- DATA suppresses all row information from the output data set.
- PRINT suppresses all row information from the SAS listing.

The NOROW option can be useful when the rows of the contingency table are replications.

**NVARS=\(n\)**

NVA=\(n\)

specifies the number of classification variables that were used to create the Burt table. For example, if the Burt table was originally created with the statement
tables a b c;

you must specify NVARS=3 to read the table with a VAR statement.

The NVARS= option is required when you specify both the MCA option and a VAR statement. (See the section “VAR Statement” on page 1081 for an example.)

**OBSERVED | OBS**

displays the contingency table of observed frequencies and its row, column, and grand totals. If you do not specify the OBSERVED or ALL option, the contingency table is not displayed.

**OUTC=SAS-data-set**

**OUT=SAS-data-set**

creates an output coordinate SAS data set to contain the row, column, supplementary observation, and supplementary variable coordinates. This data set also contains the masses, squared cosines, quality of each point’s representation in the DIMENS=n dimensional display, relative inertias, partial contributions to inertia, and best indicators.

**OUTF=SAS-data-set**

creates an output frequency SAS data set to contain the contingency table, row, and column profiles, the expected values, and the observed minus expected values and contributions to the chi-square statistic.

**PRINT=BOTH | FREQ | PERCENT**

**PRI=BOT | FRE | PER**

affects the OBSERVED, RP, CP, CELLCHI2, EXPECTED, and DEVIATION options. The default is PRINT=FREQ.

- The PRINT=FREQ option displays output in the appropriate raw or natural units. (That is, PROC CORRESP displays raw frequencies for the OBSERVED option, relative frequencies with row marginals of 1.0 for the RP option, and so on.)
- The PRINT=PERCENT option scales results to percentages for the display of the output. (All elements in the OBSERVED matrix sum to 100.0, the row marginals are 100.0 for the RP option, and so on.)
- The PRINT=BOTH option displays both percentages and frequencies.

**PROFILE=BOTH | COLUMN | NONE | ROW**

**PRO=BOT | COL | NON | ROW**

specifies the standardization for the row and column coordinates. The default is PROFILE=BOTH.

PROFILE=BOTH specifies a standard correspondence analysis, which jointly displays the principal row and column coordinates. Row coordinates are computed from the row profile matrix, and column coordinates are computed from the column profile matrix.
PROFILE=ROW specifies a correspondence analysis of the row profile matrix. The row coordinates are weighted centroids of the column coordinates.

PROFILE=COLUMN specifies a correspondence analysis of the column profile matrix. The column coordinates are weighted centroids of the row coordinates.

PROFILE=NONE is rarely needed. Row and column coordinates are the generalized singular vectors, without the customary standardizations.

ROW=A | AD | DA | DAD | DAD1/2 | DAID1/2 provides other standardizations of the row coordinates. The ROW= option is rarely needed. Typically, you should use the PROFILE= option instead (see the section “The PROFILE=, ROW=, and COLUMN= Options” on page 1099). By default, ROW=DAD.

RP displays the row profile matrix. Row profiles contain the observed conditional probabilities of column membership given row membership. See also the CP option.

SHORT | SHO suppresses the display of all point and coordinate statistics except the coordinates. The following information is suppressed: each point’s mass, relative contribution to the total inertia, and quality of representation in the DIMENS=n dimensional display; the squared cosines of the angles between each axis and a vector from the origin to the point; the partial contributions of each point to the inertia of each dimension; and the best indicators.

SINGULAR=n
SIN=n specifies the largest value that is considered to be within rounding error of zero. The default value is 1E−8. This parameter is used when checking for zero rows and columns, when checking Burt table diagonal sums for equality, when checking denominators before dividing, and so on. Typically, you should not assign a value outside the range 1E−6 to 1E−12.

SOURCE | SOU adds the variable _VAR_, which contains the name or label of the variable corresponding to the current level, to the OUTC= and OUTF= data sets.

UNADJUSTED | UNA displays unadjusted inertias when performing multiple correspondence analysis. By default, unadjusted inertias, the usual inertias from multiple correspondence analysis, are displayed. However, if adjusted inertias are requested by either the GREENACRE option or the BENZECRI option, then the unadjusted inertia table is not displayed unless the UNADJUSTED option is specified. See the section “MCA Adjusted Inertias” on page 1102 for more information.
**BY Statement**

```
BY variables;
```

You can specify a BY statement with PROC CORRESP to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the CORRESP procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**ID Statement**

```
ID variable;
```

You specify the ID statement only in conjunction with the VAR statement. You cannot specify the ID statement when you use the TABLES statement or the MCA option. When you specify an ID variable, PROC CORRESP labels the rows of the tables with the ID values and places the ID variable in the output data set.

**SUPPLEMENTARY Statement**

```
SUPPLEMENTARY variables;
SUP variables;
```

The SUPPLEMENTARY statement specifies variables that are to be represented as points in the joint row and column space but that are not used when determining the locations of the other, active row and column points of the contingency table. Supplementary observations on supplementary variables are ignored in simple correspondence analysis but are needed to compute the squared cosines for multiple correspondence analysis. Variables that are specified in the SUPPLEMENTARY statement must also be specified in the TABLES or VAR statement.

When you specify a VAR statement, each SUPPLEMENTARY variable indicates one supplementary column of the table. Supplementary variables must be numeric with VAR statement input.
When you specify a TABLES statement, each SUPPLEMENTARY variable indicates a set of rows or columns of the table that is supplementary. Supplementary variables can be either character or numeric with TABLES statement input.

**TABLES Statement**

```plaintext
TABLES < row-variables, > column-variables ;
```

The TABLES statement instructs PROC CORRESP to create a contingency table, Burt table, or binary table from the values of two or more categorical variables. The TABLES statement specifies classification variables that are used to construct the rows and columns of the contingency table. The variables can be either numeric or character. The variable lists in the TABLES statement and the CROSS= option together determine the row and column labels of the contingency table.

You can specify both row variables and column variables separated by a comma, or you can specify only column variables and no comma. If you do not specify row variables (that is, if you list variables but do not use the comma as a delimiter), then you should specify either the MCA or the BINARY option. With the MCA option, PROC CORRESP creates a Burt table, which is a crosstabulation of each variable with itself and every other variable. The Burt table is symmetric. With the BINARY option, PROC CORRESP creates a binary table, which consists of one row for each input data set observation and one column for each category of each TABLES statement variable. If the binary matrix is $Z$, then the Burt table is $Z'Z$.

Specifying the BINARY option with the NOROWS option produces the same results as specifying the MCA option (except for the chi-square statistics).

See Figure 24.3 for an example or see the section “The MCA Option” on page 1101 for a detailed description of Burt tables.

You can use the WEIGHT statement with the TABLES statement to read category frequencies. Specify the SUPPLEMENTARY statement to name variables with categories that are supplementary rows or columns. You cannot specify the ID or VAR statement with the TABLES statement.

See the section “Using the TABLES Statement” on page 1088 for an example.

**VAR Statement**

```plaintext
VAR variables ;
```

You should specify the VAR statement when your data are in tabular form. The VAR variables must be numeric. The VAR statement instructs PROC CORRESP to read an existing contingency table, binary indicator matrix, fuzzy-coded indicator matrix, or Burt table, rather than raw data. See the “Algorithm and Notation” section on page 1097 for a description of a binary indicator matrix and a fuzzy-coded indicator matrix.

You can specify the WEIGHT statement with the VAR statement to read category frequencies and designate supplementary rows. Specify the SUPPLEMENTARY statement to name supplementary variables. You cannot specify the TABLES statement with the VAR statement.
WEIGHT Statement

`WEIGHT variable ;`

The WEIGHT statement specifies weights for each observation and indicates supplementary observations for simple correspondence analyses with VAR statement input. You can include only one WEIGHT statement, and the weight variable must be numeric.

If you omit the WEIGHT statement, each observation contributes a value of 1 to the frequency count for its category. That is, each observation represents one subject. When you specify a WEIGHT statement, each observation contributes the value of the weighting variable for that observation. For example, a weight of 3 means that the observation represents 3 subjects. Weight values are not required to be integers.

You can specify the WEIGHT statement with a TABLES statement to indicate category frequencies, as in the following example:

```plaintext
proc freq;
   tables a*b / out=outfreq sparse;
run;

proc corresp freqout;
   tables a, b;
   weight count;
run;
```

If you specify a VAR statement, you can specify the WEIGHT statement to indicate supplementary observations and to weight some rows of the table more heavily than others. When the value of the WEIGHT variable is negative, the observation is treated as supplementary, and the absolute value of the weight is used as the weighting value.

You cannot specify a WEIGHT statement with a VAR statement and the MCA option, because the table must be symmetric. Supplementary variables are indicated with the SUPPLEMENTARY statement, so differential weighting of rows is inappropriate.

Details

Input Data Set

PROC CORRESP can read two kinds of input:

- raw category responses on two or more classification variables with the TABLES statement
- a two-way contingency table with the VAR statement

You can use output from PROC FREQ as input for PROC CORRESP.

The classification variables referred to by the TABLES statement can be either numeric or character variables. Normally, all observations for a given variable that have
the same formatted value are placed in the same level, and observations with different values are placed in different levels.

The variables in the VAR statement must be numeric. The values of the observations specify the cell frequencies. These values are not required to be integers, but only those observations with all nonnegative, nonmissing values are used in the correspondence analysis. Observations with one or more negative values are removed from the analysis.

The WEIGHT variable must be numeric. Observations with negative weights are treated as supplementary observations. The absolute values of the weights are used to weight the observations.

Types of Tables Used as Input

The following example explains correspondence analysis and illustrates some capabilities of PROC CORRESP.

```plaintext
data Neighbor;
  input Name $ 1-10 Age $ 12-18 Sex $ 19-25 Height $ 26-30 Hair $ 32-37;
datalines;
  Jones     Old     Male     Short     White
  Smith     Young   Female    Tall     Brown
  Kasavitz  Old     Male     Short     Brown
  Ernst     Old     Female    Tall     White
  Zannoria  Old     Female    Short     Brown
  Spangel   Young   Male     Tall     Blond
  Myers     Young   Male     Tall     Brown
  Kasinski  Old     Male     Short     Blond
  Colman    Young   Female    Short     Blond
  Delafave  Old     Male     Tall     Brown
  Singer    Young   Male     Tall     Brown
  Igor      Old     Short
;
```

There are several types of tables, \( N \), that can be used as input to correspondence analysis — all tables can be defined using a binary matrix, \( Z \).

With the BINARY option, \( N = Z \) is directly analyzed. The binary matrix has one column for each category and one row for each individual or case. A binary table constructed from \( m \) categorical variables has \( m \) partitions. The following table has four partitions, one for each of the four categorical variables. Each partition has a 1 in each row, and each row contains exactly four 1s since there are four categorical variables. More generally, the binary design matrix has exactly \( m \) 1s in each row. The 1s indicate the categories to which the observation applies.

With the MCA option, the Burt table \((Z'Z)\) is analyzed. A Burt table is a partitioned symmetric matrix containing all pairs of crosstabulations among a set of categorical variables. Each diagonal partition is a diagonal matrix containing marginal frequencies (a crosstabulation of a variable with itself). Each off-diagonal partition is an ordinary contingency table. Each contingency table above the diagonal has a transposed counterpart below the diagonal.

</table>

This Burt table is composed of all pairs of crosstabulations among the variables Hair, Height, Sex, and Age. It is composed of sixteen individual subtables —the number of variables squared. Both the rows and the columns have the same nine categories (in this case Blond, Brown, White, Short, Tall, Female, Male, Old, and Young). The off-diagonal partitions are crosstabulations of each variable with every other variable. Below the diagonal are the following crosstabulations (from left to right, top to bottom): Height * Hair, Sex * Hair, Sex * Height, Age * Hair, Age * Height, and Age * Sex. Each crosstabulation below the diagonal has a transposed counterpart above the diagonal. Each diagonal partition contains a crosstabulation of a variable with itself (Hair * Hair, Height * Height, Sex * Sex, and Age * Age). The diagonal elements of the diagonal partitions contain marginal frequencies of the off-diagonal partitions.
For example, the table Hair * Height has three rows for Hair and two columns for Height. The values of the Hair * Height table, summed across rows, sum to the diagonal values of the Height * Height table, as displayed in the following table.

**Table 24.4.** \( Z_{\text{Hair,Height}} \) \( Z_{\text{Height}} \)

</tbody>
</table>

A simple crosstabulation of Hair × Height is \( N = Z_{\text{Hair}} Z_{\text{Height}} \). Crosstabulations such as this, involving only two variables, are the input to simple correspondence analysis.

**Table 24.5.** \( Z_{\text{Hair}} \) \( Z_{\text{Height}} \)

**Coding, Fuzzy Coding, and Doubling**

You can use an indicator matrix as input to PROC CORRESP using the VAR statement. An indicator matrix is composed of several submatrices, each of which is a design matrix with one column for each category of a categorical variable. In order
to create an indicator matrix, you must code an indicator variable for each level of each categorical variable. For example, the categorical variable `Sex`, with two levels (Female and Male), would be coded using two indicator variables.

A binary indicator variable is coded 1 to indicate the presence of an attribute and 0 to indicate its absence. For the variable `Sex`, a male would be coded `Female`=0 and `Male`=1, and a female would be coded `Female`=1 and `Male`=0. The indicator variables representing a categorical variable must sum to 1.0. You can specify the BINARY option to create a binary table.

Sometimes binary data such as Yes/No data are available. For example, 1 means “Yes, I have bought this brand in the last month” and 0 means “No, I have not bought this brand in the last month”.

title 'Doubling Yes/No Data';
proc format;
  value yn 0 = 'No' 1 = 'Yes';
run;
data BrandChoice;
  input a b c;
  label a = 'Brand A' b = 'Brand B' c = 'Brand B';
  format a b c yn.;
datalines;
  0 0 1
  1 1 0
  0 1 1
  0 1 0
  1 0 0;
;
Data such as these cannot be analyzed directly because the raw data do not consist of partitions, each with one column per level and exactly one 1 in each row. The data must be doubled so that both Yes and No are both represented by a column in the data matrix. The TRANSREG procedure provides one way of doubling. In the following statements, the DESIGN option specifies that PROC TRANSREG is being used only for coding, not analysis. The option SEPARATORS=':' specifies that labels for the coded columns are constructed from input variable labels, followed by a colon and space, followed by the formatted value. The variables are designated in the MODEL statement as CLASS variables, and the ZERO=NONE option creates binary variables for all levels. The OUTPUT statement specifies the output data set and drops the _NAME_, _TYPE_, and Intercept variables. PROC TRANSREG stores a list of coded variable names in a macro variable &TRGIND, which in this case has the value “aNo aYes bNo bYes cNo cYes”. This macro can be used directly in the VAR statement in PROC CORRESP.

proc transreg data=BrandChoice design separators=': ';
  model class(a b c / zero=none);
  output out=Doubled(drop=_: Intercept);
A fuzzy-coded indicator also sums to 1.0 across levels of the categorical variable, but it is coded with fractions rather than with 1 and 0. The fractions represent the distribution of the attribute across several levels of the categorical variable.

Ordinal variables, such as survey responses of 1 to 3 can be represented as two design variables.

**Table 24.7. Coding an Ordinal Variable**

<table>
<thead>
<tr>
<th>Ordinal Values</th>
<th>Coding</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.25</td>
</tr>
<tr>
<td></td>
<td>0.75</td>
</tr>
<tr>
<td>2</td>
<td>0.50</td>
</tr>
<tr>
<td></td>
<td>0.50</td>
</tr>
<tr>
<td>3</td>
<td>0.75</td>
</tr>
<tr>
<td></td>
<td>0.25</td>
</tr>
</tbody>
</table>

Values of the coding sum to one across the two coded variables.

This next example illustrates the use of binary and fuzzy-coded indicator variables. Fuzzy-coded indicators are used to represent missing data. Note that the missing values in the observation Igor are coded with equal proportions.

```
proc transreg data=Neighbor design cprefix=0;
  model class(Age Sex Height Hair / zero=none);
  output out=Neighbor2(drop=_: Intercept);
  id Name;
run;

data Neighbor3;
  set Neighbor2;
  if Sex = '' then do;
    Female = 0.5;
    Male   = 0.5;
  end;
  if Hair = '' then do;
    White = 1/3;
    Brown = 1/3;
    Blond = 1/3;
  end;
run;

proc print label;
run;
```
Figure 24.3. Fuzzy Coding of Missing Values

There is one set of coded variables for each input categorical variable. If observation 12 is excluded, each set is a binary design matrix. Each design matrix has one column for each category and exactly one 1 in each row.

Fuzzy-coding is shown in the final observation, Igor. The observation Igor has missing values for the variables Sex and Hair. The design matrix variables are coded with fractions that sum to one within each categorical variable.

An alternative way to represent missing data is to treat missing values as an additional level of the categorical variable. This alternative is available with the MISSING option in the PROC statement. This approach yields coordinates for missing responses, allowing the comparison of “missing” along with the other levels of the categorical variables.

Greenacre and Hastie (1987) discuss additional coding schemes, including one for continuous variables. Continuous variables can be coded with PROC TRANSREG by specifying BSPLINE(variables / degree=1) in the MODEL statement.

Using the TABLES Statement

In the following TABLES statement, each variable list consists of a single variable:

```
proc corresp data=Neighbor dimens=1 observed short;
   ods select observed;
   tables Sex, Age;
run;
```

These statements create a contingency table with two rows (Female and Male) and two columns (Old and Young) and show the neighbors broken down by age and sex. The DIMENS=1 option overrides the default, which is DIMENS=2. The OBSERVED option displays the contingency table. The SHORT option limits the displayed output. Because it contains missing values, the observation where Name='Igor' is omitted from the analysis. Figure 24.4 displays the contingency table.
The CORRESP Procedure

Figure 24.4. Contingency Table for Sex, Age

The following statements create a table with six rows (Blond*Short, Blond*Tall, Brown*Short, Brown*Tall, White*Short, and White*Tall), and four columns (Female, Male, Old, and Young). The levels of the row variables are crossed, forming mutually exclusive categories, whereas the categories of the column variables overlap.

```sas
proc corresp data=Neighbor cross=row observed short;
ods select observed;
tables Hair Height, Sex Age;
run;
```

Figure 24.5. Contingency Table for Hair * Height, Sex Age

You can enter supplementary variables with TABLES input by including a SUPPLEMENTARY statement. Variables named in the SUPPLEMENTARY statement indicate TABLES variables with categories that are supplementary. In other words, the categories of the variable Age are represented in the row and column space, but they are not used in determining the scores of the categories of the variables Hair, Height, and Sex. The variable used in the SUPPLEMENTARY statement must be listed in the TABLES statement as well. For example, the following statements create a Burt table with seven active rows and columns (Blond, Brown, White, Short, Tall, Female, Male) and two supplementary rows and columns (Old and Young).

Figure 24.6. Burt Table from PROC CORRESP

The following statements create a binary table with 7 active columns (Blond, Brown, White, Short, Tall, Female, Male), 2 supplementary columns (Old and Young), and 11 rows for the 11 observations with nonmissing values.

```
proc corresp data=Neighbor observed short binary;
  ods select binary supcols;
  tables Hair Height Sex Age;
  supplementary Age;
run;
```
Using the VAR Statement

With VAR statement input, the rows of the contingency table correspond to the observations of the input data set, and the columns correspond to the VAR statement variables. The values of the variables typically contain the table frequencies. The example displayed in Figure 24.4 could be run with VAR statement input using the following code:

```sas
data Ages;
  input Sex $ Old Young;
datalines;
Female 2 2
Male 4 3
;
proc corresp data=Ages dimens=1 observed short;
  var Old Young;
  id Sex;
run;
```

**Figure 24.7.** Binary Table from PROC CORRESP
Only nonnegative values are accepted. Negative values are treated as missing, causing the observation to be excluded from the analysis. The values are not required to be integers. Row labels for the table are specified with an ID variable. Column labels are constructed from the variable name or variable label if one is specified. When you specify multiple correspondence analysis (MCA), the row and column labels are the same and are constructed from the variable names or labels, so you cannot include an ID statement. With MCA, the VAR statement must list the variables in the order in which the rows occur. For example, the table displayed in Figure 24.6, which was created with the following TABLES statement,

`tables Hair Height Sex Age;`

is input as follows with the VAR statement:

```
proc corresp data=table nvars=4 mca;
    var Blond Brown White Short Tall Female Male Old Young;
run;
```

You must specify the NVARS= option to specify the number of original categorical variables with the MCA option. The option NVARS=n is needed to find boundaries between the subtables of the Burt table. If $f$ is the sum of all elements in the Burt table $Z'Z$, then $fn^{-2}$ is the number of rows in the binary matrix $Z$. The sum of all elements in each diagonal subtable of the Burt table must be $fn^{-2}$.

To enter supplementary observations, include a WEIGHT statement with negative weights for those observations. Specify the SUPPLEMENTARY statement to include supplementary variables. You must list supplementary variables in both the VAR and SUPPLEMENTARY statements.

### Missing and Invalid Data

With VAR statement input, observations with missing or negative frequencies are excluded from the analysis. Supplementary variables and supplementary observations with missing or negative frequencies are also excluded. Negative weights are valid with VAR statement input.

With TABLES statement input, observations with negative weights are excluded from the analysis. With this form of input, missing cell frequencies cannot occur. Observations with missing values on the categorical variables are excluded unless you specify the MISSING option. If you specify the MISSING option, ordinary missing values and special missing values are treated as additional levels of a categorical variable. In all cases, if any row or column of the constructed table contains only zeros, that row or column is excluded from the analysis.

Observations with missing weights are excluded from the analysis.
Creating a Data Set Containing the Crosstabulation

The CORRESP procedure can read or create a contingency or Burt table. PROC CORRESP is generally more efficient with VAR statement input than with TABLES statement input. TABLES statement input requires that the table be created from raw categorical variables, whereas the VAR statement is used to read an existing table. If PROC CORRESP runs out of memory, it may be possible to use some other method to create the table and then use VAR statement input with PROC CORRESP.

The following example uses the CORRESP, FREQ, and TRANSPOSE procedures to create rectangular tables from a SAS data set WORK.A that contains the categorical variables V1–V5. The Burt table examples assume that no categorical variable has a value found in any of the other categorical variables (that is, that each row and column label is unique).

You can use PROC CORRESP and ODS to create a rectangular two-way contingency table from two categorical variables.

```
proc corresp data=a observed short;
   ods listing close;
   ods output Observed=Obs(drop=Sum where=(Label ne 'Sum'));
   tables v1, v2;
run;
ods listing;
```

You can use PROC FREQ and PROC TRANSPOSE to create a rectangular two-way contingency table from two categorical variables.

```
proc freq data=a;
   tables v1 * v2 / sparse noprint out=freqs;
run;
proc transpose data=freqs out=rfreqs;
   id v2;
   var count;
   by v1;
run;
```

You can use PROC CORRESP and ODS to create a Burt table from five categorical variables.

```
proc corresp data=a observed short mca;
   ods listing close;
   ods output Burt=Obs;
   tables v1-v5;
run;
ods listing;
```
You can use a DATA step, PROC FREQ, and PROC TRANSPOSE to create a Burt table from five categorical variables.

```sas
data b;
  set a;
  array v[5] $ v1-v5;
  do i = 1 to 5;
    row = v[i];
    do j = 1 to 5;
      column = v[j];
      output;
    end;
  end;
  keep row column;
run;

proc freq data=b;
  tables row * column / sparse noprint out=freqs;
run;

proc transpose data=freqs out=rfreqs;
  id column;
  var count;
  by row;
run;
```

### Output Data Sets

#### The OUTC= Data Set

The OUTC= data set contains two or three character variables and \(4n + 4\) numeric variables, where \(n\) is the number of axes from DIMENS=\(n\) (two by default). The OUTC= data set contains one observation for each row, column, supplementary row, and supplementary column point, and one observation for inertias.

The first variable is named `_TYPE_` and identifies the type of observation. The values of `_TYPE_` are as follows:

- The ‘INERTIA’ observation contains the total inertia in the INERTIA variable, and each dimension’s inertia in the Contr1–Contr\(n\) variables.
- The ‘OBS’ observations contain the coordinates and statistics for the rows of the table.
- The ‘SUPOBS’ observations contain the coordinates and statistics for the supplementary rows of the table.
- The ‘VAR’ observations contain the coordinates and statistics for the columns of the table.
- The ‘SUPVAR’ observations contain the coordinates and statistics for the supplementary columns of the table.
If you specify the SOURCE option, then the data set also contains a variable `_VAR_` containing the name or label of the input variable from which that row originates. The name of the next variable is either `_NAME_` or (if you specify an ID statement) the name of the ID variable.

For observations with a value of ‘OBS’ or ‘SUPOBS’ for the `_TYPE_` variable, the values of the second variable are constructed as follows:

- When you use a VAR statement without an ID statement, the values are ‘Row1’, ‘Row2’, and so on.
- When you specify a VAR statement with an ID statement, the values are set equal to the values of the ID variable.
- When you specify a TABLES statement, the `_NAME_` variable has values formed from the appropriate row variable values.

For observations with a value of ‘VAR’ or ‘SUPVAR’ for the `_TYPE_` variable, the values of the second variable are equal to the names or labels of the VAR (or SUPPLEMENTARY) variables. When you specify a TABLES statement, the values are formed from the appropriate column variable values.

The third and subsequent variables contain the numerical results of the correspondence analysis.

- **Quality** contains the quality of each point’s representation in the DIMENS=n dimensional display, which is the sum of squared cosines over the first n dimensions.
- **Mass** contains the masses or marginal sums of the relative frequency matrix.
- **Inertia** contains each point’s relative contribution to the total inertia.
- **Dim1–Dimn** contain the point coordinates.
- **Contr1–Contrn** contain the partial contributions to inertia.
- **SqCos1–SqCosn** contain the squared cosines.
- **Best1–Bestn** and **Best** contain the summaries of the partial contributions to inertia.

### The OUTF= Data Set

The OUTF= data set contains frequencies and percentages. It is similar to a PROC FREQ output data set. The OUTF= data set begins with a variable called `_TYPE_`, which contains the observation type. If the SOURCE option is specified, the data set contains two variables `_ROWVAR_` and `_COLVAR_` that contain the names or labels of the row and column input variables from which each cell originates. The next two variables are classification variables that contain the row and column levels. If you use TABLES statement input and each variable list consists of a single variable, the names of the first two variables match the names of the input variables; otherwise, these variables are named **Row** and **Column**. The next two variables are **Count** and **Percent**, which contain frequencies and percentages.

The `_TYPE_` variable can have the following values:
• ‘OBSERVED’ observations contain the contingency table.
• ‘SUPOBS’ observations contain the supplementary rows.
• ‘SUPVAR’ observations contain the supplementary columns.
• ‘EXPECTED’ observations contain the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequency matrix under the hypothesis of row and column independence.
• ‘DEVIATION’ observations contain the matrix of deviations between the observed frequency matrix and the product of its row marginals and column marginals divided by its grand frequency. For ordinary two-way contingency tables, these are the observed minus expected frequencies under the hypothesis of row and column independence.
• ‘CELLCHI2’ observations contain contributions to the total chi-square test statistic.
• ‘RP’ observations contain the row profiles.
• ‘SUPRP’ observations contain supplementary row profiles.
• ‘CP’ observations contain the column profiles.
• ‘SUPCP’ observations contain supplementary column profiles.

**Computational Resources**

Let

\[
\begin{align*}
    n_r &= \text{number of rows in the table} \\
    n_c &= \text{number of columns in the table} \\
    n &= \text{number of observations} \\
    v &= \text{number of VAR statement variables} \\
    t &= \text{number of TABLES statement variables} \\
    c &= \max(n_r, n_c) \\
    d &= \min(n_r, n_c)
\end{align*}
\]

For TABLES statement input, more than

\[
32(t + 1) + 8(\max(2tn, (n_r + 3)(n_c + 3)))
\]

bytes of array space are required.

For VAR statement input, more than

\[
16(v + 2) + 8(n_r + 3)(n_c + 3)
\]

bytes of array space are required.
**Memory**

The computational resources formulas are underestimates of the amounts of memory needed to handle most problems. If you use a utility data set, and if memory could be used with perfect efficiency, then roughly the stated amount of memory would be needed. In reality, most problems require at least two or three times the minimum.

PROC CORRESP tries to store the raw data (TABLES input) and the contingency table in memory. If there is not enough memory, a utility data set is used, potentially resulting in a large increase in execution time.

**Time**

The time required to perform the generalized singular value decomposition is roughly proportional to $2cd^2 + 5d^3$. Overall computation time increases with table size at a rate roughly proportional to $(n_r n_c)^{\frac{3}{2}}$.

**Algorithm and Notation**

This section is primarily based on the theory of correspondence analysis found in Greenacre (1984). If you are interested in other references, see the “Background” section on page 1069.

Let $N$ be the contingency table formed from those observations and variables that are not supplementary and from those observations that have no missing values and have a positive weight. This table is an $(n_r \times n_c)$ rank $q$ matrix of nonnegative numbers with nonzero row and column sums. If $Z_a$ is the binary coding for variable $A$, and $Z_b$ is the binary coding for variable $B$, then $N = Z_a'Z_b$ is a contingency table. Similarly, if $Z_{b,c}$ contains the binary coding for both variables $B$ and $C$, then $N = Z_a'Z_{b,c}$ can also be input to a correspondence analysis. With the BINARY option, $N = Z$, and the analysis is based on a binary table. In multiple correspondence analysis, the analysis is based on a Burt table, $Z'Z$.

Let $1$ be a vector of 1s of the appropriate order, let $I$ be an identity matrix, and let diag($\cdot$) be a matrix-valued function that creates a diagonal matrix from a vector. Let

- $f = 1'N1$
- $P = \frac{1}{f}N$
- $r = P1$
- $c = P'1$
- $D_r = \text{diag}(r)$
- $D_c = \text{diag}(c)$
- $R = D_r^{-1}P$
- $C' = D_c^{-1}P'$

The scalar $f$ is the sum of all elements in $N$. The matrix $P$ is a matrix of relative frequencies. The vector $r$ contains row marginal proportions or row “masses.” The
vector \( c \) contains column marginal proportions or column masses. The matrices \( D_r \) and \( D_c \) are diagonal matrices of marginals.

The rows of \( R \) contain the “row profiles.” The elements of each row of \( R \) sum to one. Each \((i, j)\) element of \( R \) contains the observed probability of being in column \( j \) given membership in row \( i \). Similarly, the columns of \( C \) contain the column profiles. The coordinates in correspondence analysis are based on the generalized singular value decomposition of \( P \),

\[
P = AD_uB'
\]

where

\[
A'D_r^{-1}A = B'D_c^{-1}B = I
\]

In multiple correspondence analysis,

\[
P = BD_u^2B'
\]

The matrix \( A \), which is the rectangular matrix of left generalized singular vectors, has \( n_r \) rows and \( q \) columns; the matrix \( D_u \), which is a diagonal matrix of singular values, has \( q \) rows and columns; and the matrix \( B \), which is the rectangular matrix of right generalized singular vectors, has \( n_c \) rows and \( q \) columns. The columns of \( A \) and \( B \) define the principal axes of the column and row point clouds, respectively.

The generalized singular value decomposition of \( P - re' \), discarding the last singular value (which is zero) and the last left and right singular vectors, is exactly the same as a generalized singular value decomposition of \( P \), discarding the first singular value (which is one), the first left singular vector, \( r \), and the first right singular vector, \( c \). The first (trivial) column of \( A \) and \( B \) and the first singular value in \( D_u \) are discarded before any results are displayed. You can obtain the generalized singular value decomposition of \( P - re' \) from the ordinary singular value decomposition of \( D_r^{-1/2}(P - re')D_c^{-1/2} \).

\[
D_r^{-1/2}(P - re')D_c^{-1/2} = UD_u'V' = (D_r^{-1/2}A)D_u'(D_c^{-1/2}B)'
\]

\[
P - re' = D_r^{1/2}UD_u'V'D_c^{1/2} = (D_r^{1/2}U)D_u'(D_c^{1/2}V)' = AD_u'B'
\]

Hence, \( A = D_r^{1/2}U \) and \( B = D_c^{1/2}V \).

The default row coordinates are \( D_r^{-1}AD_u \), and the default column coordinates are \( D_c^{-1}BD_u \). Typically the first two columns of \( D_r^{-1}AD_u \) and \( D_c^{-1}BD_u \) are plotted to display graphically associations between the row and column categories. The plot consists of two overlaid plots, one for rows and one for columns. The row points are row profiles, rescaled so that distances between profiles can be displayed as ordinary Euclidean distances, then orthogonally rotated to a principal axes orientation. The column points are column profiles, rescaled so that distances between profiles can be
displayed as ordinary Euclidean distances, then orthogonally rotated to a principal axes orientation. Distances between row points and other row points have meaning. Distances between column points and other column points have meaning. However, distances between column points and row points are not interpretable.

The PROFILE=, ROW=, and COLUMN= Options

The PROFILE=, ROW=, and COLUMN= options standardize the coordinates before they are displayed and placed in the output data set. The options PROFILE=BOTH, PROFILE=ROW, and PROFILE=COLUMN provide the standardizations that are typically used in correspondence analysis. There are six choices each for row and column coordinates. However, most of the combinations of the ROW= and COLUMN= options are not useful. The ROW= and COLUMN= options are provided for completeness, but they are not intended for general use.

</tbody>
</table>

When PROFILE=ROW (ROW=DAD and COLUMN=DB), the row coordinates $D^{-1}_r AD_u$ and column coordinates $D^{-1}_c B$ provide a correspondence analysis based on the row profile matrix. The row profile (conditional probability) matrix is defined as $R = D^{-1}_r P = D^{-1}_r AD_u B'$. The elements of each row of $R$ sum to one. Each $(i, j)$ element of $R$ contains the observed probability of being in column $j$ given membership in row $i$. The “principal” row coordinates $D^{-1}_r AD_u$ and “standard” column coordinates $D^{-1}_c B$ provide a decomposition of $D^{-1}_r AD_u B'D^{-1}_c = D^{-1}_r PD^{-1}_c = RD^{-1}_c$. Since $D^{-1}_r AD_u = RD^{-1}_c B$, the row coordinates are weighted centroids of the column coordinates. Each column point, with coordinates scaled to standard coordinates, defines a vertex in $(n_c - 1)$-dimensional space. All of the principal row coordinates are located in the space defined by the standard column
coordinates. Distances among row points have meaning, but distances among column points and distances between row and column points are not interpretable.

The option PROFILE=COLUMN can be described as applying the PROFILE=ROW formulas to the transpose of the contingency table. When PROFILE=COLUMN (ROW=DA and COLUMN=DBD), the principal column coordinates $D_c^{-1} BD_u$ are weighted centroids of the standard row coordinates $D_r^{-1} A$. Each row point, with coordinates scaled to standard coordinates, defines a vertex in $(n_r - 1)$-dimensional space. All of the principal column coordinates are located in the space defined by the standard row coordinates. Distances among column points have meaning, but distances among row points and distances between row and column points are not interpretable.

The usual sets of coordinates are given by the default PROFILE=BOTH (ROW=DAD and COLUMN=DBD). All of the summary statistics, such as the squared cosines and contributions to inertia, apply to these two sets of points. One advantage to using these coordinates is that both sets ($D_r^{-1} AD_u$ and $D_c^{-1} BD_u$) are postmultiplied by the diagonal matrix $D_u$, which has diagonal values that are all less than or equal to one. When $D_u$ is a part of the definition of only one set of coordinates, that set forms a tight cluster near the centroid whereas the other set of points is more widely dispersed. Including $D_u$ in both sets makes a better graphical display. However, care must be taken in interpreting such a plot. No correct interpretation of distances between row points and column points can be made.

Another property of this choice of coordinates concerns the geometry of distances between points within each set. The default row coordinates can be decomposed into $D_r^{-1} AD_u = D_r^{-1} AD_u B' D_c^{-1} B = (D_r^{-1} P) (D_c^{-1}/2) (D_c^{-1/2} B)$. The row coordinates are row profiles ($D_r^{-1} P$), rescaled by $D_c^{-1/2}$ (rescaled so that distances between profiles are transformed from a chi-square metric to a Euclidean metric), then orthogonally rotated (with $D_c^{-1/2} B$) to a principal axes orientation. Similarly, the column coordinates are column profiles rescaled to a Euclidean metric and orthogonally rotated to a principal axes orientation.

The rationale for computing distances between row profiles using the non-Euclidean chi-square metric is as follows. Each row of the contingency table can be viewed as a realization of a multinomial distribution conditional on its row marginal frequency. The null hypothesis of row and column independence is equivalent to the hypothesis of homogeneity of the row profiles. A significant chi-square statistic is geometrically interpreted as a significant deviation of the row profiles from their centroid, $c'$. The chi-square metric is the Mahalanobis metric between row profiles based on their estimated covariance matrix under the homogeneity assumption (Greenacre and Hastie 1987). A parallel argument can be made for the column profiles.

When ROW=DAD1/2 and COLUMN=DBD1/2 (Gifi 1990; van der Heijden and de Leeuw 1985), the row coordinates $D_r^{-1} AD_u^{1/2}$ and column coordinates $D_c^{-1} BD_u^{1/2}$ are a decomposition of $D_r^{-1} PD_c^{-1}$.

In all of the preceding pairs, distances between row and column points are not meaningful. This prompted Carroll, Green, and Schaffer (1986) to propose that row coordinates $D_r^{-1} A(I + D_u)^{1/2}$ and column coordinates $D_c^{-1} B(I + D_u)^{1/2}$ be used.
These coordinates are (except for a constant scaling) the coordinates from a multiple correspondence analysis of a Burt table created from two categorical variables. This standardization is available with ROW=DAID1/2 and COLUMN=DBID1/2. However, this approach has been criticized on both theoretical and empirical grounds by Greenacre (1989). The Carroll, Green, and Schaffer standardization relies on the assumption that the chi-square metric is an appropriate metric for measuring the distance between the columns of a bivariate indicator matrix. See the section “Types of Tables Used as Input” on page 1083 for a description of indicator matrices. Greenacre (1989) showed that this assumption cannot be justified.

The MCA Option

The MCA option performs a multiple correspondence analysis (MCA). This option requires a Burt table. You can specify the MCA option with a table created from a design matrix with fuzzy coding schemes as long as every row of every partition of the design matrix has the same marginal sum. For example, each row of each partition could contain the probabilities that the observation is a member of each level. Then the Burt table constructed from this matrix no longer contains all integers, and the diagonal partitions are no longer diagonal matrices, but MCA is still valid.

A TABLES statement with a single variable list creates a Burt table. Thus, you can always specify the MCA option with this type of input. If you use the MCA option when reading an existing table with a VAR statement, you must ensure that the table is a Burt table.

If you perform MCA on a table that is not a Burt table, the results of the analysis are invalid. If the table is not symmetric, or if the sums of all elements in each diagonal partition are not equal, PROC CORRESP displays an error message and quits.

A subset of the columns of a Burt table is not necessarily a Burt table, so in MCA it is not appropriate to designate arbitrary columns as supplementary. You can, however, designate all columns from one or more categorical variables as supplementary.

The results of a multiple correspondence analysis of a Burt table $Z'Z$ are the same as the column results from a simple correspondence analysis of the binary (or fuzzy) matrix $Z$. Multiple correspondence analysis is not a simple correspondence analysis of the Burt table. It is not appropriate to perform a simple correspondence analysis of a Burt table. The MCA option is based on $P = BD_u B'$, whereas a simple correspondence analysis of the Burt table would be based on $P = BD_a B'$.

Since the rows and columns of the Burt table are the same, no row information is displayed or written to the output data sets. The resulting inertias and the default (COLUMN=DBD) column coordinates are the appropriate inertias and coordinates for an MCA. The supplementary column coordinates, cosines, and quality of representation formulas for MCA differ from the simple correspondence analysis formulas because the design matrix column profiles and left singular vectors are not available.

The following statements create a Burt table and perform a multiple correspondence analysis:
Both the rows and the columns have the same nine categories (Blond, Brown, White, Short, Tall, Female, Male, Old, and Young).

**MCA Adjusted Inertias**

The usual principal inertias of a Burt Table constructed from $m$ categorical variables in MCA are the eigenvalues $u_k$ from $D^2_u$. The problem with these inertias is that they provide a pessimistic indication of fit. Benzécri (1979) proposed the following inertia adjustment, which is also described by Greenacre (1984, p. 145):

$$\left( \frac{m}{m-1} \right)^2 \times \left( u_k - \frac{1}{m} \right)^2 \quad \text{for } u_k > \frac{1}{m}$$

The Benzécri adjustment is available with the BENZECRI option.

Greenacre (1994, p. 156) argues that the Benzécri adjustment overestimates the quality of fit. Greenacre proposes instead the following inertia adjustment:

$$\left( \frac{m}{m-1} \right)^2 \times \left( \sqrt{u_k} - \frac{1}{m} \right)^2 \quad \text{for } \sqrt{u_k} > \frac{1}{m}$$

The Greenacre adjustment is available with the GREENACRE option.

Ordinary unadjusted inertias are printed by default with MCA when neither the BENZECRI nor the GREENACRE option is specified. However, the unadjusted inertias are not printed by default when either the BENZECRI or the GREENACRE option is specified. To display both adjusted and unadjusted inertias, specify the UNADJUSTED option in addition to the relevant adjusted inertia option (BENZECRI, GREENACRE, or both).

**Supplementary Rows and Columns**

Supplementary rows and columns are represented as points in the joint row and column space, but they are not used when determining the locations of the other active rows and columns of the table. The formulas that are used to compute coordinates for the supplementary rows and columns depend on the PROFILE= option or on the ROW= and COLUMN= options. Let $S_o$ be the matrix with rows that contain the supplementary observations and $S_v$ be a matrix with rows that contain the supplementary variables. Note that $S_v$ is defined to be the transpose of the supplementary variable partition of the table. Let $R_s = \text{diag}(S_o 1)^{-1} S_o$ be the supplementary observation profile matrix and $C_s = \text{diag}(S_v 1)^{-1} S_v$ be the supplementary variable profile matrix. Note that the notation $\text{diag}(\cdot)^{-1}$ means to convert the vector to a diagonal matrix, then invert the diagonal matrix. The coordinates for the supplementary observations and variables are as follows.
### Algorithm and Notation

**ROW= Matrix Formula**

<table>
<thead>

| DBID1/2   | $C_sD_r^{-1}BD_u^2(I + D_u)^{1/2}$  |

### Statistics that Aid Interpretation

The partial contributions to inertia, squared cosines, quality of representation, inertia, and mass provide additional information about the coordinates. These statistics are displayed by default. Include the SHORT or NOPRINT option in the PROC CORRESP statement to avoid having these statistics displayed.

These statistics pertain to the default PROFILE=BOTH coordinates, no matter what values you specify for the ROW=, COLUMN=, or PROFILE= option. Let $\text{sq}(\cdot)$ be a matrix-valued function denoting element-wise squaring of the argument matrix. Let $t$ be the total inertia (the sum of the elements in $D_u^2$).

In MCA, let $D_s$ be the Burt table partition containing the intersection of the supplementary columns and the supplementary rows. The matrix $D_s$ is a diagonal matrix of marginal frequencies of the supplemental columns of the binary matrix $Z$. Let $p$ be the number of rows in this design matrix.
The quality of representation in the DIMENS=n dimensional display of any point is the sum of its squared cosines over only the n dimensions. Inertia and mass are not defined for supplementary points.

A table that summarizes the partial contributions to inertia table is also computed. The points that best explain the inertia of each dimension and the dimension to which each point contributes the most inertia are indicated. The output data set variable names for this table are Best1–Bestn (where DIMENS=n) and Best. The Best column contains the dimension number of the largest partial contribution to inertia for each point (the index of the maximum value in each row of \( D_{r}^{-1}sq(A) \) or \( D_{c}^{-1}sq(B) \)).

For each row, the Best1–Bestn columns contain either the corresponding value of Best if the point is one of the biggest contributors to the dimension’s inertia or 0 if it is not. Specifically, Best1 contains the value of Best for the point with the largest contribution to dimension one’s inertia. A cumulative proportion sum is initialized to this point’s partial contribution to the inertia of dimension one. If this sum is less than the value for the MININERTIA= option, then Best1 contains the value of Best for the point with the second largest contribution to dimension one’s inertia. Otherwise, this point’s Best1 is 0. This point’s partial contribution to inertia is added to the sum. This process continues for the point with the third largest partial contribution, and so on, until adding a point’s contribution to the sum increases the sum beyond the value of the MININERTIA= option. This same algorithm is then used for Best2, and so on.

For example, the following table contains contributions to inertia and the correspond-

<table>
<thead>
<tr>
<th>Statistic</th>
<th>Matrix Formula</th>
</tr>
</thead>
<tbody>
<tr>
<td>Row partial contributions to inertia</td>
<td>( D_{r}^{-1}sq(A) )</td>
</tr>
<tr>
<td>Column partial contributions to inertia</td>
<td>( D_{c}^{-1}sq(B) )</td>
</tr>
<tr>
<td>Row squared cosines</td>
<td>diag(sq(AD_u)1)^{-1}sq(A)</td>
</tr>
<tr>
<td>Column squared cosines</td>
<td>diag(sq(BD_u)1)^{-1}sq(BD_u)</td>
</tr>
<tr>
<td>Row mass</td>
<td>r</td>
</tr>
<tr>
<td>Column mass</td>
<td>c</td>
</tr>
<tr>
<td>Row inertia</td>
<td>( \frac{1}{r}D_{r}^{-1}sq(AD_u)1 )</td>
</tr>
<tr>
<td>Column inertia</td>
<td>( \frac{1}{c}D_{c}^{-1}sq(BD_u)1 )</td>
</tr>
<tr>
<td>Supplementary row squared cosines</td>
<td>diag(sq(Re = 1c')D_c^{-1}1)^{-1}sq(ReD_c^{-1}B)</td>
</tr>
<tr>
<td>Supplementary column squared cosines</td>
<td>diag(sq(Cs = 1r')D_r^{-1}1)^{-1}sq(CsD_r^{-1}A)</td>
</tr>
<tr>
<td>MCA supplementary column squared cosines</td>
<td>( D_{s}(pI - D_{s})^{-1}sq(CsD_r^{-1}BD_u^{-1}) )</td>
</tr>
</tbody>
</table>
ing \textit{Best} variables. The contribution to inertia variables are proportions that sum to 1 within each column. The first point makes its greatest contribution to the inertia of dimension two, so \textit{Best} for point one is set to 2 and \textit{Best1--Best3} for point one must all be 0 or 2. The second point also makes its greatest contribution to the inertia of dimension two, so \textit{Best} for point two is set to 2 and \textit{Best1--Best3} for point two must all be 0 or 2, and so on.

Assume MININERTIA=0.8, the default. In dimension one, the largest contribution is 0.41302 for the fourth point, so \textit{Best1} is set to 1, the value of \textit{Best} for the fourth point. Because this value is less than 0.8, the second largest value (0.36456 for point five) is found and its \textit{Best1} is set to its \textit{Best}'s value of 1. Because 0.41302 + 0.36456 = 0.77758 is less than 0.8, the third point (0.0882 at point eight) is found and \textit{Best1} is set to 3 since the contribution to dimension 3 for that point is greater than the contribution to dimension 1. This increases the sum of the partial contributions to greater than 0.8, so the remaining \textit{Best1} values are all 0.

\subsection*{Displayed Output}

The display options control the amount of displayed output. By default, the following information is displayed:

- an inertia and chi-square decomposition table including the total inertia, the principal inertias of each dimension (eigenvalues), the singular values (square roots of the eigenvalues), each dimension’s percentage of inertia, a horizontal bar chart of the percentages, and the total chi-square with its degrees of freedom and decomposition. The chi-square statistics and degrees of freedom are valid only when the constructed table is an ordinary two-way contingency table.
- the coordinates of the rows and columns on the dimensions
- the mass, relative contribution to the total inertia, and quality of representation in the DIMENS=n dimensional display of each row and column
- the squared cosines of the angles between each axis and a vector from the origin to the point
- the partial contributions of each point to each dimension’s inertia
• the Best table, indicators of which points best explain the inertia of each dimension

Specific display options and combinations of options display output as follows.

If you specify the OBSERVED or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays

- the contingency table including the row and column marginal frequencies; or with BINARY, the binary table; or the Burt table in MCA
- the supplementary rows
- the supplementary columns

If you specify the OBSERVED or ALL option, with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays

- the contingency table or Burt table in MCA, scaled to percentages, including the row and column marginal percentages
- the supplementary rows, scaled to percentages
- the supplementary columns, scaled to percentages

If you specify the EXPECTED or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the product of the row marginals and the column marginals divided by the grand frequency of the observed frequency table. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence.

If you specify the EXPECTED or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the product of the row marginals and the column marginals divided by the grand frequency of the observed percentages table. For ordinary two-way contingency tables, these are the expected percentages under the hypothesis of row and column independence.

If you specify the DEVIATION or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the observed minus expected frequencies. For ordinary two-way contingency tables, these are the expected frequencies under the hypothesis of row and column independence.

If you specify the DEVIATION or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the observed minus expected percentages. For ordinary two-way contingency tables, these are the expected percentages under the hypothesis of row and column independence.

If you specify the CELLCHI2 or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays contributions to the total chi-square test statistic, including the row and column marginals. The intersection of the marginals contains the total chi-square statistic.
If you specify the CELLCHI2 or ALL option with the PRINT=PERCENT or the PRINT=BOTH option, PROC CORRESP displays contributions to the total chi-square, scaled to percentages, including the row and column marginals.

If you specify the RP or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the row profiles and the supplementary row profiles.

If you specify the RP or ALL option with the PRINT=PERCENT or the PRINT=BOTH option, PROC CORRESP displays the row profiles (scaled to percentages) and the supplementary row profiles (scaled to percentages).

If you specify the CP or ALL option and you do not specify PRINT=PERCENT, PROC CORRESP displays the column profiles and the supplementary column profiles.

If you specify the CP or ALL option with the PRINT=PERCENT or PRINT=BOTH option, PROC CORRESP displays the column profiles (scaled to percentages) and the supplementary column profiles (scaled to percentages).

If you do not specify the NOPRINT option, PROC CORRESP displays the inertia and chi-square decomposition table. This includes the nonzero singular values of the contingency table (or, in MCA, the binary matrix $Z$ used to create the Burt table), the nonzero principal inertias (or eigenvalues) for each dimension, the total inertia, the total chi-square, the decomposition of chi-square, the chi-square degrees of freedom (appropriate only when the table is an ordinary two-way contingency table), the percent of the total chi-square and inertia for each dimension, and a bar chart of the percents.

If you specify the MCA option and you do not specify the NOPRINT option, PROC CORRESP displays the adjusted inertias. This includes the nonzero adjusted inertias, percents, cumulative percents, and a bar chart of the percents.

If you do not specify the NOROW, NOPRINT, or MCA option, PROC CORRESP displays

- the summary statistics for the row points including the quality of representation of the row points in the $n$-dimensional display, the mass, and the relative contributions to inertia
- the quality of representation of the supplementary row points in the $n$-dimensional display (displayed when there are supplementary row points)
- the partial contributions to inertia for the row points
- the row Best table, indicators of which row points best explain the inertia of each dimension
- the squared cosines for the row points
- the squared cosines for the supplementary row points (displayed when there are supplementary row points)
If you do not specify the NOCOLUMN or NOPRINT option, PROC CORRESP displays the column coordinates and the supplementary column coordinates (displayed when there are supplementary column points).

If you do not specify the NOCOLUMN, NOPRINT, or SHORT option, PROC CORRESP displays

- the summary statistics for the column points including the quality of representation of the column points in the \( n \)-dimensional display, the mass, and the relative contributions to inertia for the supplementary column points
- the quality of representation of the supplementary column points in the \( n \)-dimensional display (displayed when there are supplementary column points)
- the partial contributions to inertia for the column points
- the column Best table, indicators of which column points best explain the inertia of each dimension
- the squared cosines for the column points
- the squared cosines for the supplementary column points

**ODS Table Names**

PROC CORRESP assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

This section describes the use of ODS for creating graphics with the CORRESP procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release. To request a graph you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

### ODS Graph Names

PROC CORRESP assigns a name to the graph it creates using ODS. You can use this name to reference the graph when using ODS. The name is listed in Table 24.9.

Examples

Example 24.1. Simple Correspondence Analysis of Cars and Their Owners

In this example, PROC CORRESP creates a contingency table from categorical data and performs a simple correspondence analysis. The data are from a sample of individuals who were asked to provide information about themselves and their cars. The questions included origin of the car (American, Japanese, European) and family status (single, married, single and living with children, and married living with children). These data are used again in Example 24.2.

The first steps read the input data and assign formats. PROC CORRESP is used to perform the simple correspondence analysis. The ALL option displays all tables including the contingency table, chi-square information, profiles, and all results of the correspondence analysis. The OUTC= option creates an output coordinate data set. The TABLES statement specifies the row and column categorical variables. The %PLOTIT macro is used to plot the results.

Normally, you only need to tell the %PLOTIT macro the name of the input data set, DATA=Coor, and the type of analysis performed on the data, DATATYPE=CORRESP.

The following statements produce Output 24.1.1:

```plaintext
title 'Car Owners and Car Origin';

proc format;
  value Origin 1 = 'American' 2 = 'Japanese' 3 = 'European';
  value Size 1 = 'Small' 2 = 'Medium' 3 = 'Large';
  value Type 1 = 'Family' 2 = 'Sporty' 3 = 'Work';
  value Home 1 = 'Own' 2 = 'Rent';
  value Sex 1 = 'Male' 2 = 'Female';
  value Income 1 = '1 Income' 2 = '2 Incomes';
  value Marital 1 = 'Single with Kids' 2 = 'Married with Kids' 3 = 'Single' 4 = 'Married';
run;

data Cars;
  missing a;
  input (Origin Size Type Home Income Marital Kids Sex) (1.) @@;

*---Perform Simple Correspondence Analysis---;
proc corresp all data=Cars outc=Coor;
tables Marital, Origin;
run;

*---Plot the Simple Correspondence Analysis Results---;
%plotit(data=Coor, datatype=corresp)

Correspondence analysis locates all the categories in a Euclidean space. The first two dimensions of this space are plotted to examine the associations among the categories. Since the smallest dimension of this table is three, there is no loss of information when only two dimensions are plotted. The plot should be thought of as two different overlaid plots, one for each categorical variable. Distances between points within a
variable have meaning, but distances between points from different variables do not.

</tbody>
</table>
To interpret the plot, start by interpreting the row points separately from the column points. The European point is near and to the left of the centroid, so it makes a relatively small contribution to the chi-square statistic (because it is near the centroid), it contributes almost nothing to the inertia of dimension one (since its coordinate on dimension one has a small absolute value relative to the other column points), and it makes a relatively large contribution to the inertia of dimension two (since its coordinate on dimension two has a large absolute value relative to the other column points). Its squared cosines for dimension one and two, approximately 0 and 1, respectively, indicate that its position is almost completely determined by its location on dimension two. Its quality of display is 1.0, indicating perfect quality, since the table is two-dimensional after the centering. The American and Japanese points are far from the centroid, and they lie along dimension one. They make relatively large contributions to the chi-square statistic and the inertia of dimension one. The horizontal dimension seems to be largely determined by Japanese versus American car ownership.

In the row points, the Married point is near the centroid, and the Single with Kids point has a small coordinate on dimension one that is near zero. The horizontal dimension seems to be largely determined by the Single versus the Married with
Kids points. The two interpretations of dimension one show the association with being Married with Kids and owning an American car, and being single and owning a Japanese car. The fact that the Married with Kids point is close to the American point and the fact that the Japanese point is near the Single point should be ignored. Distances between row and column points are not defined. The plot shows that more people who are married with kids than you would expect if the rows and columns were independent drive an American car, and more people who are single than you would expect if the rows and columns were independent drive a Japanese car.

**Example 24.2. Multiple Correspondence Analysis of Cars and Their Owners**

In this example, PROC CORRESP creates a Burt table from categorical data and performs a multiple correspondence analysis. The data are from a sample of individuals who were asked to provide information about themselves and their cars. The questions included origin of the car (American, Japanese, European), size of car (Small, Medium, Large), type of car (Family, Sporty, Work Vehicle), home ownership (Owns, Rents), marital/family status (single, married, single and living with children, and married living with children), and sex (Male, Female).

The data are read and formats assigned in a previous step, displayed in Example 24.1. The variables used in this example are Origin, Size, Type, Income, Home, Marital, and Sex. MCA specifies multiple correspondence analysis, OBSERVED displays the Burt table, and the OUTC= option creates an output coordinate data set. The TABLES statement with only a single variable list and no comma creates the Burt table. The %PLOTIT macro is used to plot the results with vertical and horizontal reference lines.

The data used to produce Output 24.2.1 and Output 24.2.2 can be found in Example 24.1.

```plaintext
  title 'MCA of Car Owners and Car Attributes';
  *---Perform Multiple Correspondence Analysis---;
  proc corresp mca observed data=Cars outc=Coor;
    tables Origin Size Type Income Home Marital Sex;
  run;

  *---Plot the Multiple Correspondence Analysis Results---;
  %plotit(data=Coor, datatype=corresp, href=0, vref=0)
```
Output 24.2.1. Multiple Correspondence Analysis of a Burt Table

</tbody>
</table>
Multiple correspondence analysis locates all the categories in a Euclidean space. The first two dimensions of this space are plotted to examine the associations among the categories. The top-right quadrant of the plot shows that the categories single, single with kids, 1 income, and renting a home are associated. Proceeding clockwise, the categories sporty, small, and Japanese are associated. The bottom-left quadrant shows the association between being married, owning your own home, and having...
two incomes. Having children is associated with owning a large American family car. Such information could be used in market research to identify target audiences for advertisements.

This interpretation is based on points found in approximately the same direction from the origin and in approximately the same region of the space. Distances between points do not have a straightforward interpretation in multiple correspondence analysis. The geometry of multiple correspondence analysis is not a simple generalization of the geometry of simple correspondence analysis (Greenacre and Hastie 1987; Greenacre 1988).

Output 24.2.2. Plot of Multiple Correspondence Analysis of a Burt Table

If you want to perform a multiple correspondence analysis and get scores for the individuals, you can specify the BINARY option to analyze the binary table. In the interest of space, only the first ten rows of coordinates are printed.

```sql
   title 'Car Owners and Car Attributes';
   title2 'Binary Table';

   *---Perform Multiple Correspondence Analysis---;
   proc corresp data=Cars binary;
```

Example 24.3. Cars and Their Owners, ODS Graphics (Experimental)

These graphical displays are requested by specifying the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the CORRESP procedure, see the “ODS Graphics” section on page 1109.

```

    tables Sex Marital, Origin;
    supvar Sex;
run;

*---Perform Multiple Correspondence Analysis---;
proc corresp mca short data=Cars;
    tables Origin Size Type Income Home Marital Sex;
run;

ods graphics off;
ods html close;
```
Output 24.3.1. Simple Correspondence Analysis (Experimental)
Example 24.4. Simple Correspondence Analysis of U.S. Population

In this example, PROC CORRESP reads an existing contingency table with supplementary observations and performs a simple correspondence analysis. The data are populations of the fifty states, grouped into regions, for each of the census years from 1920 to 1970 (U.S. Bureau of the Census 1979). Alaska and Hawaii are treated as supplementary regions. They were not states during this entire period and they are not physically connected to the other 48 states. Consequently, it is reasonable to expect that population changes in these two states operate differently from population changes in the other states. The correspondence analysis is performed giving the supplementary points negative weight, then the coordinates for the supplementary points are computed in the solution defined by the other points.

The initial DATA step reads the table, provides labels for the years, flags the supplementary rows with negative weights, and specifies absolute weights of 1000 for all observations since the data were originally reported in units of 1000 people.

In the PROC CORRESP statement, PRINT=PERCENT and the display options display the table of cell percentages (OBSERVED), cell contributions to the total chi-square scaled to sum to 100 (CELLCHI2), row profile rows that sum to 100 (RP),...
and column profile columns that sum to 100 (CP). The SHORT option specifies that
the correspondence analysis summary statistics, contributions to inertia, and squared
cosines should not be displayed. The option OUTC=COOR creates the output co-
dordinate data set. Since the data are already in table form, a VAR statement is used
to read the table. Row labels are specified with the ID statement, and column la-
be ls come from the variable labels. The WEIGHT statement flags the supplementary
observations and restores the table values to populations.

The %PLOTIT macro is used to plot the results. Normally, you only need to tell the
%PLOTIT macro the name of the input data set, DATA=Coor, and the type of analy-
sis performed on the data, DATATYPE=CORRESP. In this case, PLOTVARS=Dim1
Dim2 is also specified to indicate that Dim1 is the vertical axis variable, as opposed
to the default PLOTVARS=Dim2 Dim1.

For an essentially one-dimensional plot such as this, specifying PLOTVARS=Dim1
Dim2 improves the graphical display.

The following statements produce Output 24.4.1 and Output 24.4.2:

title 'United States Population';

data USPop;

* Regions:
* New England - ME, NH, VT, MA, RI, CT.
* Great Lake - OH, IN, IL, MI, WI.

  short outc=Coor;
  var y1920 -- y1970;
  id Region;
  weight w;
run;

*---Plot the Simple Correspondence Analysis Results---;
%plotit(data=Coor, datatype=corresp, plotvars=Dim1 Dim2)

The contingency table shows that the population of all regions increased over this time period. The row profiles show that population is increasing at a different rate for the different regions. There is a small increase in population in the Midwest, for example, but the population has more than quadrupled in the Pacific region over the same period. The column profiles show that in 1920, the US population was concentrated in the NY, NJ, PA, Great Lakes, Midwest, and South Atlantic regions. With time, the population is shifting more to the South Atlantic, Mountain, and Pacific regions. This is also clear from the correspondence analysis. The inertia and chi-square decomposition table shows that there are five nontrivial dimensions in the table, but the association between the rows and columns is almost entirely one-dimensional.

The plot shows that the first dimension correctly orders the years. There is nothing in the correspondence analysis that forces this to happen; PROC CORRESP knows nothing about the inherent ordering of the column categories. The ordering of the regions and the ordering of the years reflect the shift over time of the U.S. population.
from the Northeast quadrant of the country to the South and to the West. The results show that the West and Southeast are growing faster than the rest of the contiguous 48 states.

The plot also shows that the growth pattern for Hawaii is similar to the growth pattern for the mountain states and that Alaska’s growth is even more extreme than the Pacific states’ growth. The row profiles confirm this interpretation.

The Pacific region is farther from the origin than all other active points. The Midwest is the extreme region in the other direction. The table of contributions to the total chi-square shows that 62% of the total chi-square statistic is contributed by the Pacific region, which is followed by the Midwest at over 14%. Similarly the two extreme years, 1920 and 1970, together contribute over 63% to the total chi-square, whereas the years nearer the origin of the plot contribute less.

Chapter 25
The DISCRIM Procedure

Overview

For a set of observations containing one or more quantitative variables and a classification variable defining groups of observations, the DISCRIM procedure develops a discriminant criterion to classify each observation into one of the groups. The derived discriminant criterion from this data set can be applied to a second data set during the same execution of PROC DISCRIM. The data set that PROC DISCRIM uses to derive the discriminant criterion is called the training or calibration data set.

When the distribution within each group is assumed to be multivariate normal, a parametric method can be used to develop a discriminant function. The discriminant function, also known as a classification criterion, is determined by a measure of generalized squared distance (Rao 1973). The classification criterion can be based on either the individual within-group covariance matrices (yielding a quadratic function) or the pooled covariance matrix (yielding a linear function); it also takes into account the prior probabilities of the groups. The calibration information can be stored in a special SAS data set and applied to other data sets.

When no assumptions can be made about the distribution within each group, or when the distribution is assumed not to be multivariate normal, nonparametric methods can be used to estimate the group-specific densities. These methods include the kernel and $k$-nearest-neighbor methods (Rosenblatt 1956; Parzen 1962). The DISCRIM procedure uses uniform, normal, Epanechnikov, biweight, or triweight kernels for density estimation.

Either Mahalanobis or Euclidean distance can be used to determine proximity. Mahalanobis distance can be based on either the full covariance matrix or the diagonal matrix of variances. With a $k$-nearest-neighbor method, the pooled covariance matrix is used to calculate the Mahalanobis distances. With a kernel method, either the individual within-group covariance matrices or the pooled covariance matrix can be used to calculate the Mahalanobis distances. With the estimated group-specific densities and their associated prior probabilities, the posterior probability estimates of group membership for each class can be evaluated.

Canonical discriminant analysis is a dimension-reduction technique related to principal component analysis and canonical correlation. Given a classification variable and several quantitative variables, PROC DISCRIM derives canonical variables (linear combinations of the quantitative variables) that summarize between-class variation in much the same way that principal components summarize total variation. (See Chapter 21, “The CANDISC Procedure,” for more information on canonical discriminant analysis.) A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of a discriminant criterion, you should use the CANDISC procedure.
The DISCRIM procedure can produce an output data set containing various statistics such as means, standard deviations, and correlations. If a parametric method is used, the discriminant function is also stored in the data set to classify future observations. When canonical discriminant analysis is performed, the output data set includes canonical coefficients that can be rotated by the FACTOR procedure. PROC DISCRIM can also create a second type of output data set containing the classification results for each observation. When canonical discriminant analysis is performed, this output data set also includes canonical variable scores. A third type of output data set containing the group-specific density estimates at each observation can also be produced.

PROC DISCRIM evaluates the performance of a discriminant criterion by estimating error rates (probabilities of misclassification) in the classification of future observations. These error-rate estimates include error-count estimates and posterior probability error-rate estimates. When the input data set is an ordinary SAS data set, the error rate can also be estimated by cross validation.

Do not confuse discriminant analysis with cluster analysis. All varieties of discriminant analysis require prior knowledge of the classes, usually in the form of a sample from each class. In cluster analysis, the data do not include information on class membership; the purpose is to construct a classification.

See Chapter 6, “Introduction to Discriminant Procedures,” for a discussion of discriminant analysis and the SAS/STAT procedures available.

Getting Started

The data in this example are measurements taken on 159 fish caught in Finland’s lake Laengelmavesi. The species, weight, three different length measurements, height, and width of each fish are tallied. The full data set is displayed in Chapter 67, “The STEPDISC Procedure.” The STEPDISC procedure identifies all the variables as significant indicators of the differences among the seven fish species. The goal now is to find a discriminant function based on these six variables that best classifies the fish into species.

First, assume that the data are normally distributed within each group with equal covariances across groups. The following program uses PROC DISCRIM to analyze the Fish data and create Figure 25.1 through Figure 25.5.

```sas
proc format;
   value specfmt
      1='Bream'
      2='Roach'
      3='Whitefish'
      4='Parkki'
      5='Perch'
      6='Pike'
      7='Smelt';
data fish (drop=HtPct WidthPct);
title 'Fish Measurement Data';
```
input Species Weight Length1 Length2 Length3 HtPct WidthPct @0;
Height = HtPct*Length3/100;
Width = WidthPct*Length3/100;
format Species specfmt.;
symbol = put(Species, specfmt.);
datalines;
1 242.0 23.2 25.4 30.0 38.4 13.4
1 290.0 24.0 26.3 31.2 40.0 13.8
1 340.0 23.9 26.5 31.1 39.8 15.1
1 363.0 26.3 29.0 33.5 38.0 13.3
...[155 more records]
;
proc discrim data=fish;
   class Species;
run;

The DISCRIM procedure begins by displaying summary information about the variables in the analysis. This information includes the number of observations, the number of quantitative variables in the analysis (specified with the VAR statement), and the number of classes in the classification variable (specified with the CLASS statement). The frequency of each class, its weight, proportion of the total sample, and prior probability are also displayed. Equal priors are assigned by default.

The natural log of the determinant of the pooled covariance matrix is displayed next (Figure 25.2). The squared distances between the classes are shown in Figure 25.3.
### Figure 25.2. Pooled Covariance Matrix Information

The coefficients of the linear discriminant function are displayed (in Figure 25.4) with the default options METHOD=NORMAL and POOL=YES.
**Figure 25.4.** Linear Discriminant Function

A summary of how the discriminant function classifies the data used to develop the function is displayed last. In Figure 25.5, you see that only three of the observations are misclassified. The error-count estimates give the proportion of misclassified observations in each group. Since you are classifying the same data that are used to derive the discriminant function, these error-count estimates are biased. One way to reduce the bias of the error-count estimates is to split the Fish data into two sets, use one set to derive the discriminant function, and use the other to run validation tests; Example 25.4 on page 1231 shows how to analyze a test data set. Another method of reducing bias is to classify each observation using a discriminant function computed from all of the other observations; this method is invoked with the CROSSVALIDATE option.

Figure 25.5. Resubstitution Misclassification Summary
Syntax

The following statements are available in PROC DISCRIM.

```
PROC DISCRIM < options > ;
   CLASS variable ;
   BY variables ;
   FREQ variable ;
   ID variable ;
   PRIORS probabilities ;
   TESTCLASS variable ;
   TESTFREQ variable ;
   TESTID variable ;
   VAR variables ;
   WEIGHT variable ;
```

Only the PROC DISCRIM and CLASS statements are required. The following sections describe the PROC DISCRIM statement and then describe the other statements in alphabetical order.

**PROC DISCRIM Statement**

PROC DISCRIM < options > ;

This statement invokes the DISCRIM procedure. You can specify the following options in the PROC DISCRIM statement.

<table>

</tbody>
</table>
ALL
activates all options that control displayed output. When the derived classification criterion is used to classify observations, the ALL option also activates the POSTERR option.

ANOVA
displays univariate statistics for testing the hypothesis that the class means are equal in the population for each variable.

BCORR
displays between-class correlations.

BCOV
displays between-class covariances. The between-class covariance matrix equals the between-class SSCP matrix divided by \( n(c - 1)/c \), where \( n \) is the number of observations and \( c \) is the number of classes. You should interpret the between-class covariances in comparison with the total-sample and within-class covariances, not as formal estimates of population parameters.

BSSCP
displays the between-class SSCP matrix.

CANONICAL
performs canonical discriminant analysis.

CANPREFIX=\( name \)
specifies a prefix for naming the canonical variables. By default, the names are Can1, Can2, ..., Can\( n \). If you specify CANPREFIX=ABC, the components are named ABC1, ABC2, ABC3, and so on. The number of characters in the prefix, plus the number of digits required to designate the canonical variables, should not exceed 32. The prefix is truncated if the combined length exceeds 32.

The CANONICAL option is activated when you specify either the NCAN= or the CANPREFIX= option. A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of discriminant criteria, you should use PROC CANDISC.

CROSSLIST
displays the cross validation classification results for each observation.

CROSSLISTERR
displays the cross validation classification results for misclassified observations only.

CROSSVALIDATE
specifies the cross validation classification of the input DATA= data set. When a parametric method is used, PROC DISCRIM classifies each observation in the DATA= data set using a discriminant function computed from the other observations in the DATA= data set, excluding the observation being classified. When a nonparametric method is used, the covariance matrices used to compute the distances are based on all observations in the data set and do not exclude the observation being classified. However, the observation being classified is excluded from the nonparametric density
estimation (if you specify the R= option) or the $k$ nearest neighbors (if you specify the K= option) of that observation. The CROSSVALIDATE option is set when you specify the CROSSLIST, CROSSLISTERR, or OUTCROSS= option.

**DATA=** SAS-data-set

specifies the data set to be analyzed. The data set can be an ordinary SAS data set or one of several specially structured data sets created by SAS/STAT procedures. These specially structured data sets include TYPE=CORR, TYPE=COV, TYPE=CSSCP, TYPE=SSCP, TYPE=LINEAR, TYPE=QUAD, and TYPE=MIXED. The input data set must be an ordinary SAS data set if you specify METHOD=NPAR. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

**DISTANCE**

**MAHALANOBIS**

displays the squared Mahalanobis distances between the group means, $F$ statistics, and the corresponding probabilities of greater Mahalanobis squared distances between the group means. The squared distances are based on the specification of the POOL= and METRIC= options.

**K=** $k$

specifies a $k$ value for the $k$-nearest-neighbor rule. An observation $x$ is classified into a group based on the information from the $k$ nearest neighbors of $x$. Do not specify both the K= and R= options.

**KERNEL=** BIWEIGHT | BIW

**KERNEL=** EPANECHNIKOV | EPA

**KERNEL=** NORMAL | NOR

**KERNEL=** TRIWEIGHT | TRI

**KERNEL=** UNIFORM | UNI

specifies a kernel density to estimate the group-specific densities. You can specify the KERNEL= option only when the R= option is specified. The default is KERNEL=UNIFORM.

**LIST**

displays the resubstitution classification results for each observation. You can specify this option only when the input data set is an ordinary SAS data set.

**LISTERR**

displays the resubstitution classification results for misclassified observations only. You can specify this option only when the input data set is an ordinary SAS data set.

**MANOVA**

displays multivariate statistics for testing the hypothesis that the class means are equal in the population.

**METHOD=** NORMAL | NPAR

determines the method to use in deriving the classification criterion. When you specify METHOD=NORMAL, a parametric method based on a multivariate normal distribution within each class is used to derive a linear or quadratic discriminant function. The default is METHOD=NORMAL. When you specify METHOD=NPAR, a nonparametric method is used and you must also specify either the K= or R= option.
METRIC=DIAGONAL | FULL | IDENTITY

specifies the metric in which the computations of squared distances are performed. If you specify METRIC=FULL, PROC DISCRIM uses either the pooled covariance matrix (POOL=YES) or individual within-group covariance matrices (POOL=NO) to compute the squared distances. If you specify METRIC=DIAGONAL, PROC DISCRIM uses either the diagonal matrix of the pooled covariance matrix (POOL=YES) or diagonal matrices of individual within-group covariance matrices (POOL=NO) to compute the squared distances. If you specify METRIC=IDENTITY, PROC DISCRIM uses Euclidean distance. The default is METRIC=FULL. When you specify METHOD=NORMAL, the option METRIC=FULL is used.

NCAN=number

specifies the number of canonical variables to compute. The value of number must be less than or equal to the number of variables. If you specify the option NCAN=0, the procedure displays the canonical correlations but not the canonical coefficients, structures, or means. Let $v$ be the number of variables in the VAR statement and $c$ be the number of classes. If you omit the NCAN= option, only $\min(v, c - 1)$ canonical variables are generated. If you request an output data set (OUT=, OUTCROSS=, TESTOUT=), $v$ canonical variables are generated. In this case, the last $v - (c - 1)$ canonical variables have missing values.

The CANONICAL option is activated when you specify either the NCAN= or the CANPREFIX= option. A discriminant criterion is always derived in PROC DISCRIM. If you want canonical discriminant analysis without the use of discriminant criterion, you should use PROC CANDISC.

NOCLASSIFY

suppresses the resubstitution classification of the input DATA= data set. You can specify this option only when the input data set is an ordinary SAS data set.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

OUT=SAS-data-set

creates an output SAS data set containing all the data from the DATA= data set, plus the posterior probabilities and the class into which each observation is classified by resubstitution. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. See the “OUT= Data Set” section on page 1170.

OUTCROSS=SAS-data-set

creates an output SAS data set containing all the data from the DATA= data set, plus the posterior probabilities and the class into which each observation is classified by cross validation. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. See the “OUT= Data Set” section on page 1170.
OUTD=SAS-data-set
creates an output SAS data set containing all the data from the DATA= data set, plus the group-specific density estimates for each observation. See the “OUT= Data Set” section on page 1170.

OUTSTAT=SAS-data-set
creates an output SAS data set containing various statistics such as means, standard deviations, and correlations. When the input data set is an ordinary SAS data set or when TYPE=CORR, TYPE=COV, TYPE=CSSCP, or TYPE=SSCP, this option can be used to generate discriminant statistics. When you specify the CANONICAL option, canonical correlations, canonical structures, canonical coefficients, and means of canonical variables for each class are included in the data set. If you specify METHOD=NORMAL, the output data set also includes coefficients of the discriminant functions, and the output data set is TYPE=LINEAR (POOL=YES), TYPE=QUAD (POOL=NO), or TYPE=MIXED (POOL=TEST). If you specify METHOD=NPAR, this output data set is TYPE=CORR. This data set also holds calibration information that can be used to classify new observations. See the “Saving and Using Calibration Information” section on page 1167 and the “OUT= Data Set” section on page 1170.

PCORR
displays pooled within-class correlations.

PCOV
displays pooled within-class covariances.

POOL=NO | TEST | YES
determines whether the pooled or within-group covariance matrix is the basis of the measure of the squared distance. If you specify POOL=YES, PROC DISCRIM uses the pooled covariance matrix in calculating the (generalized) squared distances. Linear discriminant functions are computed. If you specify POOL=NO, the procedure uses the individual within-group covariance matrices in calculating the distances. Quadratic discriminant functions are computed. The default is POOL=YES.

When you specify METHOD=NORMAL, the option POOL=TEST requests Bartlett’s modification of the likelihood ratio test (Morrison 1976; Anderson 1984) of the homogeneity of the within-group covariance matrices. The test is unbiased (Perlman 1980). However, it is not robust to nonnormality. If the test statistic is significant at the level specified by the SLPOOL= option, the within-group covariance matrices are used. Otherwise, the pooled covariance matrix is used. The discriminant function coefficients are displayed only when the pooled covariance matrix is used.

POSTERR
displays the posterior probability error-rate estimates of the classification criterion based on the classification results.
PSSCP

displays the pooled within-class corrected SSCP matrix.

R= r

specifies a radius r value for kernel density estimation. With uniform, Epanechnikov, biweight, or triweight kernels, an observation x is classified into a group based on the information from observations y in the training set within the radius r of x, that is, the group t observations y with squared distance \( d_t^2(x, y) \leq r^2 \). When a normal kernel is used, the classification of an observation x is based on the information of the estimated group-specific densities from all observations in the training set. The matrix \( r^2V_t \) is used as the group t covariance matrix in the normal-kernel density, where \( V_t \) is the matrix used in calculating the squared distances. Do not specify both the K= and R= options. For more information on selecting r, see the “Nonparametric Methods” section on page 1158.

SHORT

suppresses the display of certain items in the default output. If you specify METHOD= NORMAL, PROC DISCRIM suppresses the display of determinants, generalized squared distances between-class means, and discriminant function coefficients. When you specify the CANONICAL option, PROC DISCRIM suppresses the display of canonical structures, canonical coefficients, and class means on canonical variables; only tables of canonical correlations are displayed.

SIMPLE

displays simple descriptive statistics for the total sample and within each class.

SINGULAR= p

specifies the criterion for determining the singularity of a matrix, where \( 0 < p < 1 \). The default is SINGULAR=1E-8.

Let \( S \) be the total-sample correlation matrix. If the \( R^2 \) for predicting a quantitative variable in the VAR statement from the variables preceding it exceeds \( 1 - p \), then \( S \) is considered singular. If \( S \) is singular, the probability levels for the multivariate test statistics and canonical correlations are adjusted for the number of variables with \( R^2 \) exceeding \( 1 - p \).

Let \( S_t \) be the group t covariance matrix and \( S_p \) be the pooled covariance matrix. In group t, if the \( R^2 \) for predicting a quantitative variable in the VAR statement from the variables preceding it exceeds \( 1 - p \), then \( S_t \) is considered singular. Similarly, if the partial \( R^2 \) for predicting a quantitative variable in the VAR statement from the variables preceding it, after controlling for the effect of the CLASS variable, exceeds \( 1 - p \), then \( S_p \) is considered singular.

If PROC DISCRIM needs to compute either the inverse or the determinant of a matrix that is considered singular, then it uses a quasi-inverse or a quasi-determinant. For details, see the “Quasi-Inverse” section on page 1164.

SLPOOL= p

specifies the significance level for the test of homogeneity. You can specify the SLPOOL= option only when POOL=TEST is also specified. If you specify POOL=
TEST but omit the SLPOOL= option, PROC DISCRIM uses 0.10 as the significance level for the test.

**STDMEAN**

displays total-sample and pooled within-class standardized class means.

**TCORR**
displays total-sample correlations.

**TCOV**
displays total-sample covariances.

**TESTDATA=SAS-data-set**
names an ordinary SAS data set with observations that are to be classified. The quantitative variable names in this data set must match those in the DATA= data set. When you specify the TESTDATA= option, you can also specify the TESTCLASS, TESTFREQ, and TESTID statements. When you specify the TESTDATA= option, you can use the TESTOUT= and TESTOUTD= options to generate classification results and group-specific density estimates for observations in the test data set. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

**TESTLIST**
lists classification results for all observations in the TESTDATA= data set.

**TESTLISTERR**
lists only misclassified observations in the TESTDATA= data set but only if a TESTCLASS statement is also used.

**TESTOUT=SAS-data-set**
creates an output SAS data set containing all the data from the TESTDATA= data set, plus the posterior probabilities and the class into which each observation is classified. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. See the “OUT= Data Set” section on page 1170.

**TESTOUTD=SAS-data-set**
creates an output SAS data set containing all the data from the TESTDATA= data set, plus the group-specific density estimates for each observation. See the “OUT= Data Set” section on page 1170.

**THRESHOLD=p**
specifies the minimum acceptable posterior probability for classification, where $0 \leq p \leq 1$. If the largest posterior probability of group membership is less than the THRESHOLD value, the observation is classified into group OTHER. The default is THRESHOLD=0.

**TSSCP**
displays the total-sample corrected SSCP matrix.
displays within-class correlations for each class level.

WCOV

displays within-class covariances for each class level.

WSSCP

displays the within-class corrected SSCP matrix for each class level.

**BY Statement**

```
BY variables;
```

You can specify a BY statement with PROC DISCRIM to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the DISCRIM procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, see the discussion in the *SAS Procedures Guide*.

If you specify the TESTDATA= option and the TESTDATA= data set does not contain any of the BY variables, then the entire TESTDATA= data set is classified according to the discriminant functions computed in each BY group in the DATA= data set.

If the TESTDATA= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the TESTDATA= data set as in the DATA= data set, then PROC DISCRIM displays an error message and stops.

If all BY variables appear in the TESTDATA= data set with the same type and length as in the DATA= data set, then each BY group in the TESTDATA= data set is classified by the discriminant function from the corresponding BY group in the DATA= data set. The BY groups in the TESTDATA= data set must be in the same order as in the DATA= data set. If you specify the NOTSORTED option in the BY statement, there must be exactly the same BY groups in the same order in both data sets. If you omit the NOTSORTED option, some BY groups may appear in one data set but not in the other. If some BY groups appear in the TESTDATA= data set but not in the DATA= data set, and you request an output test data set using the TESTOUT= or TESTOUTD= option, these BY groups are not included in the output data set.
**CLASS Statement**

```plaintext
CLASS variable;
```

The values of the classification variable define the groups for analysis. Class levels are determined by the formatted values of the CLASS variable. The specified variable can be numeric or character. A CLASS statement is required.

**FREQ Statement**

```plaintext
FREQ variable;
```

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable’s name in a FREQ statement. The procedure then treats the data set as if each observation appears \( n \) times, where \( n \) is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, it is truncated to an integer.

**ID Statement**

```plaintext
ID variable;
```

The ID statement is effective only when you specify the LIST or LISTERR option in the PROC DISCRIM statement. When the DISCRIM procedure displays the classification results, the ID variable (rather than the observation number) is displayed for each observation.

**PRIORS Statement**

```plaintext
PRIORS EQUAL;
PRIORS PROPORTIONAL | PROP;
PRIORS probabilities;
```

The PRIORS statement specifies the prior probabilities of group membership. To set the prior probabilities equal, use

```plaintext
priors equal;
```

To set the prior probabilities proportional to the sample sizes, use

```plaintext
priors proportional;
```

For other than equal or proportional priors, specify the prior probability for each level of the classification variable. Each class level can be written as either a SAS name or a quoted string, and it must be followed by an equal sign and a numeric constant between zero and one. A SAS name begins with a letter or an underscore and can
contain digits as well. Lowercase character values and data values with leading blanks must be enclosed in quotes. For example, to define prior probabilities for each level of Grade, where Grade’s values are A, B, C, and D, the PRIORS statement can be

\[
priors A=0.1 \ B=0.3 \ C=0.5 \ D=0.1;
\]

If Grade’s values are ‘a’, ‘b’, ‘c’, and ‘d’, each class level must be written as a quoted string:

\[
priors ‘a’=0.1 \ ‘b’=0.3 \ ‘c’=0.5 \ ‘d’=0.1;
\]

If Grade is numeric, with formatted values of ‘1’, ‘2’, and ‘3’, the PRIORS statement can be

\[
priors ‘1’=0.3 \ ‘2’=0.6 \ ‘3’=0.1;
\]

The specified class levels must exactly match the formatted values of the CLASS variable. For example, if a CLASS variable C has the format 4.2 and a value 5, the PRIORS statement must specify ‘5.00’, not ‘5.0’ or ‘5’. If the prior probabilities do not sum to one, these probabilities are scaled proportionally to have the sum equal to one. The default is PRIORS EQUAL.

**TESTCLASS Statement**

```
TESTCLASS variable;
```

The TESTCLASS statement names the variable in the TESTDATA= data set that is used to determine whether an observation in the TESTDATA= data set is misclassified. The TESTCLASS variable should have the same type (character or numeric) and length as the variable given in the CLASS statement. PROC DISCRIM considers an observation misclassified when the formatted value of the TESTCLASS variable does not match the group into which the TESTDATA= observation is classified. When the TESTCLASS statement is missing and the TESTDATA= data set contains the variable given in the CLASS statement, the CLASS variable is used as the TESTCLASS variable. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

**TESTFREQ Statement**

```
TESTFREQ variable;
```

If a variable in the TESTDATA= data set represents the frequency of occurrence for the other values in the observation, include the variable’s name in a TESTFREQ statement. The procedure then treats the data set as if each observation appears \( n \) times, where \( n \) is the value of the TESTFREQ variable for the observation.

If the value of the TESTFREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, it is truncated to an integer.
**TESTID Statement**

```
TESTID  variable ;
```

The TESTID statement is effective only when you specify the TESTLIST or TESTLISTERR option in the PROC DISCRIM statement. When the DISCRIM procedure displays the classification results for the TESTDATA= data set, the TESTID variable (rather than the observation number) is displayed for each observation. The variable given in the TESTID statement must be in the TESTDATA= data set.

**VAR Statement**

```
VAR  variables ;
```

The VAR statement specifies the quantitative variables to be included in the analysis. The default is all numeric variables not listed in other statements.

**WEIGHT Statement**

```
WEIGHT  variable ;
```

To use relative weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. If the value of the WEIGHT variable is missing or is less than zero, then a value of zero for the weight is used.

The WEIGHT and FREQ statements have a similar effect except that the WEIGHT statement does not alter the degrees of freedom.

**Details**

**Missing Values**

Observations with missing values for variables in the analysis are excluded from the development of the classification criterion. When the values of the classification variable are missing, the observation is excluded from the development of the classification criterion, but if no other variables in the analysis have missing values for that observation, the observation is classified and displayed with the classification results.

**Background**

The following notation is used to describe the classification methods:

- $\mathbf{x}$: a $p$-dimensional vector containing the quantitative variables of an observation
- $S_p$: the pooled covariance matrix
- $t$: a subscript to distinguish the groups
- $n_t$: the number of training set observations in group $t$
\( \mathbf{m}_t \) the \( p \)-dimensional vector containing variable means in group \( t \)

\( \mathbf{S}_t \) the covariance matrix within group \( t \)

\( |\mathbf{S}_t| \) the determinant of \( \mathbf{S}_t \)

\( q_t \) the prior probability of membership in group \( t \)

\( p(t|x) \) the posterior probability of an observation \( x \) belonging to group \( t \)

\( f_t \) the probability density function for group \( t \)

\( f_t(x) \) the group-specific density estimate at \( x \) from group \( t \)

\( f(x) \sum_t q_t f_t(x) \), the estimated unconditional density at \( x \)

\( e_t \) the classification error rate for group \( t \)

**Bayes’ Theorem**

Assuming that the prior probabilities of group membership are known and that the group-specific densities at \( x \) can be estimated, PROC DISCRIM computes \( p(t|x) \), the probability of \( x \) belonging to group \( t \), by applying Bayes’ theorem:

\[
p(t|x) = \frac{q_t f_t(x)}{f(x)}
\]

PROC DISCRIM partitions a \( p \)-dimensional vector space into regions \( R_t \), where the region \( R_t \) is the subspace containing all \( p \)-dimensional vectors \( y \) such that \( p(t|y) \) is the largest among all groups. An observation is classified as coming from group \( t \) if it lies in region \( R_t \).

**Parametric Methods**

Assuming that each group has a multivariate normal distribution, PROC DISCRIM develops a discriminant function or classification criterion using a measure of generalized squared distance. The classification criterion is based on either the individual within-group covariance matrices or the pooled covariance matrix; it also takes into account the prior probabilities of the classes. Each observation is placed in the class from which it has the smallest generalized squared distance. PROC DISCRIM also computes the posterior probability of an observation belonging to each class.

The squared Mahalanobis distance from \( x \) to group \( t \) is

\[
d^2_t(x) = (x - \mathbf{m}_t)\mathbf{V}_t^{-1}(x - \mathbf{m}_t)
\]

where \( \mathbf{V}_t = \mathbf{S}_t \) if the within-group covariance matrices are used, or \( \mathbf{V}_t = \mathbf{S}_p \) if the pooled covariance matrix is used.

The group-specific density estimate at \( x \) from group \( t \) is then given by

\[
f_t(x) = (2\pi)^{-\frac{p}{2}}|\mathbf{V}_t|^{-\frac{1}{2}}\exp\left(-0.5d^2_t(x)\right)
\]
Using Bayes’ theorem, the posterior probability of \( x \) belonging to group \( t \) is
\[
p(t|x) = \frac{q_t f_t(x)}{\sum_u q_u f_u(x)}
\]
where the summation is over all groups.

The generalized squared distance from \( x \) to group \( t \) is defined as
\[
D_t^2(x) = d_t^2(x) + g_1(t) + g_2(t)
\]
where
\[
g_1(t) = \begin{cases} 
\ln |S_t| & \text{if the within-group covariance matrices are used} \\
0 & \text{if the pooled covariance matrix is used}
\end{cases}
\]
and
\[
g_2(t) = \begin{cases} 
-2 \ln(q_t) & \text{if the prior probabilities are not all equal} \\
0 & \text{if the prior probabilities are all equal}
\end{cases}
\]
The posterior probability of \( x \) belonging to group \( t \) is then equal to
\[
p(t|x) = \frac{\exp \left(-0.5D_t^2(x)\right)}{\sum_u \exp \left(-0.5D_u^2(x)\right)}
\]
The discriminant scores are \(-0.5D_t^2(x)\). An observation is classified into group \( u \) if setting \( t = u \) produces the largest value of \( p(t|x) \) or the smallest value of \( D_t^2(x) \). If this largest posterior probability is less than the threshold specified, \( x \) is classified into group OTHER.

**Nonparametric Methods**

Nonparametric discriminant methods are based on nonparametric estimates of group-specific probability densities. Either a kernel method or the \( k \)-nearest-neighbor method can be used to generate a nonparametric density estimate in each group and to produce a classification criterion. The kernel method uses uniform, normal, Epanechnikov, biweight, or triweight kernels in the density estimation.

Either Mahalanobis distance or Euclidean distance can be used to determine proximity. When the \( k \)-nearest-neighbor method is used, the Mahalanobis distances are based on the pooled covariance matrix. When a kernel method is used, the Mahalanobis distances are based on either the individual within-group covariance matrices or the pooled covariance matrix. Either the full covariance matrix or the diagonal matrix of variances can be used to calculate the Mahalanobis distances.

The squared distance between two observation vectors, \( x \) and \( y \), in group \( t \) is given by
\[
d_t^2(x, y) = (x - y)' V_t^{-1} (x - y)
\]
where $V_t$ has one of the following forms:

$$V_t = \begin{cases} 
S_p & \text{the pooled covariance matrix} \\
\text{diag}(S_p) & \text{the diagonal matrix of the pooled covariance matrix} \\
S_t & \text{the covariance matrix within group } t \\
\text{diag}(S_t) & \text{the diagonal matrix of the covariance matrix within group } t \\
I & \text{the identity matrix}
\end{cases}$$

The classification of an observation vector $x$ is based on the estimated group-specific densities from the training set. From these estimated densities, the posterior probabilities of group membership at $x$ are evaluated. An observation $x$ is classified into group $u$ if setting $t = u$ produces the largest value of $p(t|x)$. If there is a tie for the largest probability or if this largest probability is less than the threshold specified, $x$ is classified into group OTHER.

The kernel method uses a fixed radius, $r$, and a specified kernel, $K_t$, to estimate the group $t$ density at each observation vector $x$. Let $z$ be a $p$-dimensional vector. Then the volume of a $p$-dimensional unit sphere bounded by $z'z = 1$ is

$$v_0 = \frac{\pi^{\frac{p}{2}}}{\Gamma\left(\frac{p}{2} + 1\right)}$$

where $\Gamma$ represents the gamma function (refer to SAS Language Reference: Dictionary).

Thus, in group $t$, the volume of a $p$-dimensional ellipsoid bounded by $\{z \mid z'V_t^{-1}z = r^2\}$ is

$$v_r(t) = r^p|V_t|^{\frac{1}{2}}v_0$$

The kernel method uses one of the following densities as the kernel density in group $t$.

**Uniform Kernel**

$$K_t(z) = \begin{cases} 
\frac{1}{v_r(t)} & \text{if } z'V_t^{-1}z \leq r^2 \\
0 & \text{elsewhere}
\end{cases}$$

**Normal Kernel** (with mean zero, variance $r^2V_t$)

$$K_t(z) = \frac{1}{c_0(t)} \exp\left(-\frac{1}{2r^2}z'V_t^{-1}z\right)$$

where $c_0(t) = (2\pi)^{\frac{p}{2}}r^p|V_t|^{\frac{1}{2}}$. 
Epanechnikov Kernel

$$K_t(z) = \begin{cases} c_1(t) \left(1 - \frac{1}{r^2} z'V_t^{-1}z\right) & \text{if } z'V_t^{-1}z \leq r^2 \\ 0 & \text{otherwise} \end{cases}$$

where $c_1(t) = \frac{1}{\nu(r(t))} \left(1 + \frac{p}{2}\right)$.

Biweight Kernel

$$K_t(z) = \begin{cases} c_2(t) \left(1 - \frac{1}{r^2} z'V_t^{-1}z\right)^2 & \text{if } z'V_t^{-1}z \leq r^2 \\ 0 & \text{otherwise} \end{cases}$$

where $c_2(t) = \left(1 + \frac{p}{4}\right) c_1(t)$.

Triweight Kernel

$$K_t(z) = \begin{cases} c_3(t) \left(1 - \frac{1}{r^2} z'V_t^{-1}z\right)^3 & \text{if } z'V_t^{-1}z \leq r^2 \\ 0 & \text{otherwise} \end{cases}$$

where $c_3(t) = \left(1 + \frac{p}{6}\right) c_2(t)$.

The group $t$ density at $x$ is estimated by

$$f_t(x) = \frac{1}{n_t} \sum_y K_t(x - y)$$

where the summation is over all observations $y$ in group $t$, and $K_t$ is the specified kernel function. The posterior probability of membership in group $t$ is then given by

$$p(t|x) = \frac{q_t f_t(x)}{f(x)}$$

where $f(x) = \sum_u q_u f_u(x)$ is the estimated unconditional density. If $f(x)$ is zero, the observation $x$ is classified into group OTHER.

The uniform-kernel method treats $K_t(z)$ as a multivariate uniform function with density uniformly distributed over $z'V_t^{-1}z \leq r^2$. Let $k_t$ be the number of training set observations $y$ from group $t$ within the closed ellipsoid centered at $x$ specified by $d_t^2(x, y) \leq r^2$. Then the group $t$ density at $x$ is estimated by

$$f_t(x) = \frac{k_t}{n_t \nu(r(t))}$$
When the identity matrix or the pooled within-group covariance matrix is used in calculating the squared distance, \( v_r(t) \) is a constant, independent of group membership. The posterior probability of \( x \) belonging to group \( t \) is then given by

\[
p(t|x) = \frac{q_t k_t}{n_t} \sum_u \frac{q_u k_u}{n_u}
\]

If the closed ellipsoid centered at \( x \) does not include any training set observations, \( f(x) \) is zero and \( x \) is classified into group OTHER. When the prior probabilities are equal, \( p(t|x) \) is proportional to \( k_t/n_t \) and \( x \) is classified into the group that has the highest proportion of observations in the closed ellipsoid. When the prior probabilities are proportional to the group sizes, \( p(t|x) = k_t/\sum_u k_u \), \( x \) is classified into the group that has the largest number of observations in the closed ellipsoid.

The nearest-neighbor method fixes the number, \( k \), of training set points for each observation \( x \). The method finds the radius \( r_k(x) \) that is the distance from \( x \) to the \( k \)th nearest training set point in the metric \( V_t^{-1} \). Consider a closed ellipsoid centered at \( x \) bounded by \( \{ z \mid (z - x)'V_t^{-1}(z - x) = r_k^2(x) \} \); the nearest-neighbor method is equivalent to the uniform-kernel method with a location-dependent radius \( r_k(x) \). Note that, with ties, more than \( k \) training set points may be in the ellipsoid.

Using the \( k \)-nearest-neighbor rule, the \( k_n \) (or more with ties) smallest distances are saved. Of these \( k \) distances, let \( k_t \) represent the number of distances that are associated with group \( t \). Then, as in the uniform-kernel method, the estimated group \( t \) density at \( x \) is

\[
f_t(x) = \frac{k_t}{n_t v_k(x)}
\]

where \( v_k(x) \) is the volume of the ellipsoid bounded by \( \{ z \mid (z - x)'V_t^{-1}(z - x) = r_k^2(x) \} \). Since the pooled within-group covariance matrix is used to calculate the distances used in the nearest-neighbor method, the volume \( v_k(x) \) is a constant independent of group membership. When \( k = 1 \) is used in the nearest-neighbor rule, \( x \) is classified into the group associated with the \( y \) point that yields the smallest squared distance \( d_i^2(x, y) \). Prior probabilities affect nearest-neighbor results in the same way that they affect uniform-kernel results.

With a specified squared distance formula (METRIC=, POOL=), the values of \( r \) and \( k \) determine the degree of irregularity in the estimate of the density function, and they are called smoothing parameters. Small values of \( r \) or \( k \) produce jagged density estimates, and large values of \( r \) or \( k \) produce smoother density estimates. Various methods for choosing the smoothing parameters have been suggested, and there is as yet no simple solution to this problem.

For a fixed kernel shape, one way to choose the smoothing parameter \( r \) is to plot estimated densities with different values of \( r \) and to choose the estimate that is most in accordance with the prior information about the density. For many applications, this approach is satisfactory.
Another way of selecting the smoothing parameter $r$ is to choose a value that optimizes a given criterion. Different groups may have different sets of optimal values. Assume that the unknown density has bounded and continuous second derivatives and that the kernel is a symmetric probability density function. One criterion is to minimize an approximate mean integrated square error of the estimated density (Rosenblatt 1956). The resulting optimal value of $r$ depends on the density function and the kernel. A reasonable choice for the smoothing parameter $r$ is to optimize the criterion with the assumption that group $t$ has a normal distribution with covariance matrix $V_t$. Then, in group $t$, the resulting optimal value for $r$ is given by

$$
\left( \frac{A(K_t)}{n_t} \right)^{1/(p+4)}
$$

where the optimal constant $A(K_t)$ depends on the kernel $K_t$ (Epanechnikov 1969). For some useful kernels, the constants $A(K_t)$ are given by

$$
A(K_t) = \frac{1}{p}2^{p+1}(p+2)\Gamma \left( \frac{p}{2} \right) \quad \text{with a uniform kernel}
$$

$$
A(K_t) = \frac{4}{2p+1} \quad \text{with a normal kernel}
$$

$$
A(K_t) = \frac{2^{p+2}p^2(p+2)(p+4)}{2p+1} \frac{\Gamma \left( \frac{p}{2} \right)}{\Gamma \left( \frac{p}{2} \right)} \quad \text{with an Epanechnikov kernel}
$$

These selections of $A(K_t)$ are derived under the assumption that the data in each group are from a multivariate normal distribution with covariance matrix $V_t$. However, when the Euclidean distances are used in calculating the squared distance ($V_t = I$), the smoothing constant should be multiplied by $s$, where $s$ is an estimate of standard deviations for all variables. A reasonable choice for $s$ is

$$
s = \left( \frac{1}{p} \sum s_{jj} \right)^{\frac{1}{2}}
$$

where $s_{jj}$ are group $t$ marginal variances.

The DISCRIM procedure uses only a single smoothing parameter for all groups. However, with the selection of the matrix to be used in the distance formula (using the METRIC= or POOL= option), individual groups and variables can have different scalings. When $V_t$, the matrix used in calculating the squared distances, is an identity matrix, the kernel estimate on each data point is scaled equally for all variables in all groups. When $V_t$ is the diagonal matrix of a covariance matrix, each variable in group $t$ is scaled separately by its variance in the kernel estimation, where the variance can be the pooled variance ($V_t = S_p$) or an individual within-group variance ($V_t = S_t$). When $V_t$ is a full covariance matrix, the variables in group $t$ are scaled simultaneously by $V_t$ in the kernel estimation.
In nearest-neighbor methods, the choice of \( k \) is usually relatively uncritical (Hand 1982). A practical approach is to try several different values of the smoothing parameters within the context of the particular application and to choose the one that gives the best cross validated estimate of the error rate.

**Classification Error-Rate Estimates**

A classification criterion can be evaluated by its performance in the classification of future observations. PROC DISCRIM uses two types of error-rate estimates to evaluate the derived classification criterion based on parameters estimated by the training sample:

- error-count estimates
- posterior probability error-rate estimates.

The error-count estimate is calculated by applying the classification criterion derived from the training sample to a test set and then counting the number of misclassified observations. The group-specific error-count estimate is the proportion of misclassified observations in the group. When the test set is independent of the training sample, the estimate is unbiased. However, it can have a large variance, especially if the test set is small.

When the input data set is an ordinary SAS data set and no independent test sets are available, the same data set can be used both to define and to evaluate the classification criterion. The resulting error-count estimate has an optimistic bias and is called an *apparent error rate*. To reduce the bias, you can split the data into two sets, one set for deriving the discriminant function and the other set for estimating the error rate. Such a split-sample method has the unfortunate effect of reducing the effective sample size.

Another way to reduce bias is cross validation (Lachenbruch and Mickey 1968). Cross validation treats \( n - 1 \) out of \( n \) training observations as a training set. It determines the discriminant functions based on these \( n - 1 \) observations and then applies them to classify the one observation left out. This is done for each of the \( n \) training observations. The misclassification rate for each group is the proportion of sample observations in that group that are misclassified. This method achieves a nearly unbiased estimate but with a relatively large variance.

To reduce the variance in an error-count estimate, smoothed error-rate estimates are suggested (Glick 1978). Instead of summing terms that are either zero or one as in the error-count estimator, the smoothed estimator uses a continuum of values between zero and one in the terms that are summed. The resulting estimator has a smaller variance than the error-count estimate. The posterior probability error-rate estimates provided by the POSTERR option in the PROC DISCRIM statement (see the following section, “Posterior Probability Error-Rate Estimates”) are smoothed error-rate estimates. The posterior probability estimates for each group are based on the posterior probabilities of the observations classified into that same group. The posterior probability estimates provide good estimates of the error rate when the posterior probabilities are accurate. When a parametric classification criterion (linear or
quadratic discriminant function) is derived from a nonnormal population, the resulting posterior probability error-rate estimators may not be appropriate.

The overall error rate is estimated through a weighted average of the individual group-specific error-rate estimates, where the prior probabilities are used as the weights.

To reduce both the bias and the variance of the estimator, Hora and Wilcox (1982) compute the posterior probability estimates based on cross validation. The resulting estimates are intended to have both low variance from using the posterior probability estimate and low bias from cross validation. They use Monte Carlo studies on two-group multivariate normal distributions to compare the cross validation posterior probability estimates with three other estimators: the apparent error rate, cross validation estimator, and posterior probability estimator. They conclude that the cross validation posterior probability estimator has a lower mean squared error in their simulations.

**Quasi-Inverse**

Consider the plot shown in Figure 25.6 with two variables, $X_1$ and $X_2$, and two classes, A and B. The within-class covariance matrix is diagonal, with a positive value for $X_1$ but zero for $X_2$. Using a Moore-Penrose pseudo-inverse would effectively ignore $X_2$ in doing the classification, and the two classes would have a zero generalized distance and could not be discriminated at all. The quasi-inverse used by PROC DISCRIM replaces the zero variance for $X_2$ by a small positive number to remove the singularity. This allows $X_2$ to be used in the discrimination and results correctly in a large generalized distance between the two classes and a zero error rate. It also allows new observations, such as the one indicated by N, to be classified in a reasonable way. PROC CANDISC also uses a quasi-inverse when the total-sample covariance matrix is considered to be singular and Mahalanobis distances are requested. This problem with singular within-class covariance matrices is discussed in Ripley (1996, p. 38). The use of the quasi-inverse is an innovation introduced by SAS Institute Inc.

![Quasi-Inverse Example](image)

**Figure 25.6.** Plot of Data with Singular Within-Class Covariance Matrix

Let $S$ be a singular covariance matrix. The matrix $S$ can be either a within-group covariance matrix, a pooled covariance matrix, or a total-sample covariance matrix. Let $v$ be the number of variables in the VAR statement and the nullity $n$ be the number
of variables among them with (partial) $R^2$ exceeding 1 — $p$. If the determinant of $S$ (Testing of Homogeneity of Within Covariance Matrices) or the inverse of $S$ (Squared Distances and Generalized Squared Distances) is required, a quasi-determinant or quasi-inverse is used instead. PROC DISCRIM scales each variable to unit total-sample variance before calculating this quasi-inverse. The calculation is based on the spectral decomposition $S = \Gamma \Lambda \Gamma'$, where $\Lambda$ is a diagonal matrix of eigenvalues $\lambda_j$, $j = 1, \ldots, v$, where $\lambda_i \geq \lambda_j$ when $i < j$, and $\Gamma$ is a matrix with the corresponding orthonormal eigenvectors of $S$ as columns. When the nullity $n$ is less than $v$, set $\lambda^0_j = \lambda_j$ for $j = 1, \ldots, v - n$, and $\lambda^0_j = p \bar{\lambda}$ for $j = v - n + 1, \ldots, v$, where

$$\bar{\lambda} = \frac{1}{v - n} \sum_{k=1}^{v-n} \lambda_k$$

When the nullity $n$ is equal to $v$, set $\lambda^0_j = p$, for $j = 1, \ldots, v$. A quasi-determinant is then defined as the product of $\lambda^0_j$, $j = 1, \ldots, v$. Similarly, a quasi-inverse is then defined as $S^* = \Gamma \Lambda^* \Gamma'$, where $\Lambda^*$ is a diagonal matrix of values $1/\lambda^0_j$, $j = 1, \ldots, v$.

### Posterior Probability Error-Rate Estimates

The posterior probability error-rate estimates (Fukunaga and Kessell 1973; Glick 1978; Hora and Wilcox 1982) for each group are based on the posterior probabilities of the observations classified into that same group.

A sample of observations with classification results can be used to estimate the posterior error rates. The following notation is used to describe the sample.

- $S$ the set of observations in the (training) sample
- $n$ the number of observations in $S$
- $n_t$ the number of observations in $S$ in group $t$
- $R_t$ the set of observations such that the posterior probability belonging to group $t$ is the largest
- $R_{ut}$ the set of observations from group $u$ such that the posterior probability belonging to group $t$ is the largest.

The classification error rate for group $t$ is defined as

$$e_t = 1 - \int_{R_t} f_t(x) dx$$

The posterior probability of $x$ for group $t$ can be written as

$$p(t|x) = \frac{q_t f_t(x)}{f(x)}$$

where $f(x) = \sum_u q_u f_u(x)$ is the unconditional density of $x$. 
Thus, if you replace $f_t(x)$ with $p(t|x)f(x)/q_t$, the error rate is

$$e_t = 1 - \frac{1}{q_t} \int_{\mathcal{R}_t} p(t|x)f(x)dx$$

An estimator of $e_t$, unstratified over the groups from which the observations come, is then given by

$$\hat{e}_t \text{ (unstratified)} = 1 - \frac{1}{nq_t} \sum_{\mathcal{R}_t} p(t|x)$$

where $p(t|x)$ is estimated from the classification criterion, and the summation is over all sample observations of $S$ classified into group $t$. The true group membership of each observation is not required in the estimation. The term $nq_t$ is the number of observations that are expected to be classified into group $t$, given the priors. If more observations than expected are classified into group $t$, then $\hat{e}_t$ can be negative.

Further, if you replace $f(x)$ with $\sum_u q_u f_u(x)$, the error rate can be written as

$$e_t = 1 - \frac{1}{q_t} \sum_u q_u \int_{\mathcal{R}_{ut}} p(t|x)f_u(x)dx$$

and an estimator stratified over the group from which the observations come is given by

$$\hat{e}_t \text{ (stratified)} = 1 - \frac{1}{q_t} \sum_u q_u \frac{1}{n_u} \left( \sum_{\mathcal{R}_{ut}} p(t|x) \right)$$

The inner summation is over all sample observations of $S$ coming from group $u$ and classified into group $t$, and $n_u$ is the number of observations originally from group $u$. The stratified estimate uses only the observations with known group membership. When the prior probabilities of the group membership are proportional to the group sizes, the stratified estimate is the same as the unstratified estimator.

The estimated group-specific error rates can be less than zero, usually due to a large discrepancy between prior probabilities of group membership and group sizes. To have a reliable estimate for group-specific error rate estimates, you should use group sizes that are at least approximately proportional to the prior probabilities of group membership.

A total error rate is defined as a weighted average of the individual group error rates

$$e = \sum_t q_t e_t$$

and can be estimated from

$$\hat{e} \text{ (unstratified)} = \sum_t q_t \hat{e}_t \text{ (unstratified)}$$
or

\[ \hat{e} \text{ (stratified)} = \sum t q_t \hat{e}_t \text{ (stratified)} \]

The total unstratified error-rate estimate can also be written as

\[ \hat{e} \text{ (unstratified)} = 1 - \frac{1}{n} \sum t \sum R_t p(t|x) \]

which is one minus the average value of the maximum posterior probabilities for each observation in the sample. The prior probabilities of group membership do not appear explicitly in this overall estimate.

**Saving and Using Calibration Information**

When you specify METHOD=NORMAL to derive a linear or quadratic discriminant function, you can save the calibration information developed by the DISCRIM procedure in a SAS data set by using the OUTSTAT= option in the procedure. PROC DISCRIM then creates a specially structured SAS data set of TYPE=LINEAR, TYPE=QUAD, or TYPE=MIXED that contains the calibration information. For more information on these data sets, see Appendix A, “Special SAS Data Sets.” Calibration information cannot be saved when METHOD=NPAR, but you can classify a TESTDATA= data set in the same step. For an example of this, see Example 25.1 on page 1180.

To use this calibration information to classify observations in another data set, specify both of the following:

- the name of the calibration data set after the DATA= option in the PROC DISCRIM statement
- the name of the data set to be classified after the TESTDATA= option in the PROC DISCRIM statement.

Here is an example:

```sas
data original;
  input position x1 x2;
datalines;
...

proc discrim outstat=info;
  class position;
run;

data check;
  input position x1 x2;
datalines;
```
The first DATA step creates the SAS data set *Original*, which the DISCRIM procedure uses to develop a classification criterion. Specifying OUTSTAT=INFO in the PROC DISCRIM statement causes the DISCRIM procedure to store the calibration information in a new data set called *Info*. The next DATA step creates the data set *Check*. The second PROC DISCRIM statement specifies DATA=INFO and TESTDATA=CHECK so that the classification criterion developed earlier is applied to the *Check* data set. Note that if the CLASS variable is not present in the TESTDATA= data set, the output will not include misclassification statistics.

### Input Data Sets

**DATA= Data Set**

When you specify METHOD=NPAR, an ordinary SAS data set is required as the input DATA= data set. When you specify METHOD=NORMAL, the DATA= data set can be an ordinary SAS data set or one of several specially structured data sets created by SAS/STAT procedures. These specially structured data sets include:

- TYPE=CORR data sets created by PROC CORR using a BY statement
- TYPE=COV data sets created by PROC PRINCOMP using both the COV option and a BY statement
- TYPE=CSSCP data sets created by PROC CORR using the CSSCP option and a BY statement, where the OUT= data set is assigned TYPE=CSSCP with the TYPE= data set option
- TYPE=SSCP data sets created by PROC REG using both the OUTSSCP= option and a BY statement
- TYPE=LINEAR, TYPE=QUAD, and TYPE=MIXED data sets produced by previous runs of PROC DISCRIM that used both METHOD=NORMAL and OUTSTAT= options

When the input data set is TYPE=CORR, TYPE=COV, TYPE=CSSCP, or TYPE=SSCP, the BY variable in these data sets becomes the CLASS variable in the DISCRIM procedure.

When the input data set is TYPE=CORR, TYPE=COV, or TYPE=CSSCP, PROC DISCRIM reads the number of observations for each class from the observations with _TYPE_='N' and reads the variable means in each class from the observations with _TYPE_='MEAN'. PROC DISCRIM then reads the within-class correlations from the observations with _TYPE_='CORR' and reads the standard deviations from the observations with _TYPE_='STD' (data set TYPE=CORR), the within-class covariances from the observations with _TYPE_='COV' (data set TYPE=COV), or
the within-class corrected sums of squares and cross products from the observations with _TYPE_='CSSCP' (data set TYPE=CSSCP).

When you specify POOL=YES and the data set does not include any observations with _TYPE_='CSSCP' (data set TYPE=CSSCP), _TYPE_='COV' (data set TYPE=COV), or _TYPE_='CORR' (data set TYPE=CORR) for each class, PROC DISCRIM reads the pooled within-class information from the data set. In this case, PROC DISCRIM reads the pooled within-class covariances from the observations with _TYPE_='PCOV' (data set TYPE=COV) or reads the pooled within-class correlations from the observations with _TYPE_='PCORR' and the pooled within-class standard deviations from the observations with _TYPE_='PSTD' (data set TYPE=CORR) or the pooled within-class corrected SSCP matrix from the observations with _TYPE_='PSSCP' (data set TYPE=CSSCP).

When the input data set is TYPE=SSCP, the DISCRIM procedure reads the number of observations for each class from the observations with _TYPE_='N', the sum of weights of observations for each class from the variable INTERCEPT in observations with _TYPE_='SSCP' and _NAME_='INTERCEPT', the variable sums from the variable=variablenames in observations with _TYPE_='SSCP' and _NAME_='INTERCEPT', and the uncorrected sums of squares and cross products from the variable=variablenames in observations with _TYPE_='SSCP' and _NAME_='variablenames'.

When the input data set is TYPE=LINEAR, TYPE=QUAD, or TYPE=MIXED, PROC DISCRIM reads the prior probabilities for each class from the observations with variable _TYPE_='PRIOR'.

When the input data set is TYPE=LINEAR, PROC DISCRIM reads the coefficients of the linear discriminant functions from the observations with variable _TYPE_='LINEAR' (see page 1173).

When the input data set is TYPE=QUAD, PROC DISCRIM reads the coefficients of the quadratic discriminant functions from the observations with variable _TYPE_='QUAD' (see page 1173).

When the input data set is TYPE=MIXED, PROC DISCRIM reads the coefficients of the linear discriminant functions from the observations with variable _TYPE_='LINEAR'. If there are no observations with _TYPE_='LINEAR', PROC DISCRIM then reads the coefficients of the quadratic discriminant functions from the observations with variable _TYPE_='QUAD' (see page 1173).

**TESTDATA= Data Set**

The TESTDATA= data set is an ordinary SAS data set with observations that are to be classified. The quantitative variable names in this data set must match those in the DATA= data set. The TESTCLASS statement can be used to specify the variable containing group membership information of the TESTDATA= data set observations. When the TESTCLASS statement is missing and the TESTDATA= data set contains the variable given in the CLASS statement, this variable is used as the TESTCLASS variable. The TESTCLASS variable should have the same type (character or numeric) and length as the variable given in the CLASS statement. PROC DISCRIM
Chapter 25. The DISCRIM Procedure

considers an observation misclassified when the value of the TESTCLASS variable does not match the group into which the TESTDATA= observation is classified.

Output Data Sets

When an output data set includes variables containing the posterior probabilities of group membership (OUT=, OUTCROSS=, or TESTOUT= data sets) or group-specific density estimates (OUTD= or TESTOUTD= data sets), the names of these variables are constructed from the formatted values of the class levels converted to valid SAS variable names.

OUT= Data Set

The OUT= data set contains all the variables in the DATA= data set, plus new variables containing the posterior probabilities and the resubstitution classification results. The names of the new variables containing the posterior probabilities are constructed from the formatted values of the class levels converted to SAS names. A new variable, _INTO_, with the same attributes as the CLASS variable, specifies the class to which each observation is assigned. If an observation is classified into group OTHER, the variable _INTO_ has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of canonical variables. The names of the canonical variables are constructed as described in the CANPREFIX= option. The canonical variables have means equal to zero and pooled within-class variances equal to one.

An OUT= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

OUTD= Data Set

The OUTD= data set contains all the variables in the DATA= data set, plus new variables containing the group-specific density estimates. The names of the new variables containing the density estimates are constructed from the formatted values of the class levels.

An OUTD= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

OUTCROSS= Data Set

The OUTCROSS= data set contains all the variables in the DATA= data set, plus new variables containing the posterior probabilities and the classification results of cross validation. The names of the new variables containing the posterior probabilities are constructed from the formatted values of the class levels. A new variable, _INTO_, with the same attributes as the CLASS variable, specifies the class to which each observation is assigned. When an observation is classified into group OTHER, the variable _INTO_ has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of new variables. The names of the new variables are
constructed as described in the CANPREFIX= option. The new variables have mean zero and pooled within-class variance equal to one.

An OUTCROSS= data set cannot be created if the DATA= data set is not an ordinary SAS data set.

**TESTOUT= Data Set**

The TESTOUT= data set contains all the variables in the TESTDATA= data set, plus new variables containing the posterior probabilities and the classification results. The names of the new variables containing the posterior probabilities are formed from the formatted values of the class levels. A new variable, _INTO_, with the same attributes as the CLASS variable, gives the class to which each observation is assigned. If an observation is classified into group OTHER, the variable _INTO_ has a missing value. When you specify the CANONICAL option, the data set also contains new variables with canonical variable scores. The NCAN= option determines the number of new variables. The names of the new variables are formed as described in the CANPREFIX= option.

**TESTOUTD= Data Set**

The TESTOUTD= data set contains all the variables in the TESTDATA= data set, plus new variables containing the group-specific density estimates. The names of the new variables containing the density estimates are formed from the formatted values of the class levels.

**OUTSTAT= Data Set**

The OUTSTAT= data set is similar to the TYPE=CORR data set produced by the CORR procedure. The data set contains various statistics such as means, standard deviations, and correlations. For an example of an OUTSTAT= data set, see Example 25.3 on page 1222. When you specify the CANONICAL option, canonical correlations, canonical structures, canonical coefficients, and means of canonical variables for each class are included in the data set.

If you specify METHOD=NORMAL, the output data set also includes coefficients of the discriminant functions, and the data set is TYPE=LINEAR (POOL=YES), TYPE=QUAD (POOL=NO), or TYPE=MIXED (POOL=TEST). If you specify METHOD=NPAR, this output data set is TYPE=CORR.

The OUTSTAT= data set contains the following variables:

- the BY variables, if any
- the CLASS variable
- _TYPE_, a character variable of length 8 that identifies the type of statistic
- _NAME_, a character variable of length 32 that identifies the row of the matrix, the name of the canonical variable, or the type of the discriminant function coefficients
- the quantitative variables, that is, those in the VAR statement, or, if there is no VAR statement, all numeric variables not listed in any other statement
The observations, as identified by the variable `_TYPE_`, have the following `_TYPE_` values:

<table>
<thead>
<tr>
<th>CONTENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>N</td>
</tr>
<tr>
<td>SUMWGT</td>
</tr>
<tr>
<td>MEAN</td>
</tr>
<tr>

</tr>
<tr>
<td>BSTD</td>
</tr>
<tr>
<td>RSQUARED</td>
</tr>
<tr>
<td>LNDETERM</td>
</tr>
</tbody>
</table>

The following kinds of observations are identified by the combination of the variables `_TYPE_` and `_NAME_`. When the `_TYPE_` variable has one of the following values, the `_NAME_` variable identifies the row of the matrix.

<table>
<thead>
<tr>

<td>linear coefficients of the discriminant functions</td>
</tr>
<tr>
<td><em>CONST</em></td>
<td>constant coefficients of the discriminant functions</td>
</tr>
</tbody>
</table>

In the following discussion, let

\[ n = \text{number of observations in the training data set} \]
\[ v = \text{number of variables} \]
\[ c = \text{number of class levels} \]
\[ k = \text{number of canonical variables} \]
\[ l = \text{length of the CLASS variable} \]
**Memory Requirements**

The amount of temporary storage required depends on the discriminant method used and the options specified. The least amount of temporary storage in bytes needed to process the data is approximately

\[ c(32v + 3l + 128) + 8v^2 + 104v + 4l \]

A parametric method (METHOD=NORMAL) requires an additional temporary memory of \(12v^2 + 100v\) bytes. When you specify the CROSSVALIDATE option, this temporary storage must be increased by \(4v^2 + 44v\) bytes. When a nonparametric method (METHOD=NPAR) is used, an additional temporary storage of \(10v^2 + 94v\) bytes is needed if you specify METRIC=FULL to evaluate the distances.

With the MANOVA option, the temporary storage must be increased by \(8v^2 + 96v\) bytes. The CANONICAL option requires a temporary storage of \(2v^2 + 94v + 8k(v+c)\) bytes. The POSTERR option requires a temporary storage of \(8c^2 + 64c + 96\) bytes. Additional temporary storage is also required for classification summary and for each output data set.

For example, in the following statements,

```plaintext
proc discrim manova;
class gp;
var x1 x2 x3;
run;
```

if the CLASS variable `gp` has a length of eight and the input data set contains two class levels, the procedure requires a temporary storage of 1992 bytes. This includes 1104 bytes for data processing, 480 bytes for using a parametric method, and 408 bytes for specifying the MANOVA option.

**Time Requirements**

The following factors determine the time requirements of discriminant analysis.

- The time needed for reading the data and computing covariance matrices is proportional to \(nv^2\). PROC DISCRIM must also look up each class level in the list. This is faster if the data are sorted by the CLASS variable. The time for looking up class levels is proportional to a value ranging from \(n\) to \(n \ln(c)\).
- The time for inverting a covariance matrix is proportional to \(v^3\).
- With a parametric method, the time required to classify each observation is proportional to \(cv\) for a linear discriminant function and is proportional to \(cv^2\) for a quadratic discriminant function. When you specify the CROSSVALIDATE option, the discriminant function is updated for each observation in the classification. A substantial amount of time is required.
- With a nonparametric method, the data are stored in a tree structure (Friedman, Bentley, and Finkel 1977). The time required to organize the observations into the tree structure is proportional to \(nv \ln(n)\). The time for performing each tree
search is proportional to $\ln(n)$. When you specify the normal \texttt{KERNEL=} option, all observations in the training sample contribute to the density estimation and more computer time is needed.

- The time required for the canonical discriminant analysis is proportional to $v^3$.

Each of the preceding factors has a different machine-dependent constant of proportionality.

**Displayed Output**

The displayed output from PROC DISCRIM includes the following:

- Class Level Information, including the values of the classification variable, Variable Name constructed from each class value, the Frequency and Weight of each value, its Proportion in the total sample, and the Prior Probability for each class level.

Optional output includes the following:

- Within-Class SSCP Matrices for each group
- Pooled Within-Class SSCP Matrix
- Between-Class SSCP Matrix
- Total-Sample SSCP Matrix
- Within-Class Covariance Matrices, $S_t$, for each group
- Pooled Within-Class Covariance Matrix, $S_p$
- Between-Class Covariance Matrix, equal to the between-class SSCP matrix divided by $n(c - 1)/c$, where $n$ is the number of observations and $c$ is the number of classes
- Total-Sample Covariance Matrix
- Within-Class Correlation Coefficients and $\Pr > |r|$ to test the hypothesis that the within-class population correlation coefficients are zero
- Pooled Within-Class Correlation Coefficients and $\Pr > |r|$ to test the hypothesis that the partial population correlation coefficients are zero
- Between-Class Correlation Coefficients and $\Pr > |r|$ to test the hypothesis that the between-class population correlation coefficients are zero
- Total-Sample Correlation Coefficients and $\Pr > |r|$ to test the hypothesis that the total population correlation coefficients are zero
- Simple descriptive Statistics including $N$ (the number of observations), Sum, Mean, Variance, and Standard Deviation both for the total sample and within each class
- Total-Sample Standardized Class Means, obtained by subtracting the grand mean from each class mean and dividing by the total sample standard deviation
• Pooled Within-Class Standardized Class Means, obtained by subtracting the grand mean from each class mean and dividing by the pooled within-class standard deviation

• Pairwise Squared Distances Between Groups

• Univariate Test Statistics, including Total-Sample Standard Deviations, Pooled Within-Class Standard Deviations, Between-Class Standard Deviations, $R^2$, $R^2/(1 - R^2)$, $F$, and $\Pr > F$ (univariate $F$ values and probability levels for one-way analyses of variance)

• Multivariate Statistics and $F$ Approximations, including Wilks’ Lambda, Pillai’s Trace, Hotelling-Lawley Trace, and Roy’s Greatest Root with $F$ approximations, degrees of freedom (Num DF and Den DF), and probability values ($\Pr > F$). Each of these four multivariate statistics tests the hypothesis that the class means are equal in the population. See Chapter 2, “Introduction to Regression Procedures,” for more information.

If you specify METHOD=NORMAL, the following three statistics are displayed:

• Covariance Matrix Information, including Covariance Matrix Rank and Natural Log of Determinant of the Covariance Matrix for each group (POOL=TEST, POOL=NO) and for the pooled within-group (POOL=TEST, POOL=YES)

• Optionally, Test of Homogeneity of Within Covariance Matrices (the results of a chi-square test of homogeneity of the within-group covariance matrices) (Morrison 1976; Kendall, Stuart, and Ord 1983; Anderson 1984)

• Pairwise Generalized Squared Distances Between Groups

If the CANONICAL option is specified, the displayed output contains these statistics:

• Canonical Correlations

• Adjusted Canonical Correlations (Lawley 1959). These are asymptotically less biased than the raw correlations and can be negative. The adjusted canonical correlations may not be computable and are displayed as missing values if two canonical correlations are nearly equal or if some are close to zero. A missing value is also displayed if an adjusted canonical correlation is larger than a previous adjusted canonical correlation.

• Approximate Standard Error of the canonical correlations

• Squared Canonical Correlations

• Eigenvalues of $E^{-1}H$. Each eigenvalue is equal to $\rho^2/(1 - \rho^2)$, where $\rho^2$ is the corresponding squared canonical correlation and can be interpreted as the ratio of between-class variation to within-class variation for the corresponding canonical variable. The table includes Eigenvalues, Differences between successive eigenvalues, the Proportion of the sum of the eigenvalues, and the Cumulative proportion.
- Likelihood Ratio for the hypothesis that the current canonical correlation and all smaller ones are zero in the population. The likelihood ratio for all canonical correlations equals Wilks’ lambda.

- Approximate $F$ statistic based on Rao’s approximation to the distribution of the likelihood ratio (Rao 1973, p. 556; Kshirsagar 1972, p. 326)

- Num DF (numerator degrees of freedom), Den DF (denominator degrees of freedom), and $Pr > F$, the probability level associated with the $F$ statistic

The following statistic concerns the classification criterion:

- the Linear Discriminant Function, but only if you specify METHOD=NORMAL and the pooled covariance matrix is used to calculate the (generalized) squared distances

When the input DATA= data set is an ordinary SAS data set, the displayed output includes the following:

- Optionally, the Resubstitution Results including Obs, the observation number (if an ID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation, the group into which the developed criterion would classify it, and the Posterior Probability of its Membership in each group

- Resubstitution Summary, a summary of the performance of the classification criterion based on resubstitution classification results

- Error Count Estimate of the resubstitution classification results

- Optionally, Posterior Probability Error Rate Estimates of the resubstitution classification results

If you specify the CROSSVALIDATE option, the displayed output contains these statistics:

- Optionally, the Cross-validation Results including Obs, the observation number (if an ID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation, the group into which the developed criterion would classify it, and the Posterior Probability of its Membership in each group

- Cross-validation Summary, a summary of the performance of the classification criterion based on cross validation classification results

- Error Count Estimate of the cross validation classification results

- Optionally, Posterior Probability Error Rate Estimates of the cross validation classification results

If you specify the TESTDATA= option, the displayed output contains these statistics:
Optionally, the Classification Results including Obs, the observation number (if a TESTID statement is included, the values of the ID variable are displayed instead of the observation number), the actual group for the observation (if a TESTCLASS statement is included), the group into which the developed criterion would classify it, and the Posterior Probability of its Membership in each group.

- Classification Summary, a summary of the performance of the classification criterion
- Error Count Estimate of the test data classification results
- Optionally, Posterior Probability Error Rate Estimates of the test data classification results

**ODS Table Names**

PROC DISCRIM assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Examples

The iris data published by Fisher (1936) are widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on fifty iris specimens from each of three species, *Iris setosa*, *I. versicolor*, and *I. virginica*. The iris data are used in Example 25.1 through Example 25.3.

Example 25.4 and Example 25.5 use remote-sensing data on crops. In this data set, the observations are grouped into five crops: clover, corn, cotton, soybeans, and sugar beets. Four measures called X1 through X4 make up the descriptive variables.

Example 25.1. Univariate Density Estimates and Posterior Probabilities

In this example, several discriminant analyses are run with a single quantitative variable, petal width, so that density estimates and posterior probabilities can be plotted easily. The example produces Output 25.1.1 through Output 25.1.5. The GCHART procedure is used to display the sample distribution of petal width in the three species. Note the overlap between species *I. versicolor* and *I. virginica* that the bar chart shows. These statements produce Output 25.1.1:

```plaintext

proc gchart data=iris;
  vbar PetalWidth / subgroup=Species midpoints=0 to 25
    raxis=axis1 maxis=axis2 legend=legend1 cframe=ligr;
run;
In order to plot the density estimates and posterior probabilities, a data set called `plotdata` is created containing equally spaced values from -5 to 30, covering the range of petal width with a little to spare on each end. The `plotdata` data set is used with the `TESTDATA=` option in PROC DISCRIM.

```sas
data plotdata;
  do PetalWidth=-5 to 30 by .5;
    output;
  end;
run;
```

The same plots are produced after each discriminant analysis, so a macro can be used to reduce the amount of typing required. The macro `PLOT` uses two data sets. The data set `plotd`, containing density estimates, is created by the `TESTOUTD=` option in PROC DISCRIM. The data set `plotp`, containing posterior probabilities, is created by the `TESTOUT=` option. For each data set, the macro `PLOT` removes uninteresting values (near zero) and does an overlay plot showing all three species on a single plot. The following statements create the macro `PLOT`.

```sas
%macro plot;
  data plotd;
    set plotd;
    if setosa<.002 then setosa=.;
    if versicolor<.002 then versicolor=.;
    if virginica <.002 then virginica=.;
    label PetalWidth='Petal Width in mm.';
  run;
```

In order to plot the density estimates and posterior probabilities, a data set called `plotdata` is created containing equally spaced values from -5 to 30, covering the range of petal width with a little to spare on each end. The `plotdata` data set is used with the `TESTDATA=` option in PROC DISCRIM.

```sas
data plotdata;
  do PetalWidth=-5 to 30 by .5;
    output;
  end;
run;
```

The same plots are produced after each discriminant analysis, so a macro can be used to reduce the amount of typing required. The macro `PLOT` uses two data sets. The data set `plotd`, containing density estimates, is created by the `TESTOUTD=` option in PROC DISCRIM. The data set `plotp`, containing posterior probabilities, is created by the `TESTOUT=` option. For each data set, the macro `PLOT` removes uninteresting values (near zero) and does an overlay plot showing all three species on a single plot. The following statements create the macro `PLOT`.

```sas
%macro plot;
  data plotd;
    set plotd;
    if setosa<.002 then setosa=.;
    if versicolor<.002 then versicolor=.;
    if virginica <.002 then virginica=.;
    label PetalWidth='Petal Width in mm.';
  run;
```
The first analysis uses normal-theory methods (METHOD=NORMAL) assuming equal variances (POOL=YES) in the three classes. The NOCLASSIFY option suppresses the resubstitution classification results of the input data set observations. The CROSSLISTERR option lists the observations that are misclassified under cross validation and displays cross validation error-rate estimates. The following statements produce Output 25.1.2:

```sas
proc discrim data=iris method=normal pool=yes
testdata=plotdata testout=plotp testoutd=plotd
short noclassify crosslisterr;
class Species;
var PetalWidth;
title2 'Using Normal Density Estimates with Equal Variance';
run;
%plot
```

Two more analyses are run with nonparametric methods (METHOD=NPAR), specifically kernel density estimates with normal kernels (KERNEL=NORMAL). The first of these uses equal bandwidths (smoothing parameters) (POOL=YES) in each class. The use of equal bandwidths does not constrain the density estimates to be of equal variance. The value of the radius parameter that, assuming normality, minimizes an approximate mean integrated square error is 0.48 (see the “Nonparametric Methods” section on page 1158). Choosing \( r = 0.4 \) gives a more detailed look at the irregularities in the data. The following statements produce Output 25.1.4:

```plaintext

Example 25.2. Bivariate Density Estimates and Posterior Probabilities

In this example, four more discriminant analyses of iris data are run with two quantitative variables: petal width and petal length. The example produces Output 25.2.1 through Output 25.2.5. A scatter plot shows the joint sample distribution. See Appendix B, “Using the %PLOTIT Macro,” for more information on the %PLOTIT macro.

```
%plotit(data=iris, plotvars=PetalWidth PetalLength, labelvar=_blank_, symvar=symbol, typevar=symbol, symsize=0.35, symlen=4, exttypes=symbol, ls=100);
```

Output 25.2.1. Joint Sample Distribution of Petal Width and Petal Length in Three Species

Another data set is created for plotting, containing a grid of points suitable for contour plots. The large number of points in the grid makes the following analyses very time-consuming. If you attempt to duplicate these examples, begin with a small number of points in the grid.

```
data plotdata;
    do PetalLength=-2 to 72 by 0.25;
        h = h + 1;   * Number of horizontal cells;
        do PetalWidth=-5 to 32 by 0.25;
            n = n + 1; * Total number of cells;
            output;
        end;
    end;
* Make variables to contain H and V grid sizes;
call symput('hnobs', compress(put(h , best12.)));
call symput('vnobs', compress(put(n / h, best12.)));
drop n h;
run;
```
A macro CONTOUR is defined to make contour plots of density estimates and posterior probabilities. Classification results are also plotted on the same grid.

%macro contour;
   data contour(keep=PetalWidth PetalLength symbol density);
      set plotd(in=d) iris;
      if d then density = max(setosa,versicolor,virginica);
   run;

title3 'Plot of Estimated Densities';
   %plotit(data=contour, plotvars=PetalWidth PetalLength,
            labelvar=_blank_, symvar=symbol, typevar=symbol,
            symlen=4, exttypes=symbol contour, ls=100,
            paint=density white black, rgbtypes=contour,
            hnobs=&hnobs, vnobs=&vnobs, excolors=white,
            rgbround=-16 1 1 1, extend=close, options=noclip,
            types =Setosa Versicolor Virginica ' ',
            symtype=symbol symbol symbol contour,
            symsize=0.6 0.6 0.6 1,
            symfont=swiss swiss swiss solid)

data posterior(keep=PetalWidth PetalLength symbol prob _into_);
   set plotp(in=d) iris;
   if d then prob = max(setosa,versicolor,virginica);
   run;

title3 'Plot of Posterior Probabilities ' 
   '(Black to White is Low to High Probability)';
   %plotit(data=posterior, plotvars=PetalWidth PetalLength,
            labelvar=_blank_, symvar=symbol, typevar=symbol,
            symlen=4, exttypes=symbol contour, ls=100,
            paint=prob black white 0.3 0.999, rgbtypes=contour,

Discriminant Analysis of Fisher (1936) Iris Data
Using Normal Density Estimates with Unequal Variance
Plot of Posterior Probabilities (Black to White is Low to High Probability)
A nonparametric analysis (METHOD=NPAR) follows, using normal kernels (KERNEL=NORMAL) and equal bandwidths (POOL=YES) in each class. The value of the radius parameter \( r \) that, assuming normality, minimizes an approximate mean integrated square error is 0.50 (see the “Nonparametric Methods” section on page 1158). These statements produce Output 25.2.4:

``` SAS
proc discrim data=iris method=npar kernel=normal
   r=.5 pool=yes
   testdata=plotdata testout=plotp
testoutd=plotd
   short noclassify crosslisterr;
class Species;
var Petal:;

Discriminant Analysis of Fisher (1936) Iris Data
Using Kernel Density Estimates with Unequal Bandwidth
Plot of Posterior Probabilities (Black to White is Low to High Probability)
Example 25.3. Normal-Theory Discriminant Analysis of Iris Data

In this example, PROC DISCRIM uses normal-theory methods to classify the iris data used in Example 25.1. The POOL=TEST option tests the homogeneity of the within-group covariance matrices (Output 25.3.3). Since the resulting test statistic is significant at the 0.10 level, the within-group covariance matrices are used to derive the quadratic discriminant criterion. The WCOV and PCOV options display the within-group covariance matrices and the pooled covariance matrix (Output 25.3.2). The DISTANCE option displays squared distances between classes (Output 25.3.4). The ANOVA and MANOVA options test the hypothesis that the class means are equal, using univariate statistics and multivariate statistics; all statistics are significant at the 0.0001 level (Output 25.3.5). The LISTERR option lists the misclassified observations under resubstitution (Output 25.3.6). The CROSSLISTERR option lists the observations that are misclassified under cross validation and displays cross validation error-rate estimates (Output 25.3.7). The resubstitution error count estimate, 0.02, is not larger than the cross validation error count estimate, 0.0267, as would be expected because the resubstitution estimate is optimistically biased. The OUTSTAT= option generates a TYPE=MIXED (because POOL=TEST) output data set containing various statistics such as means, covariances, and coefficients of the discriminant function (Output 25.3.8).

The following statements produce Output 25.3.1 through Output 25.3.8:

```plaintext
proc discrim data=iris outstat=irisstat
   wcov pcov method=normal pool=test
   distance anova manova listerr crosstesterr;
   class Species;
   var SepalLength SepalWidth PetalLength PetalWidth;
   title2 'Using Quadratic Discriminant Function';
run;

proc print data=irisstat;
   title2 'Output Discriminant Statistics';
run;
```

Output 25.3.3. Homogeneity Test

Discriminant Analysis of Fisher (1936) Iris Data
Using Quadratic Discriminant Function

The DISCRIM Procedure
Test of Homogeneity of Within Covariance Matrices

Notation:
- $K$ = Number of Groups
- $P$ = Number of Variables
- $N$ = Total Number of Observations - Number of Groups
- $N(i)$ = Number of Observations in the $i$'th Group - 1

\[
\begin{align*}
V &= \frac{\sum_i N(i)/2 \begin{vmatrix} \text{Within SS Matrix(i)} \end{vmatrix}} {N/2} \\
\text{Pooled SS Matrix} \\
\end{align*}
\]

\[
RHO = 1.0 - \frac{\sum_i \frac{N(i)}{N} - 1}{2P + 3P - 1} \frac{1}{6(P+1)(K-1)}
\]

\[
DF = \frac{1}{2}(K-1)P(P+1)
\]

Under the null hypothesis:
\[
-2 \ln \left( \frac{\sum_i N(i)/2 \begin{vmatrix} \text{Within SS Matrix(i)} \end{vmatrix}} {N/2} \right)
\]
is distributed approximately as Chi-Square(DF).

\[
\begin{array}{ccc}
\text{Chi-Square} & DF & Pr > \text{ChiSq} \\
140.943050 & 20 & <.0001
\end{array}
\]

Since the Chi-Square value is significant at the 0.1 level, the within covariance matrices will be used in the discriminant function.

### Example 25.4. Linear Discriminant Analysis of Crop Data

In this example, the remote-sensing data described at the beginning of the section are used. In the first PROC DISCRIM statement, the DISCRIM procedure uses normal-theory methods (METHOD=NORMAL) assuming equal variances (POOL=YES) in five crops. The PRIORS statement, PRIORS PROP, sets the prior probabilities proportional to the sample sizes. The LIST option lists the resubstitution classification results for each observation (Output 25.4.2). The CROSSVALIDATE option displays cross validation error-rate estimates (Output 25.4.3). The OUTSTAT= option stores the calibration information in a new data set to classify future observations. A second PROC DISCRIM statement uses this calibration information to classify a test data set. Note that the values of the identification variable, xvalues, are obtained by...
rereading the x1 through x4 fields in the data lines as a single character variable. The following statements produce Output 25.4.1 through Output 25.4.3.

Example 25.5. Quadratic Discriminant Analysis of Remote-Sensing Data on Crops

In this example, PROC DISCRIM uses normal-theory methods (METHOD=NORMAL) assuming unequal variances (POOL=NO) for the remote-sensing data of Example 25.4. The PRIORS statement, PRIORS PROP, sets the prior probabilities proportional to the sample sizes. The CROSSVALIDATE option displays cross validation error-rate estimates. Note that the total error count estimate by cross validation (0.5556) is much larger than the total error count estimate by resubstitution (0.1111). The following statements produce Output 25.5.1:

```plaintext
proc discrim data=crops
   method=normal pool=no
   crossvalidate;
   class Crop;
   priors prop;
   id xvalues;
   var x1-x4;
   title2 'Using Quadratic Discriminant Function';
run;
```

Chapter 26
The DISTANCE Procedure

Overview

The DISTANCE procedure computes various measures of distance, dissimilarity, or similarity between the observations (rows) of a SAS data set. These proximity measures are stored as a lower triangular matrix or a square matrix in an output data set (depending on the SHAPE= option) that can then be used as input to the CLUSTER, MDS, and MODECLUS procedures. The input data set may contain numeric or character variables, or both, depending on which proximity measure is used.

The number of rows and columns in the output matrix equals the number of observations in the input data set. If there are BY groups, an output matrix is computed for each BY group with the size determined by the maximum number of observations in any BY group.

PROC DISTANCE also provides various non-parametric and parametric methods for standardizing variables. Different variables can be standardized with different methods.

Distance matrices are used frequently in data mining, genomics, marketing, financial analysis, management science, education, chemistry, psychology, biology, and various other fields.

Levels of Measurement

Measurement of some attribute of a set of objects is the process of assigning numbers or other symbols to the objects in such a way that properties of the numbers or symbols reflect properties of the attribute being measured. There are different levels of measurement that involve different properties (relations and operations) of the numbers or symbols. Associated with each level of measurement is a set of transformations of the measurements that preserve the relevant properties; these transformations are called permissible transformations. A particular way of assigning numbers or symbols to measure something is called a scale of measurement.

The most commonly discussed levels of measurement are:

- Nominal: Two objects are assigned the same symbol if they have the same value of the attribute. Permissible transformations are any one-to-one or many-to-one transformation, although a many-to-one transformation loses information.

- Ordinal: Objects are assigned numbers such that the order of the numbers reflects an order relation defined on the attribute. Two objects \(x\) and \(y\) with attribute values \(a(x)\) and \(a(y)\) are assigned numbers \(m(x)\) and \(m(y)\) such that if \(m(x) > m(y)\), then \(a(x) > a(y)\). Permissible
transformations are any monotone increasing transformation, although a transformation that is not strictly increasing loses information.

**Interval**

Objects are assigned numbers such that differences between the numbers reflect differences of the attribute. If \( m(x) - m(y) > m(u) - m(v) \), then \( a(x) - a(y) > a(u) - a(v) \). Permissible transformations are any affine transformation \( t(m) = c* m + d \), where \( c \) and \( d \) are constants; another way of saying this is that the origin and unit of measurement are arbitrary.

**Log-interval**

Objects are assigned numbers such that ratios between the numbers reflect ratios of the attribute. If \( m(x)/m(y) > m(u)/m(v) \), then \( a(x)/a(y) > a(u)/a(v) \). Permissible transformations are any power transformation \( t(m) = c* m^d \), where \( c \) and \( d \) are constants.

**Ratio**

Objects are assigned numbers such that differences and ratios between the numbers reflect differences and ratios of the attribute. Permissible transformations are any linear (similarity) transformation \( t(m) = c* m \), where \( c \) is a constant; another way of saying this is that the unit of measurement is arbitrary.

**Absolute**

Objects are assigned numbers such that all properties of the numbers reflect analogous properties of the attribute. The only permissible transformation is the identity transformation.

Proximity measures provided in the DISTANCE procedure accept four levels of measurement: nominal, ordinal, interval, and ratio. Ordinal variables are transformed to interval variables before processing. This is done by replacing the data with their rank scores, and by assuming that the classes of an ordinal variable are spaced equally along the interval scale. See the RANKSCORE= option in the PROC DISTANCE statement for choices on assigning scores to ordinal variables. There are also different approaches on how to transform an ordinal variable to an interval variable. Refer to Anderberg (1973) for alternatives.

### Symmetric versus Asymmetric Nominal Variables

A binary variable contains two possible outcomes: 1 (positive/present) or 0 (negative/absent). If there is no preference for which outcome should be coded as 0 and which as 1, the binary variable is called symmetric. For example, the binary variable “is evergreen?” for a plant has the possible states “loses leaves in winter” and “does not lose leaves in winter.” Both are equally valuable and carry the same weight when a proximity measure is computed. Commonly used measures that accept symmetric binary variables include the Simple Matching, Hamann, Roger and Tanimoto, Sokal and Sneath 1, and Sokal and Sneath 3 coefficients.

If the outcomes of a binary variable are not equally important, the binary variable is called asymmetric. An example of such a variable is the presence or absence of a relatively rare attribute, such as “is color blind” for a human-being. While you say that two people who are color blind have something in common, you cannot say that people who are not color blind have something in common. The most important
outcome is usually coded as 1 (present) and the other is coded as 0 (absent). The agreement of two 1’s (a present-present match or a positive match) is more significant than the agreement of two 0’s (an absent-absent match or a negative match.) Usually, the negative match is treated as irrelevant. Commonly used measures that accept asymmetric binary variables include Jaccard, Dice, Russell and Rao, Binary Lance and Williams nonmetric, and Kulczynski coefficients.

When nominal variables are employed, the comparison of one data unit with another can only be in terms of whether the data units score the same or different on the variables. If a variable is defined as an asymmetric nominal variable and two data units score the same but fall into the absent category, the absent-absent match is excluded from the computation of the proximity measure.

**Standardization**

Since variables with large variances tend to have more effect on the proximity measure than those with small variances, it is recommended to standardize the variables before the computation of the proximity measure. The DISTANCE procedure provides a convenient way to standardize each variable with its own method before the proximity measures are computed. The standardization can also be performed by the STDIZE procedure with the limitation that all variables must be standardized with the same method.

**Mandatory Standardization**

Variable standardization is not required if there is only one level of measurement, or if only asymmetric nominal and nominal levels are specified; otherwise, standardization is mandatory.

When standardization is mandatory and no standardization method is specified, a default method of standardization will be used. This default method is determined by the measurement level. In general, the default method is STD for interval variables and is MAXABS for ratio variables except when METHOD= GOWER or METHOD= DGOWER is specified. See the STD= option in the VAR statement for the default methods for GOWER and DGOWER as well as methods available for standardizing variables.

When standardization is mandatory, PROC DISTANCE suppresses the REPONLY option, if it is specified.

**Getting Started**

**Creating a Distance Matrix as Input for a Subsequent Cluster Analysis**

The following example demonstrates how you can use the DISTANCE procedure to obtain a distance matrix that will be used as input to a subsequent clustering procedure.
Chapter 26. The DISTANCE Procedure

The following data, originated by A. Weber and cited in Hand et al. (1994, pp. 297), measure the amount of protein consumed for nine food groups in 25 European countries. The nine food groups are red meat (RedMeat), white meat (WhiteMeat), eggs (Eggs), milk (Milk), fish (Fish), cereal (Cereal), starch (Starch), nuts (Nuts), and fruits and vegetables (FruitVeg). Suppose you want to determine whether national figures in protein consumption can be used to determine certain types or categories of countries; specifically, you want to perform a cluster analysis to determine if these 25 countries can be formed into groups suggested by the data.

The following DATA step creates the SAS data set Protein:

```
title 'Protein Consumption in Europe';
data Protein;
datalines;
Albania  10.1  1.4  0.5  8.9  0.2  42.3  0.6  5.5  1.7
Austria  8.9  14.0  4.3  19.9  2.1  28.0  3.6  1.3  4.3

Greece  10.2  3.0  2.8  17.6  5.9  41.7  2.2  7.8  6.5
Hungary  5.3  12.4  2.9  9.7  0.3  40.1  4.0  5.4  4.2
Ireland  13.9  10.0  4.7  25.8  2.2  24.0  6.2  1.6  2.9
Italy  9.0  5.1  2.9  13.7  3.4  36.8  2.1  4.3  6.7
Netherlands  9.5  13.6  3.6  23.4  2.5  22.4  4.2  1.8  3.7
Norway  9.4  4.7  2.7  23.3  9.7  23.0  4.6  1.6  2.7
Poland  6.9  10.2  2.7  19.3  3.0  36.1  5.9  2.0  6.6
Portugal  6.2  3.7  1.1  4.9  14.2  27.0  5.9  4.7  7.9
Romania  6.2  6.3  1.5  11.1  1.0  49.6  3.1  5.3  2.8
Spain  7.1  3.4  3.1  8.6  7.0  29.2  5.7  5.9  7.2
Sweden  9.9  7.8  3.5  4.7  7.5  19.5  3.7  1.4  2.0
Switzerland  13.1  10.1  3.1  23.8  2.3  25.6  2.8  2.4  4.9
UK  17.4  5.7  4.7  20.6  4.3  24.3  4.7  3.4  3.3
USSR  9.3  4.6  2.1  16.6  3.0  43.6  6.4  3.4  2.9
W Germany  11.4  12.5  4.1  18.8  3.4  18.6  5.2  1.5  3.8
Yugoslavia  4.4  5.0  1.2  9.5  0.6  55.9  3.0  5.7  3.2
;```

The data set Protein contains the character variable Country and the nine numeric variables representing the food groups. The $14. in the INPUT statement specifies that the variable Country has a length of 14.

The following statements create the distance matrix and display part of it.

```
proc distance data=Protein out=Dist method=Euclid;
  var interval(RedMeat--FruitVeg / std=Std);
  id Country;
;```
run;

options ls=120;
proc print data=Dist(Obs=10);
title2 'First 10 observations in the output data set from PROC DISTANCE';
run;

An output SAS data set called Dist that contains the distance matrix is created through the OUT= option. METHOD= Euclid requests that Euclidean (which also is the default) distances should be computed.

The VAR statement lists the variables (RedMeat—FruitVeg) along with their measurement level to be used in the analysis. An interval level of measurement is assigned to those variables. Since variables with large variances tend to have more effect on the proximity measure than those with small variances, each variable is standardized by the STD method to have a mean of 0 and a standard deviation of 1. This is done by adding “/” with the STD= Std option at the end of the variables list specification.

The ID statement specifies that the variable Country should be copied to the OUT= data set and used to generate names for the distance variables. The distance variables in the output data set are named by the values in the ID variable, and the maximum length for the names of these variables is 14.

There are 25 observations in the input data set; therefore, the output data set Dist contains a 25 by 25 lower triangle matrix.

The PROC PRINT statement displays the first 10 observations in the output data set Dist as shown in Figure 26.1.
The following statements produce the tree diagram in Figure 26.2:

```plaintext
proc cluster data=Dist method=Ward outtree=Tree noprint;
  id Country;
run;

axis1 order=(0 to 1 by 0.1);
proc tree data=Tree haxis=axis1 horizontal;
  height _rsq_;  
  id Country;
run;
```

The CLUSTER procedure performs a Ward’s Minimum-Variance cluster analysis based on the distance matrix created by the PROC DISTANCE. The printed output has been omitted, but the output data set Tree is created (through outtree= Tree) and used as input to the TREE procedure that produces the tree diagram as shown in Figure 26.2. The height statement specifies the variable _RSQ_ (\(R^2\)) as the height variable.

![Figure 26.2. Tree Diagram of Clusters versus R-Square Values](image)

After inspecting the tree diagram in Figure 26.2, you will see that when the countries are grouped into six clusters, the proportion of variance accounted for by these clusters is slightly less than 70% (69.3%).
Syntax

The following statements are available in the DISTANCE procedure.

```
PROC DISTANCE < options > ;
    BY variables ;
    COPY variables ;
    FREQ variable ;
    ID variable ;
    VAR level(variables < / opt-list >) ;
    WEIGHT variable ;
```

Both the PROC DISTANCE statement and the VAR statement are required.

**PROC DISTANCE Statement**

You can specify the following options in the PROC DISTANCE statement.

**Table 26.1. Summary of PROC DISTANCE Statement Options**

</tr>
</tbody>
</table>

These options and their abbreviations are described, in alphabetical order, in the remainder of this section.

**ABSENT=** *num* or *qs*

specifies the value to be used as an absence value in an irrelevant absent-absent match for all of the asymmetric nominal variables. If you want to specify a different absence value for a particular variable, use the ABSENT= option in the VAR statement. See the ABSENT= option in the VAR statement later in this chapter for details.

An absence value for a variable can be either a numeric value or a quoted string consisting of combinations of characters. For instance, ., -999, “NA” are legal values for the ABSENT= option.

The default absence value for a character variable is “NONE” (notice that a blank value is considered a missing value), and the default absence value for a numeric variable is 0.

**ADD=** *c*

specifies a constant, *c*, to add to each value after standardizing and multiplying by the value you specify in the MULT= option. The default value is 0.

**DATA=** *SAS-data-set*

specifies the input data set containing observations from which the proximity is computed. If you omit the DATA= option, the most recently created SAS data set is used.
FUZZ= c

specifies the relative fuzz factor for computing the standardized scores. The default value is 1E-14. For the OUTSDZ= data set, the score is computed as follows:

\[
\text{if } |\text{standardized scores}| < \text{scale measure} \times c, \text{ then standardized scores } = 0
\]

INITIAL= method

specifies the method for computing initial estimates for the A-estimates (ABW, AWAVER, and AHUBER). The following methods are not allowed for the INITIAL= option: ABW, AHUBER, AWAVER, IN.

The default value is INITIAL=MAD.

METHOD= method

specifies the method for computing proximity measures.

For use in PROC CLUSTER, distance or dissimilarity measures such as METHOD= EUCLID or METHOD=DGOWER should be chosen.

The following six tables outline the proximity measures available for the METHOD= option. These tables are classified by levels of measurement accepted by each method. There are three to four columns in each table: the proximity measures (Method) column, the upper and lower bounds (Range) column(s), and the types of proximity (Type) column.

The Type column has two possible values: “sim” if a method generate similarity or “dis” if a method generates distance or dissimilarity measures.

For formulas and descriptions of these methods, see the “Details” section on page 1270.

Table 26.2 lists the GOWER and the DGOWER methods. These two methods accept all measurement levels including ratio, interval, ordinal, nominal, and asymmetric nominal. METHOD= GOWER or METHOD= DGOWER always implies standardization. Assuming all the numeric (ordinal, interval, and ratio) variables are standardized by their corresponding default methods, the possible range values for both methods in the second column of this table are on or between 0 and 1. To find out the default methods of standardization for METHOD= GOWER or METHOD= DGOWER, see the STD= option for the VAR statement later in this section. Entries in this table are:

<table>
<thead>
<tr>
<th>Method</th>
<th>Range</th>
<th>Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>GOWER</td>
<td>0 to 1</td>

Table 26.3 lists methods accepting ratio, interval, and ordinal variables. Entries in this table are:

- **EUCLID**: Euclidean distance
- **SQEUCLID**: Squared Euclidean distance
- **SIZE**: Size distance
- **SHAPE**: Shape distance
- **COV**: Covariance
- **CORR**: Correlation
- **DCORR**: Correlation transformed to Euclidean distance
- **SQCORR**: Squared correlation
- **DSQCORR**: One minus squared correlation
- **L(p)**: Minkowski ($L_p$) distance, where $p$ is a positive numeric value
- **CITYBLOCK**: $L_1$, City-block, or Manhattan distance
- **CHEBYCHEV**: $L_\infty$
- **POWER($p$, $r$)**: Generalized Euclidean distance where $p$ is a positive numeric value, and $r$ is a non-negative numeric value. The distance between two observations is the $r$th root of sum of the absolute differences to the $p$th power between the values for the observations.

Table 26.4 lists methods accepting ratio variables. Notice that in the second column of this table, all of the possible range values are non-negative, because ratio variables are assumed to be positive. Entries in this table are:
SIMRATIO  Similarity ratio (if variables are binary, this is the Jaccard coefficient)
DISRATIO  One minus similarity ratio
NONMETRIC  Lance and Williams nonmetric coefficient
CANBERRA  Canberra metric distance coefficient
COSINE  Cosine
DOT  Dot (inner) product
OVERLAP  Overlap similarity
DOVERLAP  Overlap dissimilarity
CHISQ  Chi-squared
CHI  Squared root of Chi-squared
PHISQ  phi-squared
PHI  Squared root of phi-squared

Table 26.7 lists methods accepting asymmetric nominal and ratio variables. Use the ABSENT= option to create a value to be considered absent. There are four instead of three columns in this table. The second column contains possible range values if only one level of measurement (either ratio or asymmetric nominal but not both) is specified; the third column contains possible range values if both levels are specified.

The JACCARD method is equivalent to the SIMRATIO method if there is no asymmetric nominal variable; if both ratio and asymmetric nominal variables are present, the coefficient is computed as the sum of the coefficient from the ratio variables and the coefficient from the asymmetric nominal variables. See “Proximity Measures” of the “Details” section on page 1270 for formulas and descriptions of the JACCARD method. Entries in this table are:
JACCARD Jaccard similarity coefficient
DJACCARD Jaccard dissimilarity coefficient

</table>

MULT= c
specifies a constant, c, by which to multiply each value after standardizing. The default value is 1.

NOMISS
While standardizing variables, omit observations with missing values from computation of the location and scale measures. While computing distances, generate undefined (missing) distances for observations with missing values. Use the UNDEF= option to specify the undefined values.

If a distance matrix is created to be used as an input to PROC CLUSTER, the NOMISS option should not be used because the CLUSTER procedure will not accept distance matrices with missing values.

NORM
normalizes the scale estimator to be consistent for the standard deviation of a normal distribution when you specify the option STD= AGK, STD= IQR, STD= MAD, or STD= SPACING in the VAR statement.

PREFIX= name
specifies a prefix for naming the distance variables in the OUT= data set. By default, the names are Dist1, Dist2, …, Distn. If you specify PREFIX=ABC, the variables are named ABC1, ABC2, …, ABCn. If the ID statement is also specified, the variables are named by appending the value of the ID variable to the prefix.

OUT= SAS-data-set
specifies the name of the SAS data set created by PROC DISTANCE. The output data set contains the BY variables, the ID variable, computed distance variables, the COPY variables, the FREQ variable, and the WEIGHT variables.

If you omit the OUT= option, PROC DISTANCE creates an output data set named according to the DATA= convention.

OUTSDZ= SAS-data-set
specifies the name of the SAS data set containing the standardized scores. The output data set contains a copy of the DATA= data set, except that the analyzed variables have been standardized. Analyzed variables are those listed in the VAR statement.

RANKSCORE= MIDRANK | INDEX
specifies the method of assigning scores to ordinal variables. The available methods are listed as follows:
MIDRANK assigns consecutive integers to each category with consideration of the frequency value. This is the default method.

INDEX assigns consecutive integers to each category regardless of frequencies.

The following example explains how each method assigns the rank scores. Suppose the data contain an ordinal variable ABC with values A, B, C. There are two ways to assign numbers. One is to use midranks, which depend on the frequencies of each category. Another is to assign consecutive integers to each category, regardless of frequencies.

</tbody>
</table>

REPLACE replaces missing data by zero in the standardized data (which corresponds to the location measure before standardizing.) To replace missing data by something else, use the MISSING= option in the VAR statement. The REPLACE option implies standardization.

You can not specify both the REPLACE and the REPONLY options.

REPONLY replaces missing data by the location measure specified by the MISSING= option or the STD= option (if the MISSING= option is not specified), but does not standardize the data. If the MISSING= option is not specified and METHOD=GOWER is specified, missing values are replaced by the location measure from the RANGE method (the minimum value), no matter what the value of the STD= option is.

When standardization is mandatory, PROC DISTANCE suppresses the REPONLY option.

You can not specify both the REPLACE and the REPONLY options.

SHAPE= TRIANGLE | TRI
SHAPE= SQUARE | SQU | SQR
specifies the shape of the proximity matrix to be stored in the OUT= data set. SHAPE= TRIANGLE requests the matrix to be stored as a lower triangular matrix; SHAPE= SQUARE requests the matrix to be stored as a squared matrix. Use SHAPE= SQUARE if the output data set is to be used as input to the MODECLUS procedures. The default is TRIANGLE.
SNORM

normalizes the scale estimator to have an expectation of approximately 1 for a standard normal distribution when the STD= SPACING option is specified.

UNDEF= \( n \)

specifies the numeric constant used to replace undefined distances, for example, when an observation has all missing values, or if a divisor is zero.

VARDEF=DF | N | WDF | WEIGHT | WGT

specifies the divisor to be used in the calculation of distance, dissimilarity, or similarity measures, and for standardizing variables whenever a variance or covariance is computed. By default, VARDEF=DF. The values and associated divisors are as follows:

<table>
<thead>
<tr>
<th>Value</th>

</tr>
</tbody>
</table>

The VAR statement lists variables from which distances are to be computed. The VAR statement is required. The variables can be numeric or character depending on their measurement levels. A variable may not appear more than once in either the same list or in a different list.

level is required. It declares the levels of measurement for those variables specified within the parentheses. Available values for level are:
ANOMINAL variables are asymmetric nominal and can be either numeric or character.

NOMINAL variables are symmetric nominal and can be either numeric or character.

ORDINAL variables are ordinal and can be either numeric or character. Values of ordinal variables will be replaced by their corresponding rank scores. If standardization is required, the standardized rank scores are output to the data set specified in the OUTSDZ= option. See the RANKSCORE= option in the PROC DISTANCE statement for methods available for assigning rank scores to ordinal variables. After being replaced by scores, ordinal variables are considered interval.

INTERVAL variables are interval, and only numeric variables are allowed.

RATIO variables are ratio, and only numeric variables are allowed. Ratio variables should always contain positive measurements.

Each variable list can be followed by an option list. Use “/” after the list of variables to start the option list. An option list contains options that are applied to the variables. The following options are available in the option list.

ABSENT= to specify the value to be used as an absence value in an irrelevant absent-absent match for asymmetric nominal variables.

MISSING= to specify the method (or value) with which to replace missing data

ORDER= to select the order for assigning scores to ordinal variables.

STD= to select the standardization method

WEIGHTS= to assign weights to the variables in the list

If an option is missing from the current attribute list, PROC DISTANCE provides default values for all the variables in the current list.

For example, in the following VAR statement:

```
var ratio(x1-x4/std= mad weights= .5  .5  .1  .5 missing= -99)
   interval(x5/std= range)
   ordinal(x6/order= desc);
```

the first option list defines x1 –x4 as ratio variables to be standardized by the MAD method. Also, any missing values in x1 –x4 should be replaced by -99. x1 is given a weight of 0.5, x2 is given a weight of 0.5, x3 is given a weight of 0.1, and x4 is given a weight of 0.5.

The second option list defines x5 as an interval variable to be standardized by the RANGE method. If the REPLACE option is specified in the PROC DISTANCE statement, missing values in x5 are replaced by the the location estimate from the RANGE method. By default, x5 is given a weight of 1.
The last option list defines \( x_6 \) as an ordinal variable. The scores are assigned from highest-to-lowest by its unformatted values. Although the STD= option is not specified, \( x_6 \) will be standardized by the default method (STD) because there is more than one level of measurements (ratio, interval, and ordinal) in the VAR statement. Again, if the REPLACE option is specified, missing values in \( x_6 \) are replaced by the location estimate from the STD method. Finally, by default, \( x_6 \) is given a weight of 1.

More details for the options are explained as follows.

**STD= std-method**

specifies the standardization method. Valid values for *std-method* are: MEAN, MEDIAN, SUM, EUCLEN, USTD, STD, RANGE, MIDRANGE, MAXABS, IQR, MAD, ABW, AHUBER, AWAVE, AGK, SPACING, and L. Table 26.9 lists available methods of standardization as well as their corresponding location and scale measures.

</table>

These standardization methods are further documented in the section on the METHOD= option in the PROC STDIZE statement of the STDIZE procedure (also see the “Standardization Methods” section on page 4136 in Chapter 66, “The STDIZE Procedure,”).

Standardization is not required if there is only one level of measurement, or if only asymmetric nominal and nominal levels are specified; otherwise, standardization is mandatory. When standardization is mandatory, a default method will be provided when the STD= option is not given. The default method is STD for standardizing interval variables and MAXABS for standardizing ratio variables unless METHOD=...
GOWER or METHOD=DGOWER is specified. If METHOD=GOWER is specified, interval variables are standardized by the RANGE method, and whatever is specified in the STD= option is ignored; if METHOD=DGOWER is specified, the RANGE method is the default standardization method for interval variables. The MAXABS method is the default standardization method for ratio variables for both the GOWER and the DGOWER.

Notice that a ratio variable should always be positive.

Table 26.10 lists standardization methods and the levels of measurement that can be accepted by each method. For example, the SUM method can be used to standardize ratio variables but not interval, or ordinal variables. Also, the AGK and SPACING methods should not be used to standardize ordinal variables. If you apply AGK and SPACING to ranks, the results are degenerate because all the spacings of a given order are equal.

</tbody>
</table>

**ABSENT= num or qs**

specifies the value to be used as an absence value in an irrelevant absent-absent match for asymmetric nominal variables. The absence value specified here overwrites the absence value specified through the ABSENT= option in the PROC DISTANCE statement for those variables in the current variable list.

An absence value for a variable can be either a numeric value or a quoted string consisting of combinations of characters. For instance, ., -999, “NA” are legal values for the ABSENT= option.
The default for an absence value for a character variable is “NONE” (notice that a blank value is considered a missing value), and the default for an absence value for a numeric variable is 0.

**MISSING=** *miss-method or value*

specifies the method or a numeric value for replacing missing values. If you omit the MISSING= option, the REPLACE option replaces missing values with the location measure given by the STD= option. Specify the MISSING= option when you want to replace missing values with a different value. You can specify any method that is valid in the STD= option. The corresponding location measure is used to replace missing values.

If a numeric value is given, the value replaces missing values after standardizing the data. However, when standardization is not mandatory, you can specify the REPONLY option with the MISSING= option to suppress standardization for cases in which you want only to replace missing values.

**ORDER=**  

specifies the order for assigning score to ordinal variables. The value for the ORDER= option can be one of the following:

- **ASCENDING** scores are assigned in lowest-to-highest order of unformatted values.
- **DESCENDING** scores are assigned in highest-to-lowest order of unformatted values.
- **ASCFORMATTED** scores are assigned in ascending order by their formatted values. This option can be applied to character variables only, since unformatted values are always used for numeric variables.
- **DESFORMATTED** scores are assigned in descending order by their formatted values. This option can be applied to character variables only, since unformatted values are always used for numeric variables.
- **DSORDER** scores are assigned according to the order of their appearance in the input data set.

The default value is **ASCENDING**.

**WEIGHTS=** *weight-list*

specifies a list of values for weighting individual variables while computing the proximity. Values in this list can be separated by blanks or commas. You can include one or more items of the form *start TO stop BY increment*. This list should contain at least one weight. The maximum number of weights you can list is equal to the number of variables. If the number of weights is less than the number of variables,
the last value in the weight-list is used for the rest of the variables; conversely, if the number of weights is greater than the number of variables, the trailing weights will be discarded.

The default value is 1.

**ID Statement**

```
ID variable
```

The ID statement specifies a single variable to be copied to the OUT= data set and used to generate names for the distance variables. The ID variable must be character.

Typically, each ID value occurs only once in the input data set or, if you use a BY statement, only once within a BY group.

If you specify both the ID and the BY statements, the ID variable must have the same values in the same order in each BY group.

**COPY Statement**

```
COPY variables
```

The COPY statement specifies a list of additional variables to be copied to the OUT= data set.

**BY Statement**

```
BY variables
```

You can specify a BY statement to obtain separate distance matrices for observations in groups defined by the BY variables.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*.

**FREQ Statement**

```
FREQ | FREQUENCY variable
```

The frequency variable is used for either standardizing variables or assigning rank scores to the ordinal variables. It has no direct effect on computing the distances.

For standardizing variables and assigning rank scores, PROC DISTANCE treats the data set as if each observation appeared \( n \) times, where \( n \) is the value of the FREQ variable for the observation. Non-integral values of the FREQ variable are truncated to the largest integer less than the FREQ value. If the FREQ variable has a value that is less than 1 or is missing, the observation is not used in the analysis.
WEIGHT Statement

WGT | WEIGHT variable

The WEIGHT statement specifies a numeric variable in the input data set with values that are used to weight each observation. This weight variable is used for standardizing variables rather than computing the distances. Only one variable can be specified.

The WEIGHT variable values can be non-integers. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero. The WEIGHT variable applies to variables that are standardized by the following options: STD=MEAN, STD=SUM, STD=EUCLEN, STD=USTD, STD=STD, STD=AGK, or STD=L. PROC DISTANCE uses the value of the WEIGHT variable \( w_i \), as follows.

The sample mean and (uncorrected) sample variances are computed as

\[
\bar{x}_w = \frac{\sum_i w_i x_i}{\sum_i w_i}
\]

\[
w^2_w = \frac{\sum_i w_i x_i^2}{d}
\]

\[
s^2_w = \frac{\sum_i w_i (x_i - \bar{x}_w)^2}{d}
\]

where \( w_i \) is the weight value of the \( i \)th observation, \( x_i \) is the value of the \( i \)th observation, and \( d \) is the divisor controlled by the VARDEF= option (see the VARDEF= option in the PROC DISTANCE statement for details.)

PROC DISTANCE uses the value of the WEIGHT variable to calculate the following statistics:

- **MEAN** the weighted mean, \( \bar{x}_w \)
- **SUM** the weighted sum, \( \sum_i w_i x_i \)
- **USTD** the weighted uncorrected standard deviation, \( \sqrt{w^2_w} \)
- **STD** the weighted standard deviation, \( \sqrt{s^2_w} \)
- **EUCLEN** the weighted Euclidean length, computed as the square root of the weighted uncorrected sum of squares:

\[
\sqrt{\sum_i w_i x_i^2}
\]

- **AGK** the AGK estimate. This estimate is documented further in the ACECLUS procedure as the METHOD=COUNT option. See the discussion of the WEIGHT statement in Chapter 16, “The ACECLUS Procedure,” for information on how the WEIGHT variable is applied to the AGK estimate.
the $L_p$ estimate. This estimate is documented further in the FASTCLUS procedure as the LEAST= option. See the discussion of the WEIGHT statement in Chapter 28, “The FASTCLUS Procedure,” for information on how the WEIGHT variable is used to compute weighted cluster means. Note that the number of clusters is always 1.

Details

Proximity Measures

The following notation is used in this section:

- $v$: the number of variables or the dimensionality
- $x_j$: data for observation $x$ and the $j$th variable, where $j = 1$ to $v$
- $y_j$: data for observation $y$ and the $j$th variable, where $j = 1$ to $v$
- $w_j$: weight for the $j$th variable from the WEIGHTS= option in the VAR statement. $w_j = 0$ when either $x_j$ or $y_j$ is missing.
- $W$: the sum of total weights. No matter if the observation is missing or not, its weight is added to this metric.
- $\bar{x}$: mean for observation $x$
  \[ \bar{x} = \frac{\sum_{i=1}^{v} w_j x_j}{\sum_{i=1}^{v} w_j} \]
- $\bar{y}$: mean for observation $y$
  \[ \bar{y} = \frac{\sum_{i=1}^{v} w_j y_j}{\sum_{i=1}^{v} w_j} \]
- $d(x, y)$: the distance or dissimilarity between observations $x$ and $y$
- $s(x, y)$: the similarity between observations $x$ and $y$

The factor $W/\sum_{i=1}^{v} w_j$ is used to adjust some of the proximity measures for missing values.

Methods Accepting All Measurement Levels

**GOWER**

Gower’s similarity
\[ s_1(x, y) = \frac{\sum_{j=1}^{v} w_j \delta_{x,y}^j d_{x,y}^j}{\sum_{j=1}^{v} w_j \delta_{x,y}^j} \]

To compute $\delta_{x,y}^j$:
- for nominal, ordinal, interval, or ratio variable,
  \[ \delta_{x,y}^j = 1; \]
- for asymmetric nominal variable,
  \[ \delta_{x,y}^j = 1, \text{ if either } x_j \text{ or } y_j \text{ is present} \]
  \[ \delta_{x,y}^j = 0, \text{ if both } x_j \text{ and } y_j \text{ are absent} \]
To compute $d_{x,y}^j$: for nominal or asymmetric nominal variable,

$$d_{x,y}^j = \begin{cases} 1, & \text{if } x_j = y_j \\ 0, & \text{if } x_j \neq y_j \end{cases}$$

for ordinal (where data are replaced by corresponding rank scores), interval, or ratio variable,

$$d_{x,y}^j = 1 - |x_j - y_j|$$

DGOWER 1 minus Gower

$$d_2(x, y) = 1 - s_1(x, y)$$

**Methods Accepting Ratio, Interval, and Ordinal Variables:**

EUCLID Euclidean distance

$$d_3(x, y) = \sqrt{\left(\sum_{j=1}^v w_j (x_j - y_j)^2\right)/\left(\sum_{j=1}^v w_j\right)}$$

SQEUCLID Squared Euclidean distance

$$d_4(x, y) = \left(\sum_{j=1}^v w_j (x_j - y_j)^2\right)/\left(\sum_{j=1}^v w_j\right)$$

SIZE Size distance

$$d_5(x, y) = \left|\sum_{j=1}^v w_j (x_j - y_j)\right|\sqrt{\left(\sum_{j=1}^v w_j\right)}$$

SHAPE Shape distance

$$d_6(x, y) = \sqrt{\left(\sum_{j=1}^v w_j [(x_j - \bar{x}) - (y_j - \bar{y})]^2\right)/\left(\sum_{j=1}^v w_j\right)}$$

**Note:** squared shape distance plus squared size distance equals squared Euclidean distance.

COV Covariance similarity coefficient

$$s_7(x, y) = \sum_{j=1}^v w_j (x_j - \bar{x})(y_j - \bar{y})/\text{vardiv}, \text{ where}$$

$$\text{vardiv} = \begin{cases} v, & \text{if } \text{VARDEF}=N \\ v - 1, & \text{if } \text{VARDEF}=DF \\ \sum_{j=1}^v w_j, & \text{if } \text{VARDEF}=\text{WEIGHT} \\ \sum_{j=1}^v w_j - 1, & \text{if } \text{VARDEF}=\text{WDF} \end{cases}$$

CORR Correlation similarity coefficient

$$s_8(x, y) = \frac{\sum_{j=1}^v w_j (x_j - \bar{x})(y_j - \bar{y})}{\sqrt{\sum_{j=1}^v w_j (x_j - \bar{x})^2 \sum_{j=1}^v w_j (y_j - \bar{y})^2}}$$

DCORR Correlation transformed to Euclidean distance as $\sqrt{1 - \text{CORR}}$

$$d_9(x, y) = \sqrt{1 - s_8(x, y)}$$
Chapter 26. The DISTANCE Procedure

SQCORR
Squred correlation

\[ s_{10}(x, y) = \frac{\sum_{i=1}^{v} w_j (x_j - \bar{x})(y_j - \bar{y})^2}{\sum_{i=1}^{v} w_j (x_j - \bar{x})^2 \sum_{i=1}^{v} w_j (y_j - \bar{y})^2} \]

DSQCORR
Squared correlation transformed to squared Euclidean distance as \((1 - SQCORR)\)

\[ d_{11}(x, y) = 1 - s_{10}(x, y) \]

L(p)
Minkowski \((L_p)\) distance, where \(p\) is a positive numeric value

\[ d_{12}(x, y) = \left( \sum_{j=1}^{v} w_j |x_j - y_j|^p \right)^{1/p} \]

CITYBLOCK
\(L_1\)

\[ d_{13}(x, y) = \left( \sum_{j=1}^{v} w_j |x_j - y_j| \right) \left/ \left( \sum_{j=1}^{v} w_j \right) \right. \]

CHEBYCHEV
\(L_\infty\)

\[ d_{14}(x, y) = \max_{j=1}^{v} w_j |x_j - y_j| \]

POWER\((p, r)\)
Generalized Euclidean distance, where \(p\) is a non-negative numeric value, and \(r\) is a positive numeric value. The distance between two observations is the \(r\)th root of sum of the absolute differences to the \(p\)th power between the values for the observations

\[ d_{15}(x, y) = \left( \sum_{j=1}^{v} w_j |x_j - y_j|^p \right)^{1/r} \left/ \left( \sum_{j=1}^{v} w_j \right) \right. \]

**Methods Accepting Ratio Variables**

SIMRATIO
Similarity ratio

\[ s_{16}(x, y) = \frac{\sum_{i=1}^{v} w_j x_i y_j}{\sum_{j=1}^{v} w_j (x_j + y_j)^2} \]

DISRATIO
one minus similarity ratio

\[ d_{17}(x, y) = 1 - s_{16}(x, y) \]

NONMETRIC
Lance-Williams nonmetric coefficient

\[ d_{18}(x, y) = \frac{\sum_{j=1}^{v} w_j (x_j - y_j)}{\sum_{j=1}^{v} w_j (x_j + y_j)} \]

CANBERRA
Canberra metric coefficient

\[ d_{19}(x, y) = \sum_{j=1}^{v} \left( \frac{w_j |x_j - y_j|}{w_j (x_j + y_j)} \right) \]

COSINE
Cosine

\[ s_{20}(x, y) = \frac{\sum_{i=1}^{v} w_j x_i y_j}{\sqrt{\sum_{j=1}^{v} w_j (x_j)^2 \sum_{j=1}^{v} w_j (y_j)^2}} \]
Proximity Measures

DOT

Dot (inner) product

\[ s_{21}(x, y) = \sum_{j=1}^{v} w_j x_i y_j / \sum_{j=1}^{v} w_j \]

OVERLAP

Sum of the minimum values

\[ s_{22}(x, y) = \sum_{j=1}^{v} w_j \min(x_j, y_j) \]

DOVERLAP

The maximum of the sum of the x and the sum of y minus overlap

\[ d_{23}(x, y) = \max(\sum_{j=1}^{v} w_i x_j, \sum_{j=1}^{v} w_i y_j) - s_{22}(x, y) \]

CHISQ

chi-squared

If the data represent the frequency counts, chi-squared dissimilarity between two sets of frequencies can be computed. A 2 by \( v \) contingency table is illustrated to explain how the chi-squared dissimilarity is computed:

<table>
<thead>
<tr>
<th>Observation</th>
<th>Variable</th>
<th>Row sum</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>( x_1 )</td>
<td>( r_x )</td>
</tr>
<tr>
<td>Y</td>
<td>( y_1 )</td>
<td>( r_y )</td>
</tr>
<tr>
<td>Column sum</td>
<td>( c_1 )</td>
<td>( T )</td>
</tr>
<tr>
<td></td>
<td>( x_2 )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( \ldots )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( x_v )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( \ldots )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( y_2 )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( \ldots )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( y_v )</td>
<td>( \ldots )</td>
</tr>
<tr>
<td></td>
<td>( \ldots )</td>
<td>( \ldots )</td>
</tr>
</tbody>
</table>

where

\[ r_x = \sum_{j=1}^{v} w_j x_j \]
\[ r_y = \sum_{j=1}^{v} w_j y_j \]
\[ c_j = w_j (x_j + y_j) \]
\[ T = r_x + r_y = \sum_{j=1}^{v} c_j \]

The chi-squared measure is computed as follows:

\[ d_{24}(x, y) = \left( \frac{\sum_{j=1}^{v} \left( w_j x_j - E(x_j) \right)^2}{E(x_j)} + \sum_{j=1}^{v} \frac{(w_j y_j - E(y_j))^2}{E(y_j)} \right) W / (\sum_{j=1}^{v} w_j) \]

where for \( j = 1, 2, \ldots, v \)

\[ E(x_j) = r_x c_j / T \]
\[ E(y_j) = r_y c_j / T \]

CHI

Squared root of chi-squared

\[ d_{25}(x, y) = \sqrt{d_{23}(x, y)} \]

PHISQ

phi-squared

This is the CHISQ dissimilarity normalized by the sum of weights

\[ d_{26}(x, y) = d_{24}(x, y) / \left( \sum_{j=1}^{v} w_j \right) \]

PHI

Squared root of phi-squared

\[ d_{27}(x, y) = \sqrt{d_{25}(x, y)} \]
Methods Accepting Symmetric Nominal Variables

The following notation is used for computing $d_{28}(x, y)$ to $s_{35}(x, y)$. Notice that only the non-missing pairs are discussed below; all the pairs with at least one missing value will be excluded from any of the computations in the following section because $w_j = 0$, if either $x_j$ or $y_j$ is missing.

$M$ non-missing matches

$$M = \sum_{j=1}^{v} w_j \delta_{x,y}^j,$$

where

\[
\begin{align*}
\delta_{x,y}^j &= 1, \text{ if } x_j = y_j \\
\delta_{x,y}^j &= 0, \text{ otherwise}
\end{align*}
\]

$X$ non-missing mismatches

$$X = \sum_{j=1}^{v} w_j \delta_{x,y}^j,$$

where

\[
\begin{align*}
\delta_{x,y}^j &= 1, \text{ if } x_j \neq y_j \\
\delta_{x,y}^j &= 0, \text{ otherwise}
\end{align*}
\]

$N$ total non-missing pairs

$$N = \sum_{j=1}^{v} w_j$$

HAMMING Hamming distance

$$d_{28}(x, y) = X$$

MATCH Simple matching coefficient

$$s_{29}(x, y) = M/N$$

DMATCH Simple matching coefficient transformed to Euclidean distance

$$d_{30}(x, y) = \sqrt{1 - M/N} = \sqrt{X/N}$$

DSQMATCH Simple matching coefficient transformed to squared Euclidean distance

$$d_{31}(x, y) = 1 - M/N = X/N$$

HAMANN Hamann coefficient

$$s_{32}(x, y) = (M - X)/N$$

RT Roger and Tanimoto

$$s_{33}(x, y) = M/(M + 2X)$$

SS1 Sokal and Sneath 1

$$s_{34}(x, y) = 2M/(2M + X)$$
SS3 Sokal and Sneath 3. The coefficient between an observation and itself is always indeterminate (missing) since there is no mismatch.

\[ s_{35}(x, y) = \frac{M}{X} \]

The following notation is used for computing \( s_{36}(x, y) \) to \( d_{41}(x, y) \). Notice that only the non-missing pairs are discussed below; all the pairs with at least one missing value will be excluded from any of the computations in the following section because \( w_j = 0 \) if either \( x_j \) or \( y_j \) is missing.

Also, the observed non-missing data of an asymmetric binary variable can possibly have only two outcomes: presence or absence. Therefore, the notation, \( PX \) (present mismatches), always has a value of zero for an asymmetric binary variable.

The following methods distinguish between the presence and absence of attributes.

\[ X = \sum_{j=1}^{v} w_j \delta^l_{x,y}, \text{ where} \]

\[ \delta^l_{x,y} = \begin{cases} 1, & \text{if } x_j \neq y_j \text{ and not both } x_j \text{ and } y_j \text{ are absent} \\ 0, & \text{otherwise} \end{cases} \]

\[ PM = \sum_{j=1}^{v} w_j \delta^l_{x,y}, \text{ where} \]

\[ \delta^l_{x,y} = \begin{cases} 1, & \text{if } x_j = y_j \text{ and both } x_j \text{ and } y_j \text{ are present} \\ 0, & \text{otherwise} \end{cases} \]

\[ PX = \sum_{j=1}^{v} w_j \delta^l_{x,y}, \text{ where} \]

\[ \delta^l_{x,y} = \begin{cases} 1, & \text{if } x_j \neq y_j \text{ and both } x_j \text{ and } y_j \text{ are present} \\ 0, & \text{ otherwise} \end{cases} \]

\[ PP = PM + PX \]

\[ P \]

at least one present = \( PM + X \)

\[ PAX = \sum_{j=1}^{v} w_j \delta^l_{x,y}, \text{ where} \]

\[ \delta^l_{x,y} = \begin{cases} 1, & \text{if } x_j \neq y_j \text{ and either } x_j \text{ is present and } y_j \text{ is absent or} \\ & x_j \text{ is absent and } y_j \text{ is present} \\ 0, & \text{otherwise} \end{cases} \]

\[ N \]

total non-missing pairs

\[ N = \sum_{j=1}^{v} w_j \]
Methods Accepting Asymmetric Nominal and Ratio Variables

**JACCARD**  Jaccard similarity coefficient

The JACCARD method is equivalent to the SIMRATIO method if there are only ratio variables; if there are both ratio and asymmetric nominal variables, the coefficient is computed as sum of the coefficient from the ratio variables (SIMRATIO) and the coefficient from the asymmetric nominal variables.

\[ s_{36}(x, y) = s_{16}(x, y) + \frac{PM}{P} \]

**DJACCARD**  Jaccard dissimilarity coefficient

The DJACCARD method is equivalent to the DISRATIO method if there are only ratio variables; if there are both ratio and asymmetric nominal variables, the coefficient is computed as sum of the coefficient from the ratio variables (DISRATIO) and the coefficient from the asymmetric nominal variables.

\[ d_{37}(x, y) = d_{17}(x, y) + \frac{X}{P} \]

Methods Accepting Asymmetric Nominal Variables

**DICE**  Dice coefficient or Czekanowski/Sorensen similarity coefficient

\[ s_{38}(x, y) = \frac{2PM}{P + PM} \]

**RR**  Russell and Rao. This is the binary equivalent of the dot product coefficient.

\[ s_{39}(x, y) = \frac{PM}{N} \]

**BLWNM**  Binary Lance and Williams, also known as Bray and Curtis coefficient

\[ d_{40}(x, y) = \frac{X}{PA + 2PP} \]

**K1**  Kulcynski 1. The coefficient between an observations and itself is always indeterminate (missing) since there is no mismatch.

\[ d_{41}(x, y) = \frac{PM}{X} \]

Missing Values

**Standardizing Variables**

Missing values can be replaced by the location measure or by any specified constant (see the REPLACE option in the PROC DISTANCE statement and the MISSING=...
option in the VAR statement.) If standardization is not mandatory, you can also suppress standardization if you want only to replace missing values (see the REPONLY option in the PROC DISTANCE statement.)

If you specify the NOMISS option, PROC DISTANCE omits observations with any missing values in the analyzed variables from computation of the location and scale measures.

**Distance Measures**

If you specify the NOMISS option, PROC DISTANCE generates missing distance for observations with missing values. If the NOMISS option is not specified, the sum of total weights, no matter if an observation is missing or not, will be incorporated to the computation of some of the proximity measures. See the “Details” section on page 1270 for formulas and descriptions.

**Formatted versus Unformatted Values**

PROC DISTANCE uses the formatted values from a character variable, if the variable has a format; for example, one assigned by a format statement. PROC DISTANCE uses the unformatted values from a numeric variable, even if it has a format.

**Output Data Sets**

**OUT= Data Set**

The DISTANCE procedure always produces an output data set, regardless of whether you specify the OUT= option in the PROC DISTANCE statement. PROC DISTANCE displays no output. Use PROC PRINT, PROC REPORT or some other SAS reporting tool to print the output data set.

The output data set contains the following variables:

- the ID variable, if any
- the BY variables, if any
- the COPY variables, if any
- the FREQ variable, if any
- the WEIGHT variable, if any
- the new distance variables, named from PREFIX= options along with the ID values, or from the default values.

**OUTSDZ= Data Set**

The output data set is a copy of the DATA= data set except that the analyzed variables have been standardized. Analyzed variables are those listed in the VAR statement.
Examples

Example 26.1. Divorce Grounds – the Jaccard Coefficient

A wide variety of distance and similarity measures are used in cluster analysis (Anderberg 1973, Sneath and Sokal 1973). If your data are in coordinate form and you want to use a non-Euclidean distance for clustering, you can compute a distance matrix using the DISTANCE procedure.

Similarity measures must be converted to dissimilarities before being used in PROC CLUSTER. Such conversion can be done in a variety of ways, such as taking reciprocals or subtracting from a large value. The choice of conversion method depends on the application and the similarity measure. If applicable, PROC DISTANCE provides a corresponding dissimilarity measure for each similarity measure.

In the following example, the observations are states. Binary-valued variables correspond to various grounds for divorce and indicate whether the grounds for divorce apply in each of the states of the USA. A value of “1” indicates that the ground for divorce applies and a value of “0” indicates the opposite. The 0-0 matches are treated totally irrelevant; therefore, each variable has an asymmetric nominal level of measurement. The absence value is 0.

The DISTANCE procedure is used to compute the Jaccard coefficient (Anderberg 1973, pp. 89, 115, and 117) between each pair of states. The Jaccard coefficient is defined as the number of variables that are coded as 1 for both states divided by the number of variables that are coded as 1 for either or both states. Since dissimilarity measures are required by the CLUSTER procedure, the DJACCARD coefficient is selected. Output 26.1.1 displays the distance matrix between the first ten states.

The CENTROID method is used to perform the cluster analysis, and the resulting tree diagram from PROC CLUSTER is saved into the tree output data set. Output 26.1.2 displays the cluster history.

The TREE procedure generates nine clusters in the output data set out. After being sorted by the state, the out data set is then merged with the input data set divorce. After being sorted by the state, the merged data set is printed to display the cluster membership as shown in Output 26.1.3.

Example 26.2. Financial Data – Stock Dividends

The following data set contains the average dividend yields for 15 utility stocks in the U.S. The observations are names of the companies, and the variables correspond to the annual dividend yields for the period of 1986-1990. The objective is to group similar stocks into clusters.

Before the cluster analysis is performed, the correlation similarity is chosen for measuring the closeness between each observation. Since distance type of measures are required by the CLUSTER procedure, METHOD=DCORR is used in the PROC DISTANCE statement to transform the correlation measures to the distance measures. Notice that in Output 26.2.1, all the values in the distance matrix are between 0. and 2.

The macro function do_cluster performs cluster analysis and presents the results in graphs. The CLUSTER procedure performs hierarchical clustering using agglomerative methods based on the distance data created from the previous PROC DISTANCE statement. The resulting tree diagrams can be saved into an output data set and later be plotted by the TREE procedure. Since the CCC statistics is not suitable for distance type of data, only the Pseudo Statistics is requested to identify the number of clusters.

Two clustering methods are invoked in the do_cluster macro: the WARD’s and the average linkage methods. Since the results of the Pseudo T statistics from both the WARD’s and the average linkage methods contain many missing values, only the graphs of the Pseudo F statistics versus the number of clusters are plotted.

Both Output 26.2.2 and Output 26.2.3 suggest a possible clusters of 4, and the resulting clusters are agreed by both clustering methods as shown from Output 26.2.4 to Output 26.2.5. The four clusters are:
data stock;
  title 'Stock Dividends';
  datalines;
  Cincinnati G&E 8.4 8.2 8.4 8.1 8.0
  Texas Utilities 7.9 8.9 10.4 8.9 8.3

Chapter 27
The FACTOR Procedure

Overview

The FACTOR procedure performs a variety of common factor and component analyses and rotations. Input can be multivariate data, a correlation matrix, a covariance matrix, a factor pattern, or a matrix of scoring coefficients. The procedure can factor either the correlation or covariance matrix, and you can save most results in an output data set.

PROC FACTOR can process output from other procedures. For example, it can rotate the canonical coefficients from multivariate analyses in the GLM procedure.

The methods for factor extraction are principal component analysis, principal factor analysis, iterated principal factor analysis, unweighted least-squares factor analysis, maximum likelihood (canonical) factor analysis, alpha factor analysis, image component analysis, and Harris component analysis. A variety of methods for prior communality estimation is also available.

Specific methods for orthogonal rotation are varimax, quartimax, biquartimax, equamax, parsimax, and factor parsimax. Oblique versions of these methods are also available. In addition, quartimin, biquartimin, and covarimin methods for (direct) oblique rotation are available. General methods for orthogonal rotation are orthomax with user-specified gamma, Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony, and generalized Crawford-Ferguson family with user-specified weights. General methods for oblique rotation are direct oblimin with user-specified tau, Crawford-Ferguson family with user-specified weights on variable parsimony and factor parsimony, generalized Crawford-Ferguson family with user-specified weights, promax with user-specified exponent, Harris-Kaiser case II with user-specified exponent, and Procrustean with a user-specified target pattern.

Output includes means, standard deviations, correlations, Kaiser’s measure of sampling adequacy, eigenvalues, a scree plot, eigenvectors, prior and final communality estimates, the unrotated factor pattern, residual and partial correlations, the rotated primary factor pattern, the primary factor structure, interfactor correlations, the reference structure, reference axis correlations, the variance explained by each factor both ignoring and eliminating other factors, plots of both rotated and unrotated factors, squared multiple correlation of each factor with the variables, standard error estimates, confidence limits, coverage displays, and scoring coefficients.

Any topics that are not given explicit references are discussed in Mulaik (1972) or Harman (1976).
Background

Common factor analysis was invented by Spearman (1904). Kim and Mueller (1978a, 1978b) provide a very elementary discussion of the common factor model. Gorsuch (1974) contains a broad survey of factor analysis, and Gorsuch (1974) and Cattell (1978) are useful as guides to practical research methodology. Harman (1976) gives a lucid discussion of many of the more technical aspects of factor analysis, especially oblique rotation. Morrison (1976) and Mardia, Kent, and Bibby (1979) provide excellent statistical treatments of common factor analysis. Mulaik (1972) is the most thorough and authoritative general reference on factor analysis and is highly recommended to anyone familiar with matrix algebra. Stewart (1981) gives a nontechnical presentation of some issues to consider when deciding whether or not a factor analysis may be appropriate.

A frequent source of confusion in the field of factor analysis is the term factor. It sometimes refers to a hypothetical, unobservable variable, as in the phrase common factor. In this sense, factor analysis must be distinguished from component analysis since a component is an observable linear combination. Factor is also used in the sense of matrix factor, in that one matrix is a factor of a second matrix if the first matrix multiplied by its transpose equals the second matrix. In this sense, factor analysis refers to all methods of data analysis using matrix factors, including component analysis and common factor analysis.

A common factor is an unobservable, hypothetical variable that contributes to the variance of at least two of the observed variables. The unqualified term “factor” often refers to a common factor. A unique factor is an unobservable, hypothetical variable that contributes to the variance of only one of the observed variables. The model for common factor analysis posits one unique factor for each observed variable.

The equation for the common factor model is

\[ y_{ij} = x_{i1}b_{1j} + x_{i2}b_{2j} + \cdots + x_{iq}b_{qj} + e_{ij} \]

where

- \( y_{ij} \) is the value of the \( i \)th observation on the \( j \)th variable
- \( x_{ik} \) is the value of the \( i \)th observation on the \( k \)th common factor
- \( b_{kj} \) is the regression coefficient of the \( k \)th common factor for predicting the \( j \)th variable
- \( e_{ij} \) is the value of the \( i \)th observation on the \( j \)th unique factor
- \( q \) is the number of common factors

It is assumed, for convenience, that all variables have a mean of 0. In matrix terms, these equations reduce to

\[ Y = XB + E \]
In the preceding equation, \( X \) is the matrix of factor scores, and \( B' \) is the factor pattern.

There are two critical assumptions:

- The unique factors are uncorrelated with each other.
- The unique factors are uncorrelated with the common factors.

In principal component analysis, the residuals are generally correlated with each other. In common factor analysis, the unique factors play the role of residuals and are defined to be uncorrelated both with each other and with the common factors. Each common factor is assumed to contribute to at least two variables; otherwise, it would be a unique factor.

When the factors are initially extracted, it is also assumed, for convenience, that the common factors are uncorrelated with each other and have unit variance. In this case, the common factor model implies that the covariance \( s_{jk} \) between the \( j \)th and \( k \)th variables, \( j \neq k \), is given by

\[
s_{jk} = b_{1j}b_{1k} + b_{2j}b_{2k} + \cdots + b_{qj}b_{qk}
\]

or

\[
S = B'B + U^2
\]

where \( S \) is the covariance matrix of the observed variables, and \( U^2 \) is the diagonal covariance matrix of the unique factors.

If the original variables are standardized to unit variance, the preceding formula yields correlations instead of covariances. It is in this sense that common factors explain the correlations among the observed variables. The difference between the correlation predicted by the common factor model and the actual correlation is the residual correlation. A good way to assess the goodness-of-fit of the common factor model is to examine the residual correlations.

The common factor model implies that the partial correlations among the variables, removing the effects of the common factors, must all be 0. When the common factors are removed, only unique factors, which are by definition uncorrelated, remain.

The assumptions of common factor analysis imply that the common factors are, in general, not linear combinations of the observed variables. In fact, even if the data contain measurements on the entire population of observations, you cannot compute the scores of the observations on the common factors. Although the common factor scores cannot be computed directly, they can be estimated in a variety of ways.

The problem of factor score indeterminacy has led several factor analysts to propose methods yielding components that can be considered approximations to common factors. Since these components are defined as linear combinations, they are computable. The methods include Harris component analysis and image component analysis. The advantage of producing determinate component scores is offset by the fact that, even
if the data fit the common factor model perfectly, component methods do not generally recover the correct factor solution. You should not use any type of component analysis if you really want a common factor analysis (Dziuban and Harris 1973; Lee and Comrey 1979).

After the factors are estimated, it is necessary to interpret them. Interpretation usually means assigning to each common factor a name that reflects the salience of the factor in predicting each of the observed variables, that is, the coefficients in the pattern matrix corresponding to the factor. Factor interpretation is a subjective process. It can sometimes be made less subjective by rotating the common factors, that is, by applying a nonsingular linear transformation. A rotated pattern matrix in which all the coefficients are close to 0 or $\pm 1$ is easier to interpret than a pattern with many intermediate elements. Therefore, most rotation methods attempt to optimize a simplicity function of the rotated pattern matrix that measures, in some sense, how close the elements are to 0 or $\pm 1$. Because the loading estimates are subject to sampling variability, it is useful to obtain the standard error estimates for the loadings for assessing the uncertainty due to random sampling. Notice that the salience of a factor loading refers to the magnitude of the loading, while statistical significance refers to the statistical evidence against a particular hypothetical value. A loading significantly different from 0 does not automatically mean it must be salient. For example, if salience is defined as a magnitude bigger than 0.4 while the entire 95% confidence interval for a loading lies between 0.1 and 0.3, the loading is statistically significant larger than 0 but it is not salient. Under the maximum likelihood method, you can obtain standard errors and confidence intervals for judging the salience of factor loadings.

After the initial factor extraction, the common factors are uncorrelated with each other. If the factors are rotated by an orthogonal transformation, the rotated factors are also uncorrelated. If the factors are rotated by an oblique transformation, the rotated factors become correlated. Oblique rotations often produce more useful patterns than do orthogonal rotations. However, a consequence of correlated factors is that there is no single unambiguous measure of the importance of a factor in explaining a variable. Thus, for oblique rotations, the pattern matrix does not provide all the necessary information for interpreting the factors; you must also examine the factor structure and the reference structure.

Rotating a set of factors does not change the statistical explanatory power of the factors. You cannot say that any rotation is better than any other rotation from a statistical point of view; all rotations, orthogonal or oblique, are equally good statistically. Therefore, the choice among different rotations must be based on nonstatistical grounds. For most applications, the preferred rotation is that which is most easily interpretable, or which is most compatible with substantive theories.

If two rotations give rise to different interpretations, those two interpretations must not be regarded as conflicting. Rather, they are two different ways of looking at the same thing, two different points of view in the common-factor space. Any conclusion that depends on one and only one rotation being correct is invalid.
Outline of Use

Principal Component Analysis

One important type of analysis performed by the FACTOR procedure is principal component analysis. The statements

```sas
proc factor;
run;
```

result in a principal component analysis. The output includes all the eigenvalues and the pattern matrix for eigenvalues greater than one.

Most applications require additional output. For example, you may want to compute principal component scores for use in subsequent analyses or obtain a graphical aid to help decide how many components to keep. You can save the results of the analysis in a permanent SAS data library by using the OUTSTAT= option. (Refer to the SAS Language Reference: Dictionary for more information on permanent SAS data libraries and librefs.) Assuming that your SAS data library has the libref `save` and that the data are in a SAS data set called `raw`, you could do a principal component analysis as follows:

```sas
proc factor data=raw method=principal scree mineigen=0 score outstat=save.fact_all;
run;
```

The SCREE option produces a plot of the eigenvalues that is helpful in deciding how many components to use. The MINEIGEN=0 option causes all components with variance greater than zero to be retained. The SCORE option requests that scoring coefficients be computed. The OUTSTAT= option saves the results in a specially structured SAS data set. The name of the data set, in this case `fact_all`, is arbitrary. To compute principal component scores, use the SCORE procedure:

```sas
proc score data=raw score=save.fact_all out=save.scores;
run;
```

The SCORE procedure uses the data and the scoring coefficients that are saved in `save.fact_all` to compute principal component scores. The component scores are placed in variables named `Factor1`, `Factor2`, ..., `Factorn` and are saved in the data set `save.scores`. If you know ahead of time how many principal components you want to use, you can obtain the scores directly from PROC FACTOR by specifying the NFACTORS= and OUT= options. To get scores from three principal components, specify

```sas
proc factor data=raw method=principal
    nfactors=3 out=save.scores;
run;
```
Chapter 27. The FACTOR Procedure

To plot the scores for the first three components, use the PLOT procedure:

```
proc plot;
  plot factor2*factor1 factor3*factor1 factor3*factor2;
run;
```

**Principal Factor Analysis**

The simplest and computationally most efficient method of common factor analysis is principal factor analysis, which is obtained the same way as principal component analysis except for the use of the PRIORS= option. The usual form of the initial analysis is

```
proc factor data=raw method=principal scree
  mineigen=0 priors=smc outstat=save.fact_all;
run;
```

The squared multiple correlations (SMC) of each variable with all the other variables are used as the prior communality estimates. If your correlation matrix is singular, you should specify PRIORS=MAX instead of PRIORS=SMC. The SCREE and MINEIGEN= options serve the same purpose as in the preceding principal component analysis. Saving the results with the OUTSTAT= option enables you to examine the eigenvalues and scree plot before deciding how many factors to rotate and to try several different rotations without re-extracting the factors. The OUTSTAT= data set is automatically marked TYPE=FACTOR, so the FACTOR procedure realizes that it contains statistics from a previous analysis instead of raw data.

After looking at the eigenvalues to estimate the number of factors, you can try some rotations. Two and three factors can be rotated with the following statements:

```
proc factor data=save.fact_all method=principal n=2
  rotate=promax reorder score outstat=save.fact_2;
proc factor data=save.fact_all method=principal n=3
  rotate=promax reorder score outstat=save.fact_3;
run;
```

The output data set from the previous run is used as input for these analyses. The options N=2 and N=3 specify the number of factors to be rotated. The specification ROTATE=PROMAX requests a promax rotation, which has the advantage of providing both orthogonal and oblique rotations with only one invocation of PROC FACTOR. The REORDER option causes the variables to be reordered in the output so that variables associated with the same factor appear next to each other.

You can now compute and plot factor scores for the two-factor promax-rotated solution as follows:

```
proc score data=raw score=save.fact_2 out=save.scores;
proc plot;
  plot factor2*factor1;
run;
```
**Maximum Likelihood Factor Analysis**

Although principal factor analysis is perhaps the most commonly used method of common factor analysis, most statisticians prefer maximum likelihood (ML) factor analysis (Lawley and Maxwell 1971). The ML method of estimation has desirable asymptotic properties (Bickel and Doksum 1977) and produces better estimates than principal factor analysis in large samples. You can test hypotheses about the number of common factors using the ML method. You can also obtain standard error and confidence interval estimates for many classes of rotated or unrotated factor loadings, factor correlations, and structure loadings under the ML theory.

The unrotated ML solution is equivalent to Rao’s (1955) canonical factor solution and Howe’s solution maximizing the determinant of the partial correlation matrix (Morrison 1976). Thus, as a descriptive method, ML factor analysis does not require a multivariate normal distribution. The validity of Bartlett’s $\chi^2$ test for the number of factors does require approximate normality plus additional regularity conditions that are usually satisfied in practice (Geweke and Singleton 1980).

Lawley and Maxwell (1971) derive the standard error formulas for unrotated loadings, while Archer and Jennrich (1973) and Jennrich (1973, 1974) derive the standard error formulas for several classes of rotated solutions. Extended results appear in Browne, Cudeck, Tateneni, and Mels (1998), Hayashi and Yung (1999), and Yung and Hayashi (2001). A combination of these methods is used to compute standard errors in an efficient manner. Confidence intervals are computed using the asymptotic normality of the estimates. To ensure that the confidence intervals are range respecting, transformation methods due to Browne (1982) are used. The validity of the standard error estimates and confidence limits requires the assumptions of multivariate normality and a fixed number of factors.

The ML method is more computationally demanding than principal factor analysis for two reasons. First, the communalities are estimated iteratively, and each iteration takes about as much computer time as principal factor analysis. The number of iterations typically ranges from about five to twenty. Second, if you want to extract different numbers of factors, as is often the case, you must run the FACTOR procedure once for each number of factors. Therefore, an ML analysis can take 100 times as long as a principal factor analysis. This does not include the time for computing standard error estimates, which is even more computationally demanding. For analyses with less than 35 variables, the computing time for the ML method, including the computation of standard errors, usually ranges from a few seconds to well under a minute. This seems to be a reasonable performance.

You can use principal factor analysis to get a rough idea of the number of factors before doing an ML analysis. If you think that there are between one and three factors, you can use the following statements for the ML analysis:
proc factor data=raw method=ml n=1
   outstat=save.fact1;
run;
proc factor data=raw method=ml n=2 rotate=promax
   outstat=save.fact2;
run;
proc factor data=raw method=ml n=3 rotate=promax
   outstat=save.fact3;
run;

The output data sets can be used for trying different rotations, computing scoring
coefficients, or restarting the procedure in case it does not converge within the allotted
number of iterations.

If you can determine how many factors should be retained before an analysis, you
can get the standard errors and confidence limits to aid interpretations for the ML
analysis:

   proc factor data=raw method=ml n=3 rotate=quartimin se
      cover=.4;
run;

In the analysis, you define salience as a magnitude greater than 0.4. You can then use
the coverage displays to determine the salience. See the section “Confidence Intervals
and the Salience of Factor Loadings” on page 1327 for more details.

The ML method cannot be used with a singular correlation matrix, and it is especially
prone to Heywood cases. (See the section “Heywood Cases and Other Anomalies”
on page 1332 for a discussion of Heywood cases.) If you have problems with ML,
the best alternative is to use the METHOD=ULS option for unweighted least-squares
factor analysis.

**Factor Rotation**

After the initial factor extraction, the factors are uncorrelated with each other. If
the factors are rotated by an orthogonal transformation, the rotated factors are also
uncorrelated. If the factors are rotated by an oblique transformation, the rotated
factors become correlated. Oblique rotations often produce more useful patterns than
do orthogonal rotations. However, a consequence of correlated factors is that there is
no single unambiguous measure of the importance of a factor in explaining a variable.
Thus, for oblique rotations, the pattern matrix does not provide all the necessary
information for interpreting the factors; you must also examine the factor structure
and the reference structure.

Nowadays, most rotations are done analytically. There are many choices for orthogo-
anal and oblique rotations. An excellent summary of a wide class of analytic rotations
is in Crawford and Ferguson (1970). The Crawford-Ferguson family of orthogonal
rotations includes the orthomax rotation as a subclass and the popular varimax ro-
tation as a special case. For example, assuming that there are nine variables in the
analysis, the following four specifications for orthogonal rotations give the same re-
sults:
You can also get the oblique versions of the varimax in two equivalent ways:

```
/* Oblique Crawford-Ferguson Family with
variable parsimony weight = 8
factor parsimony weight = 1 */
proc factor data=raw method=ml n=3 rotate=oblicf(8,1);
run;
/* Oblique Varimax */
proc factor data=raw method=ml n=3 rotate=obvarimax;
run;
```

Jennrich (1973) proposes a generalized Crawford-Ferguson family that includes the Crawford-Ferguson family and the (direct) oblimin family (refer to Harman 1976) as subclasses. The more well-known quartimin rotation is a special case of the oblimin class, and hence a special case of the generalized Crawford-Ferguson family. For example, the following four specifications of oblique rotations are equivalent:

```
/* Oblique generalized Crawford-Ferguson Family
with weights 0, 1, 0, -1 */
proc factor data=raw method=ml n=3 rotate=obligencf(0,1,0,-1);
run;
/* Oblimin family without the TAU= option */
proc factor data=raw method=ml n=3 rotate=oblimin(0);
run;
/* Oblimin family with the TAU= option */
proc factor data=raw method=ml n=3 rotate=oblimin tau=0;
run;
/* Quartimin */
proc factor data=raw method=ml n=3 rotate=quartimin;
run;
```

In addition to the generalized Crawford-Ferguson family, the available oblique rotation methods include Harris-Kaiser, promax, and Procrustean. See the section “Simplicity Functions for Rotations” on page 1329 for details about the definitions of various rotations. Refer to Harman (1976) and Mulaik (1972) for further information.
The following example demonstrates how you can use the FACTOR procedure to perform common factor analysis and use a transformation to rotate the extracted factors.

In this example, 103 police officers were rated by their supervisors on 14 scales (variables). You conduct a common factor analysis on these variables to see what latent factors are operating behind these ratings. The overall rating variable is excluded from the factor analysis.

The following DATA step creates the SAS data set jobratings:

```sas
options validvarname=any;
data jobratings;
   input ('Communication Skills'n 'Problem Solving'n 'Learning Ability'n 'Judgment Under Pressure'n 'Observational Skills'n 'Willingness to Confront Problems'n 'Interest in People'n 'Interpersonal Sensitivity'n 'Desire for Self-Improvement'n 'Appearance'n 'Dependability'n 'Physical Ability'n 'Integrity'n 'Overall Rating'n) (1.);
   datalines;
   26838853879867
   74758876857667
   56757863775875
   67869777988997
   99997798878888
   89897899887999
   89998898997998
   87794798468886
   35652335143113
   8988879576867
   7655789446397
   97889988989899
   76766775988888
   77667676776777
   63839932588856
   25738811284915
   88879966977988
   87979877959679
   879899755878798
   99889988998988
   78876765687677
   88889888998999
   88889988878988
```
The following statements invoke the FACTOR procedure:

```sas
proc factor data=jobratings(drop='Overall Rating'n) priors=smc
    rotate=varimax;
run;
```

The DATA= option in PROC FACTOR specifies the SAS data set `jobratings` as the input data set. The DROP= option drops the `Overall Rating` variable from the analysis. To conduct a common factor analysis, you need to set the prior communality estimate to less than one for each variable. Otherwise, the factor solution would simply be a recast of the principal components solution, in which “factors” are linear combinations of observed variables. However, in the common factor model you always assume that observed variables are functions of underlying factors. In this example, the PRIORS= option specifies that the squared multiple correlations (SMC) of each variable with all the other variables are used as the prior communality estimates. Note that squared multiple correlations are usually less than one. By default, the principal factor extraction is used if the METHOD= option is not specified. To facilitate interpretations, the ROTATE= option specifies the VARIMAX orthogonal factor rotation to be used.

The output from the factor analysis is displayed in the following figures.

3 factors will be retained by the PROPORTION criterion.

Figure 27.1. Table of Eigenvalues from PROC FACTOR
As displayed in Figure 27.1, the prior communality estimates are set to the squared multiple correlations. Figure 27.1 also displays the table of eigenvalues (the variances of the principal factors) of the reduced correlation matrix. Each row of the table pertains to a single eigenvalue. Following the column of eigenvalues are three measures of each eigenvalue’s relative size and importance. The first of these displays the difference between the eigenvalue and its successor. The last two columns display the individual and cumulative proportions that the corresponding factor contributes to the total variation. The last line displayed in Figure 27.1 states that three factors are retained, as determined by the PROPORTION criterion.

**Figure 27.2.** Factor Pattern Matrix from PROC FACTOR

Figure 27.2 displays the initial factor pattern matrix. The factor pattern matrix represents standardized regression coefficients for predicting the variables using the extracted factors. Because the initial factors are uncorrelated, the pattern matrix is also equal to the correlations between variables and the common factors.

The pattern matrix suggests that **Factor1** represents general ability. All loadings for **Factor1** in the Factor Pattern are at least 0.5. **Factor2** consists of high positive loadings on certain task-related skills (Willingness to Confront Problems, Observational Skills, and Learning Ability) and high negative loadings on some interpersonal skills (Interpersonal Sensitivity, Interest in People, and Integrity). This factor measures individuals’ relative strength in these skills. Theoretically, individuals with high positive scores on this factor would exhibit better task-related skills than interpersonal skills. Individuals with high negative scores would exhibit better interpersonal skills than task-related skills. Individuals with scores near zero have those skills balanced. **Factor3** does not have a cluster of very high or very low factor loadings. Therefore, interpreting this factor is difficult.

Figure 27.3. Variance Explained and Final Communality Estimates

Figure 27.3 displays the proportion of variance explained by each factor and the final communality estimates, including the total communality. The final communality estimates are the proportion of variance of the variables accounted for by the common factors. When the factors are orthogonal, the final communalities are calculated by taking the sum of squares of each row of the factor pattern matrix.

Figure 27.4 displays the results of the VARIMAX rotation of the three extracted factors and the corresponding orthogonal transformation matrix. The rotated factor pattern matrix is calculated by postmultiplying the original factor pattern matrix (Figure 27.2) by the transformation matrix.

</tbody>
</table>

Figure 27.4. Transformation Matrix and Rotated Factor Pattern

The rotated factor pattern matrix is somewhat simpler to interpret. If a magnitude of at least 0.5 is required to indicate a salient variable-factor relationship, Factor1 now represents interpersonal skills (Interpersonal Sensitivity, Interest in People, Integrity, Judgment Under Pressure, and Dependability). Factor2 measures physical skills and job enthusiasm (Observational Skills, Willingness to Confront Problems, Physical Ability, Desire for Self-Improvement, Dependability, and Appearance). Factor3 measures cognitive skills (Communication Skills, Problem Solving, Learning Ability, and Judgment Under Pressure).

However, using 0.5 for determining a salient variable-factor relationship does not take sampling variability into account. If the underlying assumptions for the maximum likelihood estimation are approximately satisfied, you can output standard error estimates and the confidence intervals with METHOD=ML. You can then determine the salience of the variable-factor relationship using the coverage displays. See the section “Confidence Intervals and the Salience of Factor Loadings” on page 1327 for more details.

Figure 27.5. Variance Explained and Final Communality Estimates after Rotation

Figure 27.5 displays the variance explained by each factor and the final communality estimates after the orthogonal rotation. Even though the variances explained by the rotated factors are different from that of the unrotated factor (compare with Figure 27.3), the cumulative variance explained by the common factors remains the same. Note also that the final communalities for variables, as well as the total communality, remain unchanged after rotation. Although rotating a factor solution will not increase or decrease the statistical quality of the factor model, it may simplify the interpretations of the factors and redistribute the variance explained by the factors.

Syntax

You can specify the following statements with the FACTOR procedure:

```
PROC FACTOR < options > ;
  VAR variables ;
  PRIORS communalities ;
  PARTIAL variables ;
  FREQ variable ;
  WEIGHT variable ;
  BY variables ;
```

Usually only the VAR statement is needed in addition to the PROC FACTOR statement. The descriptions of the BY, FREQ, PARTIAL, PRIORS, VAR, and WEIGHT
statements follow the description of the PROC FACTOR statement in alphabetical order.

**PROC FACTOR Statement**

```plaintext
PROC FACTOR < options >;
```

The options available with the PROC FACTOR statement are listed in the following table and then are described in alphabetical order:

**Table 27.1. Options Available in the PROC FACTOR Statement**

</tr>
</thead>
<tbody>
<tr>
<td>Exclude the correlation matrix from the OUTSTAT= data set</td>
<td>NOCORR</td>
</tr>
<tr>
<td>Miscellaneous</td>
<td>NOBS=</td>
</tr>
</tbody>
</table>

**ALL**

displays all optional output except plots. When the input data set is TYPE=CORR, TYPE=UCORR, TYPE=COV, TYPE=UCOV, or TYPE=FACTOR, simple statistics, correlations, and MSA are not displayed.

**ALPHA=p**

specifies the level of confidence $1 - p$ for interval construction. By default, $p = 0.05$, corresponding to $1 - p = 95\%$ confidence intervals. If $p$ is greater than one, it is interpreted as a percentage and divided by 100. Because the coverage probability is not controlled simultaneously, you may consider supplying a nonconventional $p$ using methods such as Bonferroni adjustment.

**CONVERGE=p**

specifies the convergence criterion for the METHOD=PRINIT, METHOD=ULS, METHOD=ALPHA, or METHOD=ML option. Iteration stops when the maximum change in the communalities is less than the value of the CONVERGE= option. The default value is 0.001. Negative values are not allowed.

**CORR**

C

displays the correlation matrix or partial correlation matrix.

**COVARIANCE**

COV

requests factoring of the covariance matrix instead of the correlation matrix. The COV option can be used only with the METHOD=PRINCIPAL, METHOD=PRINIT, METHOD=ULS, or METHOD=IMAGE option.
COVER <= p >
CI <= p >
computes the confidence intervals and optionally specifies the value of factor loading for coverage detection. By default, \( p = 0 \). The specified value is represented by an asterisk \( * \) in the coverage display. This is useful for determining the salience of loadings. For example, if \( \text{COVER}=.4 \), a display ‘0*[ ]’ indicates that the entire confidence interval is above 0.4, implying strong evidence for the salience of the loading. See the section “Confidence Intervals and the Salience of Factor Loadings” on page 1327 for more details.

\( \text{DATA} = \text{SAS-data-set} \)

specifies the input data set, which can be an ordinary SAS data set or a specially structured SAS data set as described in the section “Input Data Set” beginning on page 1322. If the \( \text{DATA=} \) option is omitted, the most recently created SAS data set is used.

**EIGENVECTORS**

\( \text{EV} \)
displays the eigenvectors of the reduced correlation matrix, of which the diagonal elements are replaced with the communality estimates. When \( \text{METHOD=} \text{ML} \), the eigenvectors are for the weighted reduced correlation matrix. \text{PROC FACTOR} chooses the solution that makes the sum of the elements of each eigenvector nonnegative. If the sum of the elements is equal to zero, then the sign depends on how the number is rounded off.

\( \text{FLAG=} \)
flags absolute values larger than \( p \) with an asterisk in the correlation and loading matrices. Negative values are not allowed for \( p \). Values printed in the matrices are multiplied by 100 and rounded to the nearest integer (see the \( \text{ROUND} \) option). The \( \text{FLAG=} \) option has no effect when standard errors or confidence intervals are also printed.

\( \text{FUZZ=} \)
prints correlations and factor loadings with absolute values less than \( p \) printed as missing. For partial correlations, the \( \text{FUZZ=} \) value is divided by 2. For residual correlations, the \( \text{FUZZ=} \) value is divided by 4. The exact values in any matrix can be obtained from the \( \text{OUTSTAT=} \) and ODS output data sets. Negative values are not allowed. The \( \text{FUZZ=} \) option has no effect when standard errors or confidence intervals are also printed.

\( \text{GAMMA=} \)
specifies the orthomax weight used with the option \( \text{ROTATE=} \text{ORTHOMAX} \) or \( \text{PREROTATE=} \text{ORTHOMAX} \). Alternatively, you can use \( \text{ROTATE=} \text{ORTHOMAX}(p) \) with \( p \) representing the orthomax weight. There is no restriction on valid values for the orthomax weight, although the most common values are between 0 and the number of variables. The default \( \text{GAMMA=} \) value is one, resulting in the varimax rotation.
HEYWOOD
HEY
sets to 1 any communality greater than 1, allowing iterations to proceed.

HKPOWER=ρ
HKP=ρ
specifies the power of the square roots of the eigenvalues used to rescale the eigenvectors for Harris-Kaiser (ROTATE=HK) rotation, assuming that the factors are extracted by the principal factor method. If the principal factor method is not used for factor extraction, the eigenvectors are replaced by the normalized columns of the unrotated factor matrix, and the eigenvalues replaced by the column normalizing constants. HKPOWER= values between 0.0 and 1.0 are reasonable. The default value is 0.0, yielding the independent cluster solution, in which each variable tends to have a large loading on only one factor. An HKPOWER= value of 1.0 is equivalent to an orthogonal rotation, with the varimax rotation as the default. You can also specify the HKPOWER= option with ROTATE=QUARTIMAX, ROTATE=BIQUARTIMAX, ROTATE=EQUAMAX, or ROTATE=ORTHOMAX, and so on. The only restriction is that the Harris-Kaiser rotation must be associated with an orthogonal rotation.

MAXITER=n
specifies the maximum number of iterations for factor extraction. You can use the MAXITER= option with the PRINIT, ULS, ALPHA, or ML methods. The default is 30.

METHOD=\textit{name}
M=\textit{name}
specifies the method for extracting factors. The default is METHOD=PRINCIPAL unless the DATA= data set is TYPE=FACTOR, in which case the default is METHOD=PATTERN. Valid values for \textit{name} are as follows:

\begin{itemize}
  \item \textbf{ALPHA | A} produces alpha factor analysis.
  \item \textbf{HARRIS | H} yields Harris component analysis of $S^{-1}RS^{-1}$ (Harris 1962), a noniterative approximation to canonical component analysis.
  \item \textbf{IMAGE | I} yields principal component analysis of the image covariance matrix, not Kaiser's (1963, 1970) or Kaiser and Rice's (1974) image analysis. A nonsingular correlation matrix is required.
  \item \textbf{ML | M} performs maximum likelihood factor analysis with an algorithm due, except for minor details, to Fuller (1987). The option METHOD=ML requires a nonsingular correlation matrix.
  \item \textbf{PATTERN} reads a factor pattern from a TYPE=FACTOR, TYPE=CORR, TYPE=UCORR, TYPE=COV or TYPE=UCOV data set. If you create a TYPE=FACTOR data set in a DATA step, only observations containing the factor pattern (\_\_\_\_TYPE\_\_\_='PATTERN') and, if the factors are correlated, the interfactor correlations (\_\_\_\_TYPE\_\_\_='FCORR') are required.
  \item \textbf{PRINCIPAL | PRIN | P} yields principal component analysis if no PRIORS option or statement is used or if you specify PRIORS=ONE; if you specify a
PRIORS statement or a PRIORS= value other than PRIORS=ONE, a principal factor analysis is performed.

PRIORS

PRINIT yields iterated principal factor analysis.

SCORE reads scoring coefficients (TYPE='SCORE') from a TYPE=FACTOR, TYPE=CORR, TYPE=UCORR, TYPE=COV, or TYPE=UCOV data set. The data set must also contain either a correlation or a covariance matrix. Scoring coefficients are also displayed if you specify the OUT= option.

ULS | U produces unweighted least squares factor analysis.

MINEIGEN= \( p \)
MIN= \( p \)
specifies the smallest eigenvalue for which a factor is retained. If you specify two or more of the MINEIGEN=, NFACTORS=, and PROPORTION= options, the number of factors retained is the minimum number satisfying any of the criteria. The MINEIGEN= option cannot be used with either the METHOD=PATTERN or the METHOD=SCORE option. Negative values are not allowed. The default is 0 unless you omit both the NFACTORS= and the PROPORTION= options and one of the following conditions holds:

- If you specify the METHOD=ALPHA or METHOD=HARRIS option, then MINEIGEN=1.
- If you specify the METHOD=IMAGE option, then

\[
\text{MINEIGEN} = \frac{\text{total image variance}}{\text{number of variables}}
\]

- For any other METHOD= specification, if prior communality estimates of 1.0 are used, then

\[
\text{MINEIGEN} = \frac{\text{total weighted variance}}{\text{number of variables}}
\]

When an unweighted correlation matrix is factored, this value is 1.

MSA produces the partial correlations between each pair of variables controlling for all other variables (the negative anti-image correlations) and Kaiser’s measure of sampling adequacy (Kaiser 1970; Kaiser and Rice 1974; Cerny and Kaiser 1977).

NFACTORS= \( n \)
NFAC\( T \)= \( n \)
N= \( n \)
specifies the maximum number of factors to be extracted and determines the amount of memory to be allocated for factor matrices. The default is the number of variables. Specifying a number that is small relative to the number of variables can substantially decrease the amount of memory required to run PROC FACTOR, especially with
oblique rotations. If you specify two or more of the NFACTORS=, MINEIGEN=, and PROPORTION= options, the number of factors retained is the minimum number satisfying any of the criteria. If you specify the option NFACTORS=0, eigenvalues are computed, but no factors are extracted. If you specify the option NFACTORS=−1, neither eigenvalues nor factors are computed. You can use the NFACTORS= option with the METHOD=_PATTERN or METHOD=SCORE option to specify a smaller number of factors than are present in the data set.

**NOBS=**

specifies the number of observations. If the DATA= input data set is a raw data set, nobs is defined by default to be the number of observations in the raw data set. The NOBS= option overrides this default definition. If the DATA= input data set contains a covariance, correlation, or scalar product matrix, the number of observations can be specified either by using the NOBS= option in the PROC FACTOR statement or by including a _TYPE_='N' observation in the DATA= input data set.

**NOCORR**

prevents the correlation matrix from being transferred to the OUTSTAT= data set when you specify the METHOD=_PATTERN option. The NOCORR option greatly reduces memory requirements when there are many variables but few factors. The NOCORR option is not effective if the correlation matrix is required for other requested output; for example, if the scores or the residual correlations are displayed (using SCORE, RESIDUALS, ALL options).

**NOINT**

omits the intercept from the analysis; covariances or correlations are not corrected for the mean.

**NOPRINT**

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

**NOPROMAXNORM | NOPMAXNORM**

turns off the default row normalization of the pre-rotated factor pattern, which is used in computing the promax target matrix.

**NORM=**

specifies the method for normalizing the rows of the factor pattern for rotation. If you specify the option NORM=KAISER, Kaiser’s normalization is used ($\sum_j p_{ij}^2 = 1$). If you specify the option NORM=WEIGHT, the rows are weighted by the Cureton-Mulaik technique (Cureton and Mulaik 1975). If you specify the option NORM=COV, the rows of the pattern matrix are rescaled to represent covariances instead of correlations. If you specify the option NORM=NONE or NORM=RAW, normalization is not performed. The default is NORM=KAISER.

**NPLOT=**

specifies the number of factors to be plotted. The default is to plot all factors. The smallest allowable value is 2. If you specify the option NPLOT=n, all pairs of the first n factors are plotted, producing a total of n(n − 1)/2 plots.
OUT=SAS-data-set
creates a data set containing all the data from the DATA= data set plus variables called Factor1, Factor2, and so on, containing estimated factor scores. The DATA= data set must contain multivariate data, not correlations or covariances. You must also specify the NFACTORS= option to determine the number of factor score variables. Note that OUT= option is disabled if you specify partial variables in the PARTIAL statement. In order to use the OUT= option with partialed variables, you can first regress the target variables on the partial variables. This can be done using PROC REG or PROC IML. You can then factor analyze the residuals without the PARTIAL statement. In this case, the OUT= option will not be disabled. If you want to create a permanent SAS data set, you must specify a two-level name. Refer to “SAS Files” in SAS Language Reference: Concepts for more information on permanent data sets.

OUTSTAT=SAS-data-set
specifies an output data set containing most of the results of the analysis. The output data set is described in detail in the section “Output Data Sets” on page 1325. If you want to create a permanent SAS data set, you must specify a two-level name. Refer to “SAS Files” in SAS Language Reference: Concepts for more information on permanent data sets.

PLOT
plots the factor pattern after rotation.

POWER=n
specifies the power to be used in computing the target pattern for the option ROTATE=PROMAX. Valid values must be integers \( \geq 1 \). The default value is 3. You can also specify the power= value in the ROTATE= option, e.g., ROTATE=PROMAX(4).

PREPLOT
plots the factor pattern before rotation.

PREROTATE=name
PRE=name
specifies the prerotation method for the option ROTATE=PROMAX. Any rotation method other than PROMAX or PROCRUSTES can be used. The default is PREROTATE=VARIMAX. If a previously rotated pattern is read using the option METHOD=PATTERN, you should specify the PREROTATE=None option.

PRINT
displays the input factor pattern or scoring coefficients and related statistics. In oblique cases, the reference and factor structures are computed and displayed. The PRINT option is effective only with the option METHOD=PATTERN or METHOD=SCORE.

PRIORS=name
specifies a method for computing prior communality estimates. You can specify numeric values for the prior communality estimates by using the PRIORS statement. Valid values for name are as follows:
ASMC | A sets the prior communality estimates proportional to the squared multiple correlations but adjusted so that their sum is equal to that of the maximum absolute correlations (Cureton 1968).

INPUT | I reads the prior communality estimates from the first observation with either \_TYPE\_='PRIORS' or \_TYPE\_='COMMUNAL' in the DATA= data set (which must be TYPE=FACTOR).

MAX | M sets the prior communality estimate for each variable to its maximum absolute correlation with any other variable.

ONE | O sets all prior communalities to 1.0.

RANDOM | R sets the prior communality estimates to pseudo-random numbers uniformly distributed between 0 and 1.

SMC | S sets the prior communality estimate for each variable to its squared multiple correlation with all other variables.

The default prior communality estimates are as follows:

<table>
<thead>
<tr>
<th>METHOD=</th>
<th>PRIORS=</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRINCIPAL</td>
<td>ONE</td>
</tr>
<tr>
<td>PRINIT</td>
<td>ONE</td>
</tr>
<tr>
<td>ALPHA</td>
<td>SMC</td>
</tr>
<tr>
<td>ULS</td>
<td>SMC</td>
</tr>
<tr>
<td>ML</td>
<td>SMC</td>
</tr>
<tr>
<td>HARRIS</td>
<td>(not applicable)</td>
</tr>
<tr>
<td>IMAGE</td>
<td>(not applicable)</td>
</tr>
<tr>
<td>PATTERN</td>
<td>(not applicable)</td>
</tr>
<tr>
<td>SCORE</td>
<td>(not applicable)</td>
</tr>
</tbody>
</table>

By default, the options METHOD=PRINIT, METHOD=ULS, METHOD=ALPHA, and METHOD=ML stop iterating and set the number of factors to 0 if an estimated communality exceeds 1. The options HEYWOOD and ULTRAHEYWOOD allow processing to continue.

**PROPORTION=\(p\)**

**PERCENT=\(p\)**

**\(P=p\)**

specifies the proportion of common variance to be accounted for by the retained factors using the prior communality estimates. If the value is greater than one, it is interpreted as a percentage and divided by 100. The options PROPORTION=0.75 and PERCENT=75 are equivalent. The default value is 1.0 or 100%. You cannot specify the PROPORTION= option with the METHOD=PATTERN or METHOD=SCORE option. If you specify two or more of the PROPORTION=, NFACTORS=, and
MINEIGEN= options, the number of factors retained is the minimum number satisfying any of the criteria.

**RANDOM=n**
specifies a positive integer as a starting value for the pseudo-random number generator for use with the option PRIORS=RANDOM. If you do not specify the RANDOM= option, the time of day is used to initialize the pseudo-random number sequence. Valid values must be integers \( \geq 1 \).

**RCONVERGE=p**
**RCONV=p**
specifies the convergence criterion for rotation cycles. Rotation stops when the scaled change of the simplicity function value is less than the RCONVERGE= value. The default convergence criterion is

\[
\frac{|f_{new} - f_{old}|}{K} < \epsilon
\]

where \( f_{new} \) and \( f_{old} \) are simplicity function values of the current cycle and the previous cycle, respectively, \( K = \max(1, |f_{old}|) \) is a scaling factor, and \( \epsilon \) is \( 1E-9 \) by default and is modified by the RCONVERGE= value.

**REORDER**
**RE**
causes the rows (variables) of various factor matrices to be reordered on the output. Variables with their highest absolute loading (reference structure loading for oblique rotations) on the first factor are displayed first, from largest to smallest loading, followed by variables with their highest absolute loading on the second factor, and so on. The order of the variables in the output data set is not affected. The factors are not reordered.

**RESIDUALS**
**RES**
displays the residual correlation matrix and the associated partial correlation matrix. The diagonal elements of the residual correlation matrix are the unique variances.

**RITER=n**
specifies the maximum number of cycles \( n \) for factor rotation. Except for promax and Procrustes, you can use the RITER= option with all rotation methods. The default \( n \) is the maximum between 100 and 10 times of the number of variables.

**ROTATE=name**
**R=name**
specifies the rotation method. The default is ROTATE=None.

Valid names for orthogonal rotations are as follows:

BIQUARTIMAX | BIQMAX specifies orthogonal biquartimax rotation. This corresponds to the specification ROTATE=ORTHOMAX(.5).

EQUAMAX | E specifies orthogonal equamax rotation. This corresponds to the specification ROTATE=ORTHOMAX with GAMMA=number of factors/2.
FACTORPARSIMAX | FPA specifies orthogonal factor parsimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with GAMMA=number of variables.

NONE | N specifies that no rotation be performed, leaving the original orthogonal solution.

ORTHCF(p1,p2) | ORCF(p1,p2) specifies the orthogonal Crawford-Ferguson rotation with the weights p1 and p2 for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section “Simplicity Functions for Rotations” on page 1329.

ORTHGENCF(p1,p2,p3,p4) | ORGENCF(p1,p2,p3,p4) specifies the orthogonal generalized Crawford-Ferguson rotation with the four weights p1, p2, p3, and p4. See the definitions of weights in the section “Simplicity Functions for Rotations” on page 1329.

ORTHOMAX<(p) > | ORMAX<(p) > specifies the orthomax rotation with orthomax weight p. If ROTATE=ORTHOMAX is used, the default p value is 1 unless specified otherwise in the GAMMA= option. Alternatively, ROTATE=ORTHOMAX(p) specifies p as the orthomax weight or the GAMMA= value. See the definition of the orthomax weight in the section “Simplicity Functions for Rotations” on page 1329.

PARSIMAX | PA specifies orthogonal parsimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with

\[
\text{GAMMA} = \frac{nvar \times (nfact - 1)}{nvar + nfact - 2}
\]

where nvar is the number of variables, and nfact is the number of factors.

QUARTIMAX | QMAX | Q specifies orthogonal quartimax rotation. This corresponds to the specification ROTATE=ORTHOMAX(0).

VARIMAX | V specifies orthogonal varimax rotation. This corresponds to the specification ROTATE=ORTHOMAX with GAMMA=1.

Valid names for oblique rotations are as follows:

BIQUARTIMIN | BIQMIN specifies biquartimin rotation. It corresponds to the specification ROTATE=OBLIMIN(.5) or ROTATE=OBLIMIN with TAU=.5.

COVARIMIN | CVMIN specifies covarimin rotation. It corresponds to the specification ROTATE=OBLIMIN(1) or ROTATE=OBLIMIN with TAU=1.

HK<(p) > | H<(p) > specifies Harris-Kaiser case II orthoblique rotation. When specifying this option, you can use the HKPOWER= option to set the power of the square roots of the eigenvalues by which the eigenvectors are scaled, assuming that the factors are extracted by
the principal factor method. For other extraction methods, the unrotated factor pattern is column normalized. The power is then applied to the column normalizing constants, instead of the eigenvalues. You can also use \texttt{ROTATE=HK}(p), with \( p \) representing the HKPOWER= value. The default associated orthogonal rotation with \texttt{ROTATE=HK} is the varimax rotation without Kaiser normalization. You may associate the Harris-Kaiser with other orthogonal rotations using the \texttt{ROTATE=} option together with the HKPOWER= option.

\texttt{OBBIQUARTIMAX} \mid \texttt{OBIQMAX} \quad \text{specifies oblique biquartimax rotation.}

\texttt{OBEQUAMAX} \mid \texttt{OE} \quad \text{specifies oblique equamax rotation.}

\texttt{OBFATORPARSIMAX} \mid \texttt{OFPA} \quad \text{specifies oblique factor parsimax rotation.}

\texttt{OBLICF}(p_1,p_2) \mid \texttt{OBCF}(p_1,p_2) \quad \text{specifies the oblique Crawford-Ferguson rotation with the weights} \ p_1 \ \text{and} \ p_2 \ \text{for variable parsimony and factor parsimony, respectively. See the definitions of weights in the section "Simplicity Functions for Rotations" on page 1329.}

\texttt{OBLIGENCF}(p_1,p_2,p_3,p_4) \mid \texttt{OBGENCF}(p_1,p_2,p_3,p_4) \quad \text{specifies the oblique generalized Crawford-Ferguson rotation with the four weights} \ p_1, \ p_2, \ p_3, \ \text{and} \ p_4. \ \text{See the definitions of weights in the section "Simplicity Functions for Rotations" on page 1329.}

\texttt{OBLIMIN}(p) \mid \texttt{OBMIN}(p) \quad \text{specifies the oblimin rotation with oblimin weight} \ p. \ \text{If} \ \texttt{ROTATE=OBLIMIN} \ \text{is used, the default} \ p \ \text{value is zero unless specified otherwise in the TAU=} \ \text{option. Alternatively,} \ \texttt{ROTATE=OBLIMIN}(p) \ \text{specifies} \ p \ \text{as the oblimin weight or the TAU=} \ \text{value. See the definition of the oblimin weight in the section "Simplicity Functions for Rotations" on page 1329.}

\texttt{OBPARSIMAX} \mid \texttt{OPA} \quad \text{specifies oblique parsimax rotation.}

\texttt{OBQUARTIMAX} \mid \texttt{OQMAX} \quad \text{specifies oblique quartimax rotation. This is the same as the QUARTIMIN method.}

\texttt{OBVARIMAX} \mid \texttt{OV} \quad \text{specifies oblique varimax rotation.}

\texttt{PROCRUSTES} \quad \text{specifies oblique Procrustes rotation with the target pattern provided by the TARGET=} \ \texttt{data set. The unrestricted least squares method is used with factors scaled to unit variance after rotation.}

\texttt{PROMAX}(p) \mid \texttt{P}(p) \quad \text{specifies oblique promax rotation. You can use the PRERotate=} \ \texttt{option to set the desirable pre-rotation method, orthogonal or oblique. When using with} \ \texttt{ROTATE=PROMAX}, \ \texttt{the POWER=} \ \texttt{option lets you specify the power for forming the target. You can also use} \ \texttt{ROTATE=PROMAX}(p), \ \texttt{where} \ p \ \text{represents the POWER=} \ \texttt{value.}

\texttt{QUARTIMIN} \mid \texttt{QMIN} \quad \text{specifies quartimin rotation. It is the same as the oblique quartimax method. It also corresponds to the specification} \ \texttt{ROTATE=OBLIMIN}(0) \ \texttt{or} \ \texttt{ROTATE=OBLIMIN} \ \texttt{with TAU}=0.
ROUND
prints correlation and loading matrices with entries multiplied by 100 and rounded
to the nearest integer. The exact values can be obtained from the OUTSTAT= and
ODS output data sets. The ROUND option also flags absolute values larger than the
FLAG= value with an asterisk in correlation and loading matrices (see the FLAG= option). If the FLAG= option is not specified, the root mean square of all the values
in the matrix printed is used as the default FLAG= value. The ROUND option has no
effect when standard errors or confidence intervals are also printed.

SCORE
displays the factor scoring coefficients. The squared multiple correlation of each
factor with the variables is also displayed except in the case of unrotated principal components. Unless you specify the NOINT option in PROC FACTOR, the scoring coefficients should be applied to standardized variables—variables that are centered by
subtracting the original variable means and then divided by the original variable stan-
dard deviations. With the NOINT option, the scoring coefficients should be applied
to data without centering.

SCREE
displays a scree plot of the eigenvalues (Cattell 1966, 1978; Cattell and Vogelman

SE
STDERR
computes standard errors for various classes of unrotated and rotated solutions under
the maximum likelihood estimation.

SIMPLE
S
displays means, standard deviations, and the number of observations.

SINGULAR=p
SING=p
specifies the singularity criterion, where $0 < p < 1$. The default value is $1E-8$.

TARGET=SAS-data-set
specifies an input data set containing the target pattern for Procrustes rotation (see the
description of the ROTATE= option). The TARGET= data set must contain variables
with the same names as those being factored. Each observation in the TARGET= data set becomes one column of the target factor pattern. Missing values are treated
as zeros. The _NAME_ and _TYPE_ variables are not required and are ignored if
present.

TAU=p
specifies the oblimin weight used with the option ROTATE=OBLIMIN or
PRERotate=OBLIMIN. Alternatively, you can use ROTATE=OBLIMIN($p$) with
$p$ representing the oblimin weight. There is no restriction on valid values for
the oblimin weight, although for practical purposes a negative or zero value is
recommended. The default TAU= value is 0, resulting in the quartimin rotation.
ULTRAHEYWOOD
ULTRA
allows communalities to exceed 1. The ULTRAHEYWOOD option can cause convergence problems because communalities can become extremely large, and ill-conditioned Hessians may occur.

VARDEF=DF | N | WDF | WEIGHT | WGT
specifies the divisor used in the calculation of variances and covariances. The default value is VARDEF=DF. The values and associated divisors are displayed in the following table where \( i = 0 \) if the NOINT option is used and \( i = 1 \) otherwise, and where \( k \) is the number of partial variables specified in the PARTIAL statement.

<table>
<thead>
<tr>
<th>Value</th>
<th>Description</th>
<th>Divisor</th>
</tr>
</thead>
<tbody>
<tr>
<td>DF</td>
<td>degrees of freedom</td>
<td>( n - k - i )</td>
</tr>
<tr>
<td>N</td>
<td>number of observations</td>
<td>( n - k )</td>
</tr>
<tr>
<td>WDF</td>
<td>sum of weights DF</td>
<td>( \sum_i w_i - k - i )</td>
</tr>
<tr>
<td>WEIGHT</td>
<td>sum of weights</td>
<td>( \sum_i w_i - k )</td>
</tr>
</tbody>
</table>

WEIGHT
factors a weighted correlation or covariance matrix. The WEIGHT option can be used only with the METHOD=PRINCIPAL, METHOD=PRINIT, METHOD=ULS, or METHOD=IMAGE option. The input data set must be of type CORR, UCORR, COV, UCOV, or FACTOR, and the variable weights are obtained from an observation with _TYPE_='WEIGHT'.

BY Statement

BY variables;

You can specify a BY statement with PROC FACTOR to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the FACTOR procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in Base SAS software). For more information on creating indexes and using the BY statement with indexed datasets, refer to “SAS Files” in *SAS Language Reference: Concepts*. 
If you specify the TARGET= option and the TARGET= data set does not contain any of the BY variables, then the entire TARGET= data set is used as a Procrustean target for each BY group in the DATA= data set.

If the TARGET= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the TARGET= data set as in the DATA= data set, then PROC FACTOR displays an error message and stops.

If all the BY variables appear in the TARGET= data set with the same type and length as in the DATA= data set, then each BY group in the TARGET= data set is used as a Procrustean target for the corresponding BY group in the DATA= data set. The BY groups in the TARGET= data set must be in the same order as in the DATA= data set. If you specify the NOTSORTED option in the BY statement, there must be identical BY groups in the same order in both data sets. If you do not specify the NOTSORTED option, some BY groups can appear in one data set but not in the other.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

### FREQ Statement

**FREQ** variable;

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable’s name in a FREQ statement. The procedure then treats the data set as if each observation appears \( n \) times, where \( n \) is the value of the FREQ variable for the observation. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

If the value of the FREQ variable is missing or is less than one, the observation is not used in the analysis. If the value is not an integer, the value is truncated to an integer.

The WEIGHT and FREQ statements have a similar effect, except in determining the number of observations for significance tests.

### PARTIAL Statement

**PARTIAL** variables;

If you want the analysis to be based on a partial correlation or covariance matrix, use the PARTIAL statement to list the variables that are used to partial out the variables in the analysis.
Chapter 27. The FACTOR Procedure

**PRIORS Statement**

PRIORS communalities ;

The PRIORS statement specifies numeric values between 0.0 and 1.0 for the prior communality estimates for each variable. The first numeric value corresponds to the first variable in the VAR statement, the second value to the second variable, and so on. The number of numeric values must equal the number of variables. For example,

```
proc factor;
  var x y z;
  priors .7 .8 .9;
run;
```

You can specify various methods for computing prior communality estimates with the PRIORS= option of the PROC FACTOR statement. Refer to the description of that option for more information on the default prior communality estimates.

**VAR Statement**

VAR variables ;

The VAR statement specifies the numeric variables to be analyzed. If the VAR statement is omitted, all numeric variables not specified in other statements are analyzed.

**WEIGHT Statement**

WEIGHT variable ;

If you want to use relative weights for each observation in the input data set, specify a variable containing weights in a WEIGHT statement. This is often done when the variance associated with each observation is different and the values of the weight variable are proportional to the reciprocals of the variances. If a variable value is negative or is missing, it is excluded from the analysis.

**Details**

**Input Data Set**

The FACTOR procedure can read an ordinary SAS data set containing raw data or a special data set specified as a TYPE=CORR, TYPE=UCORR, TYPE=SSCP, TYPE=COV, TYPE=UCOV, or TYPE=FACTOR data set containing previously computed statistics. A TYPE=CORR data set can be created by the CORR procedure or various other procedures such as the PRINCOMP procedure. It contains means, standard deviations, the sample size, the correlation matrix, and possibly other statistics if it is created by some procedure other than PROC CORR. A TYPE=COV data set is similar to a TYPE=CORR data set but contains a covariance matrix. A TYPE=UCORR or TYPE=UCOV data set contains a correlation or covariance matrix that is not corrected for the mean. The default VAR variable list does not include
Intercept if the DATA= data set is TYPE=SSCP. If the Intercept variable is explicitly specified in the VAR statement with a TYPE=SSCP data set, the NOINT option is activated. A TYPE=FACTOR data set can be created by the FACTOR procedure and is described in the section “Output Data Sets” on page 1325.

If your data set has many observations and you plan to run FACTOR several times, you can save computer time by first creating a TYPE=CORR data set and using it as input to PROC FACTOR.

```
proc corr data=raw out=correl; /* create TYPE=CORR data set */
proc factor data=correl method=ml; /* maximum likelihood */
proc factor data=correl; /* principal components */
```

The data set created by the CORR procedure is automatically given the TYPE=CORR data set option, so you do not have to specify TYPE=CORR. However, if you use a DATA step with a SET statement to modify the correlation data set, you must use the TYPE=CORR attribute in the new data set. You can use a VAR statement with PROC FACTOR when reading a TYPE=CORR data set to select a subset of the variables or change the order of the variables.

Problems can arise from using the CORR procedure when there are missing data. By default, PROC CORR computes each correlation from all observations that have values present for the pair of variables involved (pairwise deletion). The resulting correlation matrix may have negative eigenvalues. If you specify the NOMISS option with the CORR procedure, observations with any missing values are completely omitted from the calculations (listwise deletion), and there is no danger of negative eigenvalues.

PROC FACTOR can also create a TYPE=FACTOR data set, which includes all the information in a TYPE=CORR data set, and use it for repeated analyses. For a TYPE=FACTOR data set, the default value of the METHOD= option is PATTERN. The following statements produce the same PROC FACTOR results as the previous example:

```
proc factor data=raw method=ml outstat=fact; /* max. likelihood */
proc factor data=fact method=prin; /* principal components */
```

You can use a TYPE=FACTOR data set to try several different rotation methods on the same data without repeatedly extracting the factors. In the following example, the second and third PROC FACTOR statements use the data set fact created by the first PROC FACTOR statement:

```
proc factor data=raw outstat=fact; /* principal components */
proc factor rotate=varimax; /* varimax rotation */
proc factor rotate=quartimax; /* quartimax rotation */
```

You can create a TYPE=CORR, TYPE=UCORR, or TYPE=FACTOR data set in a DATA step. Be sure to specify the TYPE= option in parentheses after the data set name in the DATA statement and include the _TYPE_ and _NAME_ variables. In
a TYPE=CORR data set, only the correlation matrix (\_TYPE_='CORR') is necessary. It can contain missing values as long as every pair of variables has at least one nonmissing value.

```sas
data correl(type=corr);
  _TYPE_='CORR';
  input _NAME_ $ x y z;
  datalines;
  x 1.0 . .
  y .7 1.0 .
  z .5 .4 1.0
;
  proc factor;
  run;
```

You can create a TYPE=FACTOR data set containing only a factor pattern (_TYPE_='PATTERN') and use the FACTOR procedure to rotate it.

```sas
data pat(type=factor);
  _TYPE_='PATTERN';
  input _NAME_ $ x y z;
  datalines;
  factor1 .5 .7 .3
  factor2 .8 .2 .8
;
  proc factor rotate=promax prerotate=none;
  run;
```

If the input factors are oblique, you must also include the interfactor correlation matrix with _TYPE_='FCORR'.

```sas
data pat(type=factor);
  _TYPE_='PATTERN';
  input _NAME_ $ _NAME_ $ x y z;
  datalines;
  pattern factor1 .5 .7 .3
  pattern factor2 .8 .2 .8
  fcorr factor1 1.0 .2 .
  fcorr factor2 .2 1.0 .
;
  proc factor rotate=promax prerotate=none;
  run;
```

Some procedures, such as the PRINCOMP and CANDISC procedures, produce TYPE=CORR or TYPE=UCORR data sets containing scoring coefficients (_TYPE_='SCORE' or _TYPE_='USCORE'). These coefficients can be input to PROC FACTOR and rotated by using the METHOD=SCORE option. The input data set must contain the correlation matrix as well as the scoring coefficients.

```sas
proc princomp data=raw n=2 outstat=prin;
run;
proc factor data=prin method=score rotate=varimax;
run;
```
**Output Data Sets**

**The OUT= Data Set**

The OUT= data set contains all the data in the DATA= data set plus new variables called Factor1, Factor2, and so on, containing estimated factor scores. Each estimated factor score is computed as a linear combination of the standardized values of the variables that are factored. The coefficients are always displayed if the OUT= option is specified and they are labeled “Standardized Scoring Coefficients.”

**The OUTSTAT= Data Set**

The OUTSTAT= data set is similar to the TYPE=CORR or TYPE=UCORR data set produced by the CORR procedure, but it is a TYPE=FACTOR data set and it contains many results in addition to those produced by PROC CORR. The OUTSTAT= data set contains observations with _TYPE_ = ’UCORR’ and _TYPE_ = ’USTD’ if you specify the NOINT option.

The output data set contains the following variables:

- the BY variables, if any
- two new character variables, _TYPE_ and _NAME_
- the variables analyzed, that is, those in the VAR statement, or, if there is no VAR statement, all numeric variables not listed in any other statement.

Each observation in the output data set contains some type of statistic as indicated by the _TYPE_ variable. The _NAME_ variable is blank except where otherwise indicated. The values of the _TYPE_ variable are as follows:

<table>
<thead>
<tr>
<th><em>TYPE</em></th>
<th>Contents</th>
</tr>
</thead>
<tbody>
<tr>
<td>MEAN</td>
<td>means</td>
</tr>
<tr>

</tbody>
</table>
COMMUNAL  final communality estimates
PRIORS  prior communality estimates, or estimates from the last iteration for iterative methods
WEIGHT  variable weights
SUMWGT  sum of the variable weights
EIGENVAL  eigenvalues
UNROTATE  unrotated factor pattern. The _NAME_ variable contains the name of the factor.
SE_UNROT  standard error estimates for the unrotated loadings. The _NAME_ variable contains the name of the factor.
RESIDUAL  residual correlations. The _NAME_ variable contains the name of the variable corresponding to each row of the residual correlation matrix.
PRETRANS  transformation matrix from prerotation. The _NAME_ variable contains the name of the factor.
PREROTAT  pre-rotated factor pattern. The _NAME_ variable contains the name of the factor.
SE_PREPA  standard error estimates for the pre-rotated loadings. The _NAME_ variable contains the name of the factor.
PREREFER  pre-rotated reference structure. The _NAME_ variable contains the name of the factor.
PRESTRUC  pre-rotated factor structure. The _NAME_ variable contains the name of the factor.
SE_PREST  standard error estimates for pre-rotated structure loadings. The _NAME_ variable contains the name of the factor.
PRESCORE  pre-rotated scoring coefficients. The _NAME_ variable contains the name of the factor.
TRANSFOR  transformation matrix from rotation. The _NAME_ variable contains the name of the factor.
FCORR  interfactor correlations. The _NAME_ variable contains the name of the factor.
SE_FCcorr  standard error estimates for interfactor correlations. The _NAME_ variable contains the name of the factor.
PATTERN  factor pattern. The _NAME_ variable contains the name of the factor.
Confidence Intervals and the Salience of Factor Loadings

The traditional approach to determining salient loadings (loadings that are considered large in absolute values) employs rules-of-thumb such as 0.3 or 0.4. However, this does not utilize the statistical evidence efficiently. The asymptotic normality of the distribution of factor loadings enables you to construct confidence intervals to gauge the salience of factor loadings. To guarantee the range-respecting properties of confidence intervals, a transformation procedure such as in CEFA (Browne, Cudeck, Tateneni, and Mels 1998) is used. For example, because the orthogonal rotated factor loading $\theta$ must be bounded between $-1$ and $+1$, the Fisher transformation

$$\phi = \frac{1}{2} \log \left( \frac{1 + \theta}{1 - \theta} \right)$$

is employed so that $\phi$ is an unbounded parameter. Assuming the asymptotic normality of $\hat{\phi}$, a symmetric confidence interval for $\phi$ is constructed. Then, a back-transformation on the confidence limits yields an asymmetric confidence interval for $\theta$. Applying the results of Browne (1982), a $(1-\alpha)100\%$ confidence interval for the orthogonal factor loading $\theta$ is

$$\left( \hat{\theta}_l = \frac{a/b - 1}{a/b + 1}, \hat{\theta}_u = \frac{a \times b - 1}{a \times b + 1} \right)$$

where

$$a = \frac{1 + \hat{\theta}}{1 - \hat{\theta}}, \quad b = \exp \left( z_{\alpha/2} \times \frac{2\hat{\sigma}}{1 - \hat{\theta}^2} \right)$$
and \( \hat{\theta} \) is the estimated factor loading, \( \hat{\sigma} \) is the standard error estimate of the factor loading, and \( z_{\alpha/2} \) is the \( (1 - \alpha/2) \) 100 percentile point of a standard normal distribution.

Once the confidence limits are constructed, you can use the corresponding coverage displays for determining the salience of the variable-factor relationship. In a coverage display, the COVER= value is represented by an asterisk '*'. The following table summarizes the various displays and their interpretations:

**Table 27.2.** Interpretations of the Coverage Displays

<table>
<thead>
<tr>
<th>Positive Estimate</th>
<th>Negative Estimate</th>
<th>COVER=0 specified</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>[0]*</td>
<td>*[0]</td>
<td></td>
<td>The estimate is not significantly different from zero and the CI covers a region of values that are smaller in magnitude than the COVER= value. This is strong statistical evidence for the non-salience of the variable-factor relationship.</td>
</tr>
<tr>
<td>0[ ]*</td>
<td>*[ ]0</td>
<td></td>
<td>The estimate is significantly different from zero but the CI covers a region of values that are smaller in magnitude than the COVER= value. This is strong statistical evidence for the non-salience of the variable-factor relationship.</td>
</tr>
<tr>
<td>[0*]</td>
<td>*[0]</td>
<td>[0]</td>
<td>The estimate is not significantly different from zero or the COVER= value. The population value might have been larger or smaller in magnitude than the COVER= value. There is no statistical evidence for the salience of the variable-factor relationship.</td>
</tr>
<tr>
<td>0[*]</td>
<td>*[0]</td>
<td></td>
<td>The estimate is significantly different from zero but not from the COVER= value. This is marginal statistical evidence for the salience of the variable-factor relationship.</td>
</tr>
<tr>
<td>0*[ ]</td>
<td>[ ]*0</td>

See Example 27.4 on page 1369 for an illustration of the use of confidence intervals for interpreting factors.
Simplicity Functions for Rotations

To rotate a factor pattern is to apply a non-singular linear transformation to the unrotated factor pattern matrix. To arrive at an optimal transformation you must define a so-called simplicity function for assessing the optimal point. For the promax or the Procrustean transformation, the simplicity function is defined as the sum of squared differences between the rotated factor pattern and the target matrix. Thus, the solution of the optimal transformation is easily obtained by the familiar least-squares method.

For the class of the generalized Crawford-Ferguson family (Jennrich 1973), the simplicity function being optimized is

\[ f = k_1 Z + k_2 H + k_3 V + k_4 Q \]

where

\[ Z = \left( \sum_j \sum_i b_{ij}^2 \right)^2, \quad H = \sum_i \left( \sum_j b_{ij}^2 \right)^2 \]

\[ V = \sum_j \left( \sum_i b_{ij}^2 \right)^2, \quad Q = \sum_j \sum_i b_{ij}^4 \]

\( k_1, k_2, k_3, \) and \( k_4 \) are constants, and \( b_{ij} \) represents an element of the rotated pattern matrix. Except for specialized research purposes, it is rare in practice to use this simplicity function for rotation. However, it reduces to many well-known classes and special cases of rotations. One of these is the Crawford-Ferguson family (Crawford and Ferguson 1970), which minimizes

\[ f_{cf} = c_1 (H - Q) + c_2 (V - Q) \]

where \( c_1 \) and \( c_2 \) are constants and \( (H - Q) \) represents variable (row) parsimony and \( (V - Q) \) represents factor (column) parsimony. Therefore, the relative importance of both the variable parsimony and of the factor parsimony is adjusted using the constants \( c_1 \) and \( c_2 \). The orthomax class (Carroll, see Harman 1976) maximizes the function

\[ f_{or} = pQ - \gamma V \]

where \( \gamma \) is the orthomax weight and is usually between 0 and the number of variables \( p \). The oblimin class minimizes the function

\[ f_{ob} = p(H - Q) - \tau (Z - V) \]

where \( \tau \) is the oblimin weight. For practical purposes, a negative or zero value for \( \tau \) is recommended.

All the above definitions are for rotations without row normalization. For rotations with Kaiser normalization the definition of \( b_{ij} \) is replaced by \( b_{ij}/h_i \), where \( h_i \) is the communality of variable \( i \).
Missing Values

If the DATA= data set contains data (rather than a matrix or factor pattern), then observations with missing values for any variables in the analysis are omitted from the computations. If a correlation or covariance matrix is read, it can contain missing values as long as every pair of variables has at least one nonmissing entry. Missing values in a pattern or scoring coefficient matrix are treated as zeros.

Cautions

• The amount of time that FACTOR takes is roughly proportional to the cube of the number of variables. Factoring 100 variables, therefore, takes about 1,000 times as long as factoring 10 variables. Iterative methods (PRINIT, ALPHA, ULS, ML) can also take 100 times as long as noniterative methods (PRINCIPAL, IMAGE, HARRIS).
• No computer program is capable of reliably determining the optimal number of factors since the decision is ultimately subjective. You should not blindly accept the number of factors obtained by default; instead, use your own judgment to make a decision.
• Singular correlation matrices cause problems with the options PRIORS=SMC and METHOD=ML. Singularities can result from using a variable that is the sum of other variables, coding too many dummy variables from a classification variable, or having more variables than observations.
• If you use the CORR procedure to compute the correlation matrix and there are missing data and the NOMISS option is not specified, then the correlation matrix may have negative eigenvalues.
• If a TYPE=CORR, TYPE=UCORR, or TYPE=FACTOR data set is copied or modified using a DATA step, the new data set does not automatically have the same TYPE as the old data set. You must specify the TYPE= data set option in the DATA statement. If you try to analyze a data set that has lost its TYPE=CORR attribute, PROC FACTOR displays a warning message saying that the data set contains _NAME_ and _TYPE_ variables but analyzes the data set as an ordinary SAS data set.
• For a TYPE=FACTOR data set, the default is METHOD=PATTERN, not METHOD=PRIN.

Factor Scores

The FACTOR procedure can compute estimated factor scores directly if you specify the NFACTORS= and OUT= options, or indirectly using the SCORE procedure. The latter method is preferable if you use the FACTOR procedure interactively to determine the number of factors, the rotation method, or various other aspects of the analysis. To compute factor scores for each observation using the SCORE procedure,

• use the SCORE option in the PROC FACTOR statement
• create a TYPE=FACTOR output data set with the OUTSTAT= option
Variable Weights and Variance Explained

- use the SCORE procedure with both the raw data and the TYPE=FACTOR data set
- do not use the TYPE= option in the PROC SCORE statement

For example, the following statements could be used:

```plaintext
proc factor data=raw score outstat=fact;
run;
proc score data=raw score=fact out=scores;
run;
```

or

```plaintext
proc corr data=raw out=correl;
run;
proc factor data=correl score outstat=fact;
run;
proc score data=raw score=fact out=scores;
run;
```

A component analysis (principal, image, or Harris) produces scores with mean zero and variance one. If you have done a common factor analysis, the true factor scores have mean zero and variance one, but the computed factor scores are only estimates of the true factor scores. These estimates have mean zero but variance equal to the squared multiple correlation of the factor with the variables. The estimated factor scores may have small nonzero correlations even if the true factors are uncorrelated.

Variable Weights and Variance Explained

A principal component analysis of a correlation matrix treats all variables as equally important. A principal component analysis of a covariance matrix gives more weight to variables with larger variances. A principal component analysis of a covariance matrix is equivalent to an analysis of a weighted correlation matrix, where the weight of each variable is equal to its variance. Variables with large weights tend to have larger loadings on the first component and smaller residual correlations than variables with small weights.

You may want to give weights to variables using values other than their variances. Mulaik (1972) explains how to obtain a maximally reliable component by means of a weighted principal component analysis. With the FACTOR procedure, you can indirectly give arbitrary weights to the variables by using the COV option and rescaling the variables to have variance equal to the desired weight, or you can give arbitrary weights directly by using the WEIGHT option and including the weights in a TYPE=CORR data set.

Arbitrary variable weights can be used with the METHOD=PRINCIPAL, METHOD=PRINIT, METHOD=ULS, or METHOD=IMAGE option. Alpha and ML factor analyses compute variable weights based on the communalities (Harman
For alpha factor analysis, the weight of a variable is the reciprocal of its communality. In ML factor analysis, the weight is the reciprocal of the uniqueness. Harris component analysis uses weights equal to the reciprocal of one minus the squared multiple correlation of each variable with the other variables.

For uncorrelated factors, the variance explained by a factor can be computed with or without taking the weights into account. The usual method for computing variance accounted for by a factor is to take the sum of squares of the corresponding column of the factor pattern, yielding an unweighted result. If the square of each loading is multiplied by the weight of the variable before the sum is taken, the result is the weighted variance explained, which is equal to the corresponding eigenvalue except in image analysis. Whether the weighted or unweighted result is more important depends on the purpose of the analysis.

In the case of correlated factors, the variance explained by a factor can be computed with or without taking the other factors into account. If you want to ignore the other factors, the variance explained is given by the weighted or unweighted sum of squares of the appropriate column of the factor structure since the factor structure contains simple correlations. If you want to subtract the variance explained by the other factors from the amount explained by the factor in question (the Type II variance explained), you can take the weighted or unweighted sum of squares of the appropriate column of the reference structure because the reference structure contains semipartial correlations. There are other ways of measuring the variance explained. For example, given a prior ordering of the factors, you can eliminate from each factor the variance explained by previous factors and compute a Type I variance explained. Harman (1976, pp. 268-270) provides another method, which is based on direct and joint contributions.

**Heywood Cases and Other Anomalies**

Since communalties are squared correlations, you would expect them always to lie between 0 and 1. It is a mathematical peculiarity of the common factor model, however, that final communality estimates may exceed 1. If a communality equals 1, the situation is referred to as a Heywood case, and if a communality exceeds 1, it is an ultra-Heywood case. An ultra-Heywood case implies that some unique factor has negative variance, a clear indication that something is wrong. Possible causes include:

- bad prior communality estimates
- too many common factors
- too few common factors
- not enough data to provide stable estimates
- the common factor model is not an appropriate model for the data

An ultra-Heywood case renders a factor solution invalid. Factor analysts disagree about whether or not a factor solution with a Heywood case can be considered legitimate.
Theoretically, the communality of a variable should not exceed its reliability. Violation of this condition is called a quasi-Heywood case and should be regarded with the same suspicion as an ultra-Heywood case.

Elements of the factor structure and reference structure matrices can exceed 1 only in the presence of an ultra-Heywood case. On the other hand, an element of the factor pattern may exceed 1 in an oblique rotation.

The maximum likelihood method is especially susceptible to quasi- or ultra-Heywood cases. During the iteration process, a variable with high communality is given a high weight; this tends to increase its communality, which increases its weight, and so on.

It is often stated that the squared multiple correlation of a variable with the other variables is a lower bound to its communality. This is true if the common factor model fits the data perfectly, but it is not generally the case with real data. A final communality estimate that is less than the squared multiple correlation can, therefore, indicate poor fit, possibly due to not enough factors. It is by no means as serious a problem as an ultra-Heywood case. Factor methods using the Newton-Raphson method can actually produce communalities less than 0, a result even more disastrous than an ultra-Heywood case.

The squared multiple correlation of a factor with the variables may exceed 1, even in the absence of ultra-Heywood cases. This situation is also cause for alarm. Alpha factor analysis seems to be especially prone to this problem, but it does not occur with maximum likelihood. If a squared multiple correlation is negative, there are too many factors retained.

With data that do not fit the common factor model perfectly, you can expect some of the eigenvalues to be negative. If an iterative factor method converges properly, the sum of the eigenvalues corresponding to rejected factors should be 0; hence, some eigenvalues are positive and some negative. If a principal factor analysis fails to yield any negative eigenvalues, the prior communality estimates are probably too large. Negative eigenvalues cause the cumulative proportion of variance explained to exceed 1 for a sufficiently large number of factors. The cumulative proportion of variance explained by the retained factors should be approximately 1 for principal factor analysis and should converge to 1 for iterative methods. Occasionally, a single factor can explain more than 100 percent of the common variance in a principal factor analysis, indicating that the prior communality estimates are too low.

If a squared canonical correlation or a coefficient alpha is negative, there are too many factors retained.

Principal component analysis, unlike common factor analysis, has none of these problems if the covariance or correlation matrix is computed correctly from a data set with no missing values. Various methods for missing value correlation or severe rounding of the correlations can produce negative eigenvalues in principal components.
Chapter 27. The FACTOR Procedure

Time Requirements

\[ n \] = number of observations
\[ v \] = number of variables
\[ f \] = number of factors
\[ i \] = number of iterations during factor extraction
\[ r \] = length of iterations during factor rotation

Each iteration in the PRINIT or ALPHA method requires computation of eigenvalues and \( f \) eigenvectors.

Each iteration in the ML or ULS method requires computation of eigenvalues and \( v - f \) eigenvectors.

The amount of time that PROC FACTOR takes is roughly proportional to the cube of the number of variables. Factoring 100 variables, therefore, takes about 1000 times as long as factoring 10 variables. Iterative methods (PRINIT, ALPHA, ULS, ML) can also take 100 times as long as noniterative methods (PRINCIPAL, IMAGE, HARRIS).

Displayed Output

PROC FACTOR output includes

- Mean and Std Dev (standard deviation) of each variable and the number of observations, if you specify the SIMPLE option
- Correlations, if you specify the CORR option
- Inverse Correlation Matrix, if you specify the ALL option
• Partial Correlations Controlling all other Variables (negative anti-image correlations), if you specify the MSA option. If the data are appropriate for the common factor model, the partial correlations should be small.

• Kaiser's Measure of Sampling Adequacy (Kaiser 1970; Kaiser and Rice 1974; Cerny and Kaiser 1977) both overall and for each variable, if you specify the MSA option. The MSA is a summary of how small the partial correlations are relative to the ordinary correlations. Values greater than 0.8 can be considered good. Values less than 0.5 require remedial action, either by deleting the offending variables or by including other variables related to the offenders.

• Prior Communality Estimates, unless 1.0s are used or unless you specify the METHOD=IMAGE, METHOD=HARRIS, METHOD=PARTNTER, or METHOD=SCORE option

• Squared Multiple Correlations of each variable with all the other variables, if you specify the METHOD=IMAGE or METHOD=HARRIS option

• Image Coefficients, if you specify the METHOD=IMAGE option

• Image Covariance Matrix, if you specify the METHOD=IMAGE option

• Preliminary Eigenvalues based on the prior communalities, if you specify the METHOD=PRINIT, METHOD=ALPHA, METHOD=ML, or METHOD=ULS option. The table produced includes the Total and the Average of the eigenvalues, the Difference between successive eigenvalues, the Proportion of variation represented, and the Cumulative proportion of variation.

• the number of factors that are retained, unless you specify the METHOD=PARTNTER or METHOD=SCORE option

• the Scree Plot of Eigenvalues, if you specify the SCREE option. The preliminary eigenvalues are used if you specify the METHOD=PRINIT, METHOD=ALPHA, METHOD=ML, or METHOD=ULS option.

• the iteration history, if you specify the METHOD=PRINIT, METHOD=ALPHA, METHOD=ML, or METHOD=ULS option. The table produced contains the iteration number (Iter); the Criterion being optimized (Jöreskog 1977); the Ridge value for the iteration if you specify the METHOD=ML or METHOD=ULS option; the maximum Change in any communality estimate; and the Communalities.

• Significance tests, if you specify the option METHOD=ML, including Bartlett's Chi-square, df, and Prob > χ² for H₀: No common factors and H₀: factors retained are sufficient to explain the correlations. The variables should have an approximate multivariate normal distribution for the probability levels to be valid. Lawley and Maxwell (1971) suggest that the number of observations should exceed the number of variables by fifty or more, although Geweke and Singleton (1980) claim that as few as ten observations are adequate with five variables and one common factor. Certain regularity conditions must also be satisfied for Bartlett’s χ² test to be valid (Geweke and Singleton 1980), but in practice these conditions usually are satisfied. The notation Prob>chi**2 means “the probability under the null hypothesis of
obtaining a greater $\chi^2$ statistic than that observed.” The Chi-square value is displayed with and without Bartlett’s correction.

- Akaike’s Information Criterion, if you specify the METHOD=ML option. Akaike’s information criterion (AIC) (Akaike 1973, 1974, 1987) is a general criterion for estimating the best number of parameters to include in a model when maximum likelihood estimation is used. The number of factors that yields the smallest value of AIC is considered best. Like the chi-square test, AIC tends to include factors that are statistically significant but inconsequential for practical purposes.

- Schwarz’s Bayesian Criterion, if you specify the METHOD=ML option. Schwarz’s Bayesian Criterion (SBC) (Schwarz 1978) is another criterion, similar to AIC, for determining the best number of parameters. The number of factors that yields the smallest value of SBC is considered best; SBC seems to be less inclined to include trivial factors than either AIC or the chi-square test.

- Tucker and Lewis’s Reliability Coefficient, if you specify the METHOD=ML option (Tucker and Lewis 1973)

- Squared Canonical Correlations, if you specify the METHOD=ML option. These are the same as the squared multiple correlations for predicting each factor from the variables.

- Coefficient Alpha for Each Factor, if you specify the METHOD=ALPHA option

- Eigenvectors, if you specify the EIGENVECTORS or ALL option, unless you also specify the METHOD=PATTERN or METHOD=SCORE option

- Eigenvalues of the (Weighted) (Reduced) (Image) Correlation or Covariance Matrix, unless you specify the METHOD=PATTERN or METHOD=SCORE option. Included are the Total and the Average of the eigenvalues, the Difference between successive eigenvalues, the Proportion of variation represented, and the Cumulative proportion of variation.

- the Factor Pattern, which is equal to both the matrix of standardized regression coefficients for predicting variables from common factors and the matrix of correlations between variables and common factors since the extracted factors are uncorrelated. Standard error estimates are included if the SE option is specified with METHOD=ML. Confidence limits and coverage displays are included if COVER= option is specified with METHOD=ML.

- Variance explained by each factor, both Weighted and Unweighted, if variable weights are used

- Final Communality Estimates, including the Total communality; or Final Communality Estimates and Variable Weights, including the Total communality, both Weighted and Unweighted, if variable weights are used. Final communality estimates are the squared multiple correlations for predicting the variables from the estimated factors, and they can be obtained by taking the sum of squares of each row of the factor pattern, or a weighted sum of squares if variable weights are used.

- Residual Correlations with Uniqueness on the Diagonal, if you specify the RESIDUAL or ALL option
• Root Mean Square Off-diagonal Residuals, both Over-all and for each variable, if you specify the RESIDUAL or ALL option
• Partial Correlations Controlling Factors, if you specify the RESIDUAL or ALL option
• Root Mean Square Off-diagonal Partials, both Over-all and for each variable, if you specify the RESIDUAL or ALL option
• Plots of Factor Pattern for unrotated factors, if you specify the PREPLOT option. The number of plots is determined by the NPLOT= option.
• Variable Weights for Rotation, if you specify the NORM=WEIGHT option
• Factor Weights for Rotation, if you specify the HKPOWER= option
• Orthogonal Transformation Matrix, if you request an orthogonal rotation
• Rotated Factor Pattern, if you request an orthogonal rotation. Standard error estimates are included if the SE option is specified with METHOD=ML. Confidence limits and coverage displays are included if COVER= option is specified with METHOD=ML.
• Variance explained by each factor after rotation. If you request an orthogonal rotation and if variable weights are used, both weighted and unweighted values are produced.
• Target Matrix for Procrustean Transformation, if you specify the ROTATE=PROMAX or ROTATE=PROCRUSTES option
• the Procrustean Transformation Matrix, if you specify the ROTATE=PROMAX or ROTATE=PROCRUSTES option
• the Normalized Oblique Transformation Matrix, if you request an oblique rotation, which, for the option ROTATE=PROMAX, is the product of the prerotation and the Procrustean rotation
• Inter-factor Correlations, if you specify an oblique rotation. Standard error estimates are included if the SE option is specified with METHOD=ML. Confidence limits and coverage displays are included if COVER= option is specified with METHOD=ML.
• Rotated Factor Pattern (Std Reg Coefs), if you specify an oblique rotation, giving standardized regression coefficients for predicting the variables from the factors. Standard error estimates are included if the SE option is specified with METHOD=ML. Confidence limits and coverage displays are included if COVER= option is specified with METHOD=ML.
• Reference Axis Correlations if you specify an oblique rotation. These are the partial correlations between the primary factors when all factors other than the two being correlated are partialed out.
• Reference Structure (Semipartial Correlations), if you request an oblique rotation. The reference structure is the matrix of semipartial correlations (Kerlinger and Pedhazur 1973) between variables and common factors, removing from each common factor the effects of other common factors. If the common factors are uncorrelated, the reference structure is equal to the factor pattern.
• Variance explained by each factor eliminating the effects of all other factors, if you specify an oblique rotation. Both Weighted and Unweighted values are produced if variable weights are used. These variances are equal to the (weighted) sum of the squared elements of the reference structure corresponding to each factor.

• Factor Structure (Correlations), if you request an oblique rotation. The (primary) factor structure is the matrix of correlations between variables and common factors. If the common factors are uncorrelated, the factor structure is equal to the factor pattern. Standard error estimates are included if the SE option is specified with METHOD=ML. Confidence limits and coverage displays are included if COVER= option is specified with METHOD=ML.

• Variance explained by each factor ignoring the effects of all other factors, if you request an oblique rotation. Both Weighted and Unweighted values are produced if variable weights are used. These variances are equal to the (weighted) sum of the squared elements of the factor structure corresponding to each factor.

• Final Communality Estimates for the rotated factors if you specify the ROTATE= option. The estimates should equal the unrotated communalities.

• Squared Multiple Correlations of the Variables with Each Factor, if you specify the SCORE or ALL option, except for unrotated principal components.

• Standardized Scoring Coefficients, if you specify the SCORE or ALL option.

• Plots of the Factor Pattern for rotated factors, if you specify the PLOT option and you request an orthogonal rotation. The number of plots is determined by the NPLOT= option.

• Plots of the Reference Structure for rotated factors, if you specify the PLOT option and you request an oblique rotation. The number of plots is determined by the NPLOT= option. Included are the Reference Axis Correlation and the Angle between the Reference Axes for each pair of factors plotted.

If you specify the ROTATE=PROMAX option, the output includes results for both the prerotation and the Procrustean rotation.

**ODS Table Names**

PROC FACTOR assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Examples

Example 27.1. Principal Component Analysis

The following example analyzes socioeconomic data provided by Harman (1976). The five variables represent total population, median school years, total employment, miscellaneous professional services, and median house value. Each observation represents one of twelve census tracts in the Los Angeles Standard Metropolitan Statistical Area.

The first analysis is a principal component analysis. Simple descriptive statistics and correlations are also displayed. This example produces Output 27.1.1:

data SocioEconomics;
  title 'Five Socioeconomic Variables';
  title2 'See Page 14 of Harman: Modern Factor Analysis, 3rd Ed';
  input Population School Employment Services HouseValue;
datalines;
  5700  12.8  2500   270   25000
  1000  10.9   600    10    10000
  3400   8.8  1000    10     9000
  3800  13.6  1700   140   25000
  4000  12.8  1600   140   25000
  8200   8.3  2600    60    12000
  1200  11.4   400    10    16000
  9100  11.5  3300    60    14000
proc factor data=SocioEconomics simple corr;
   title3 'Principal Component Analysis';
run;

There are two large eigenvalues, 2.8733 and 1.7967, which together account for 93.4% of the standardized variance. Thus, the first two principal components provide an adequate summary of the data for most purposes. Three components, explaining 97.7% of the variation, should be sufficient for almost any application. PROC FACTOR retains two components on the basis of the eigenvalues-greater-than-one rule since the third eigenvalue is only 0.2148.

The first component has large positive loadings for all five variables. The correlation with Services (0.93239) is especially high. The second component is a contrast of Population (0.80642) and Employment (0.72605) against School (−0.54476) and HouseValue (−0.55818), with a very small loading on Services (−0.10431).

The final communality estimates show that all the variables are well accounted for by two components, with final communality estimates ranging from 0.880236 for Services to 0.987826 for Population.

Output 27.1.1. Principal Component Analysis

Example 27.2. Principal Factor Analysis

The following example uses the data presented in Example 27.1, and performs a principal factor analysis with squared multiple correlations for the prior communality estimates (PRIORS=SMC).

To help determine if the common factor model is appropriate, Kaiser’s measure of sampling adequacy (MSA) is requested, and the residual correlations and partial correlations are computed (RESIDUAL). To help determine the number of factors, a scree plot (SCREE) of the eigenvalues is displayed, and the PREPLOT option plots the unrotated factor pattern.

The ROTATE= and REORDER options are specified to enhance factor interpretability. The ROTATE=PROMAX option produces an orthogonal varimax prerotation (default) followed by an oblique Procrustean rotation, and the REORDER option re-
Example 27.2. Principal Factor Analysis

orders the variables according to their largest factor loadings. An OUTSTAT= data set is created by PROC FACTOR and displayed in Output 27.2.16.

```
proc factor data=SocioEconomics
   priors=smc msa scree residual preplot
   rotate=promax reorder plot
   outstat=fact_all;
   title3 'Principal Factor Analysis with Promax Rotation';
run;

proc print;
   title3 'Factor Output Data Set';
run;
```

</tbody>
</table>

Output 27.2.1 displays the results of the principal factor extraction.

If the data are appropriate for the common factor model, the partial correlations controlling the other variables should be small compared to the original correlations. The partial correlation between the variables School and HouseValue, for example, is 0.65, slightly less than the original correlation of 0.86. The partial correlation between Population and School is -0.54, which is much larger in absolute value than the original correlation; this is an indication of trouble. Kaiser’s MSA is a summary, for each variable and for all variables together, of how much smaller the partial correlations are than the original correlations. Values of 0.8 or 0.9 are considered good, while MSAs below 0.5 are unacceptable. The variables Population, School, and Employment have very poor MSAs. Only the Services variable has a good MSA. The overall MSA of 0.58 is sufficiently poor that additional variables should be included in the analysis to better define the common factors. A commonly used rule is that there should be at least three variables per factor. In the following analysis, there seems to be two common factors in these data, so more variables are needed for a reliable analysis.

The SMCs are all fairly large; hence, the factor loadings do not differ greatly from the principal component analysis.

The eigenvalues show clearly that two common factors are present. The first two largest positive eigenvalues account for 101.31% of the common variance. This is possible because the reduced correlation matrix, in general, needs not be positive definite, and negative eigenvalues for the matrix are possible. The scree plot displays a sharp bend at the third eigenvalue, reinforcing the preceding conclusion.

<td>0.88494998</td>
</tr>
</tbody>
</table>

As displayed in Output 27.2.3, the principal factor pattern is similar to the principal component pattern seen in Example 27.1. For example, the variable Services has the largest loading on the first factor, and the Population variable has the smallest. The variables Population and Employment have large positive loadings on the second factor, and the HouseValue and School variables have large negative loadings.

The final community estimates are all fairly close to the priors. Only the community for the variable HouseValue increased appreciably, from 0.847019 to 0.884950. Nearly 100% of the common variance is accounted for. The residual correlations (off-diagonal elements) are low, the largest being 0.03 (Output 27.2.4). The partial correlations are not quite as impressive, since the uniqueness values are also rather small. These results indicate that the SMCs are good but not quite optimal community estimates.

Output 27.2.15. Promax Rotated Factor Pattern Plot

Principal Factor Analysis with Promax Rotation

Rotation Method: Promax (power = 3)

Plot of Reference Structure for Factor1 and Factor2
Reference Axis Correlation = -0.2019  Angle = 101.6471

The oblique promax rotation (Output 27.2.10 through Output 27.2.15) places an axis through the variables Population and Employment but misses the HouseValue and School variables. Since an independent-cluster solution would be possible if it were not for the variable Services, a Harris-Kaiser rotation weighted by the Cureton-Mulaik technique should be used.

The output data set displayed in Output 27.2.16 can be used for Harris-Kaiser rotation by deleting observations with _TYPE_='PATTERN' and _TYPE_='FCORR', which are for the promax-rotated factors, and changing _TYPE_='UNROTATE' to _TYPE_='PATTERN'. In this way, the initial orthogonal factor pattern matrix is saved in the observations with _TYPE_='PATTERN'. The following factor analysis will then read in the factor pattern in the fact2 data set as an initial factor solution, which will then be rotated by the Harris-Kaiser rotation with Cureton-Mulaik weights.
The following statements produce Output 27.2.17:

```sas
data fact2(type=factor);
  set fact_all;
  if _TYPE_ in('PATTERN', 'FCORR') then delete;
  if _TYPE_='UNROTATE' then _TYPE_='PATTERN';

proc factor rotate=hk norm=weight reorder plot;
  title3 'Harris-Kaiser Rotation with Cureton-Mulaik Weights';
run;
```

The results of the Harris-Kaiser rotation are displayed in Output 27.2.17:

In the results of the Harris-Kaiser rotation, the variable Services receives a small weight, and the axes are placed as desired.
Example 27.3. Maximum Likelihood Factor Analysis

This example uses maximum likelihood factor analyses for one, two, and three factors. It is already apparent from the principal factor analysis that the best number of common factors is almost certainly two. The one- and three-factor ML solutions reinforce this conclusion and illustrate some of the numerical problems that can occur. The following statements produce Output 27.3.1:

```
proc factor data=SocioEconomics method=ml heywood n=1;
  title3 'Maximum Likelihood Factor Analysis with One Factor';
run;

proc factor data=SocioEconomics method=ml heywood n=2;
  title3 'Maximum Likelihood Factor Analysis with Two Factors';
run;

proc factor data=SocioEconomics method=ml heywood n=3;
  title3 'Maximum Likelihood Factor Analysis with Three Factors';
run;
```

Output 27.3.1 displays the results of the analysis with one factor. The solution on the second iteration is so close to the optimum that PROC FACTOR cannot find a better solution, hence you receive this message:

Convergence criterion satisfied.

When this message appears, you should try rerunning PROC FACTOR with different prior communality estimates to make sure that the solution is correct. In this case, other prior estimates lead to the same solution or possibly to worse local optima, as indicated by the information criteria or the Chi-square values.

The variable Employment has a communality of 1.0 and, therefore, an infinite weight that is displayed next to the final communality estimate as a missing/infinite value. The first eigenvalue is also infinite. Infinite values are ignored in computing the total of the eigenvalues and the total final communality.

The three-factor analysis displayed in Output 27.3.3 generates this message:

**WARNING:** Too many factors for a unique solution.

The number of parameters in the model exceeds the number of elements in the correlation matrix from which they can be estimated, so an infinite number of different perfect solutions can be obtained. The Criterion approaches zero at an improper optimum, as indicated by this message:

**Converged, but not to a proper optimum.**

The degrees of freedom for the chi-square test are $-2$, so a probability level cannot be computed for three factors. Note also that the variable Employment is a Heywood case again.

The probability levels for the chi-square test are 0.0001 for the hypothesis of no common factors, 0.0002 for one common factor, and 0.1382 for two common factors. Therefore, the two-factor model seems to be an adequate representation. Akaike’s
information criterion and Schwarz’s Bayesian criterion attain their minimum values at two common factors, so there is little doubt that two factors are appropriate for these data.

Example 27.4. Using Confidence Intervals to Locate Salient Factor Loadings

This example illustrates how you can utilize the standard errors and confidence intervals to understand the pattern of factor loadings under the maximum likelihood estimation. There are nine tests and you want a three-factor solution for a correlation matrix based on 200 observations. You apply quartimin rotation with (default) Kaiser normalization. You define loadings with magnitudes greater than 0.45 to be salient and use 90% confidence intervals to judge the salience.

```
 data test(type=corr);
   title 'Quartimin-Rotated Factor Solution with Standard Errors';
   input _name_ $ test1-test9;
   _type_ = 'corr';
   datalines;
 Test1 1 .561 .602 .290 .404 .328 .367 .179 -.268
 Test2 .561 1 .743 .414 .526 .442 .523 .289 -.399
 Test3 .602 .743 1 .286 .343 .361 .679 .456 -.532
 Test4 .290 .414 .286 1 .677 .446 .412 .400 -.491
 Test5 .404 .526 .343 .677 1 .584 .408 .299 -.466
 Test6 .328 .442 .361 .446 .584 1 .333 .178 -.306
 Test7 .367 .523 .679 .412 .408 .333 1 .711 -.760
 Test8 .179 .289 .456 .400 .299 .178 .711 1 -.725
 Test9 -.268 -.399 -.532 -.491 -.466 -.306 -.760 -.725 1
 ;

 proc factor data=test method=ml reorder rotate=quartimin
   nobis=200 n=3 se cover=.45 alpha=.1;
   title2 'A nine-variable-three-factor example';
 run;
```
After the quartimin rotation, the correlation matrix for factors is shown in **Output 27.4.1.** The factors are medium to highly correlated. The confidence intervals seem to be very wide, suggesting that the estimation of factor correlations may not be very accurate for this sample size. For example, the 90% confidence interval for the correlation between **Factor1** and **Factor2** is (0.30, 0.51), a range of 0.21. You may need a larger sample to get a narrower interval, or a better estimation.

</table>
The coverage displays in Output 27.4.2 show that Test8, Test7, and Test9 have salient relationships with Factor1. The coverage displays are either ‘0*[ ]’ or ‘[ ]*0’, indicating that the entire 90% confidence intervals for the corresponding loadings are beyond the salience value at 0.45. On the other hand, the coverage display for Test3 on Factor1 is ‘0[ ]*’. This indicates that even though the loading estimate is significantly larger than zero, it is not large enough to be salient. Similarly, Test3, Test2, and Test1 have salient relationships with Factor2, while Test5 and Test4 have salient relationships with Factor3. For Test6, its relationship with Factor3 is a little bit ambiguous; the 90% confidence interval covers approximately values between 0.40 and 0.64. This means that the population value might have been smaller or larger than 0.45. It is marginal evidence for a salient relationship.

</table>
For oblique factor solutions, some researchers prefer to examine the factor structure loadings, which represent correlations, for determining salient relationships. In Output 27.4.3, the factor structure loadings and the associated standard error estimates and coverage displays are shown. The interpretations based on the factor structure matrix do not change much except for Test3 and Test9. Test9 now has a salient correlation with Factor3. For Test3, it has salient correlations with both Factor1 and Factor2. Fortunately, there are still tests that only have salient correlations with either Factor1 or Factor2 (but not both). This would make interpretations of factors less problematic.

Chapter 28
The FASTCLUS Procedure

Overview

The FASTCLUS procedure performs a disjoint cluster analysis on the basis of distances computed from one or more quantitative variables. The observations are divided into clusters such that every observation belongs to one and only one cluster; the clusters do not form a tree structure as they do in the CLUSTER procedure. If you want separate analyses for different numbers of clusters, you can run PROC FASTCLUS once for each analysis. Alternatively, to do hierarchical clustering on a large data set, use PROC FASTCLUS to find initial clusters, then use those initial clusters as input to PROC CLUSTER.

By default, the FASTCLUS procedure uses Euclidean distances, so the cluster centers are based on least-squares estimation. This kind of clustering method is often called a k-means model, since the cluster centers are the means of the observations assigned to each cluster when the algorithm is run to complete convergence. Each iteration reduces the least-squares criterion until convergence is achieved.

Often there is no need to run the FASTCLUS procedure to convergence. PROC FASTCLUS is designed to find good clusters (but not necessarily the best possible clusters) with only two or three passes over the data set. The initialization method of PROC FASTCLUS guarantees that, if there exist clusters such that all distances between observations in the same cluster are less than all distances between observations in different clusters, and if you tell PROC FASTCLUS the correct number of clusters to find, it can always find such a clustering without iterating. Even with clusters that are not as well separated, PROC FASTCLUS usually finds initial seeds that are sufficiently good so that few iterations are required. Hence, by default, PROC FASTCLUS performs only one iteration.

The initialization method used by the FASTCLUS procedure makes it sensitive to outliers. PROC FASTCLUS can be an effective procedure for detecting outliers because outliers often appear as clusters with only one member.

The FASTCLUS procedure can use an $L_p$ (least $p$th powers) clustering criterion (Spath 1985, pp. 62–63) instead of the least-squares ($L_2$) criterion used in $k$-means clustering methods. The LEAST=p option specifies the power $p$ to be used. Using the LEAST=p option increases execution time since more iterations are usually required, and the default iteration limit is increased when you specify LEAST=p. Values of $p$ less than 2 reduce the effect of outliers on the cluster centers compared with least-squares methods; values of $p$ greater than 2 increase the effect of outliers.

The FASTCLUS procedure is intended for use with large data sets, with 100 or more observations. With small data sets, the results may be highly sensitive to the order of the observations in the data set.
PROC FASTCLUS produces brief summaries of the clusters it finds. For more extensive examination of the clusters, you can request an output data set containing a cluster membership variable.

**Background**

The FASTCLUS procedure combines an effective method for finding initial clusters with a standard iterative algorithm for minimizing the sum of squared distances from the cluster means. The result is an efficient procedure for disjoint clustering of large data sets. PROC FASTCLUS was directly inspired by Hartigan’s (1975) *leader algorithm* and MacQueen’s (1967) *k-means algorithm*. PROC FASTCLUS uses a method that Anderberg (1973) calls *nearest centroid sorting*. A set of points called *cluster seeds* is selected as a first guess of the means of the clusters. Each observation is assigned to the nearest seed to form temporary clusters. The seeds are then replaced by the means of the temporary clusters, and the process is repeated until no further changes occur in the clusters. Similar techniques are described in most references on clustering (Anderberg 1973; Hartigan 1975; Everitt 1980; Spath 1980).

The FASTCLUS procedure differs from other nearest centroid sorting methods in the way the initial cluster seeds are selected. The importance of initial seed selection is demonstrated by Milligan (1980).

The clustering is done on the basis of Euclidean distances computed from one or more numeric variables. If there are missing values, PROC FASTCLUS computes an adjusted distance using the nonmissing values. Observations that are very close to each other are usually assigned to the same cluster, while observations that are far apart are in different clusters.

The FASTCLUS procedure operates in four steps:

1. Observations called *cluster seeds* are selected.
2. If you specify the DRIFT option, temporary clusters are formed by assigning each observation to the cluster with the nearest seed. Each time an observation is assigned, the cluster seed is updated as the current mean of the cluster. This method is sometimes called *incremental*, *on-line*, or *adaptive* training.
3. If the maximum number of iterations is greater than zero, clusters are formed by assigning each observation to the nearest seed. After all observations are assigned, the cluster seeds are replaced by either the cluster means or other location estimates (cluster centers) appropriate to the LEAST=p option. This step can be repeated until the changes in the cluster seeds become small or zero (MAXITER=n ≥ 1).
4. Final clusters are formed by assigning each observation to the nearest seed.

If PROC FASTCLUS runs to complete convergence, the final cluster seeds will equal the cluster means or cluster centers. If PROC FASTCLUS terminates before complete convergence, which often happens with the default settings, the final cluster seeds may not equal the cluster means or cluster centers. If you want complete convergence, specify CONVERGE=0 and a large value for the MAXITER= option.
The initial cluster seeds must be observations with no missing values. You can specify the maximum number of seeds (and, hence, clusters) using the MAXCLUSTERS= option. You can also specify a minimum distance by which the seeds must be separated using the RADIUS= option.

PROC FASTCLUS always selects the first complete (no missing values) observation as the first seed. The next complete observation that is separated from the first seed by at least the distance specified in the RADIUS= option becomes the second seed. Later observations are selected as new seeds if they are separated from all previous seeds by at least the radius, as long as the maximum number of seeds is not exceeded.

If an observation is complete but fails to qualify as a new seed, PROC FASTCLUS considers using it to replace one of the old seeds. Two tests are made to see if the observation can qualify as a new seed.

First, an old seed is replaced if the distance between the observation and the closest seed is greater than the minimum distance between seeds. The seed that is replaced is selected from the two seeds that are closest to each other. The seed that is replaced is the one of these two with the shortest distance to the closest of the remaining seeds when the other seed is replaced by the current observation.

If the observation fails the first test for seed replacement, a second test is made. The observation replaces the nearest seed if the smallest distance from the observation to all seeds other than the nearest one is greater than the shortest distance from the nearest seed to all other seeds. If the observation fails this test, PROC FASTCLUS goes on to the next observation.

You can specify the REPLACE= option to limit seed replacement. You can omit the second test for seed replacement (REPLACE=PART), causing PROC FASTCLUS to run faster, but the seeds selected may not be as widely separated as those obtained by the default method. You can also suppress seed replacement entirely by specifying REPLACE=NONE. In this case, PROC FASTCLUS runs much faster, but you must choose a good value for the RADIUS= option in order to get good clusters. This method is similar to Hartigan’s (1975, pp. 74–78) leader algorithm and the simple cluster seeking algorithm described by Tou and Gonzalez (1974, pp. 90–92).

The following example demonstrates how to use the FASTCLUS procedure to compute disjoint clusters of observations in a SAS data set.

The data in this example are measurements taken on 159 freshwater fish caught from the same lake (Laengelmavesi) near Tampere in Finland. This data set is available from the Data Archive of the Journal of Statistics Education. The complete data set is displayed in Chapter 67, “The STEPDISC Procedure.”

The species (bream, parkki, pike, perch, roach, smelt, and whitefish), weight, three different length measurements (measured from the nose of the fish to the beginning of its tail, the notch of its tail, and the end of its tail), height, and width of each fish are tallied. The height and width are recorded as percentages of the third length variable.
Suppose that you want to group empirically the fish measurements into clusters and that you want to associate the clusters with the species. You can use the FASTCLUS procedure to perform a cluster analysis.

The following DATA step creates the SAS data set Fish.

```sas
proc format;
  value specfmt
    1='Bream'
    2='Roach'
    3='Whitefish'
    4='Parkki'
    5='Perch'
    6='Pike'
    7='Smelt';
data Fish (drop=HtPct WidthPct);
  title 'Fish Measurement Data';
  input Species Weight Length1 Length2 Length3 HtPct WidthPct @@;
  if Weight <=0 or Weight = . then delete;
  Weight3=Weight**(1/3);
  Height=HtPct*Length3/(Weight3*100);
  Width=WidthPct*Length3/(Weight3*100);
  Length1=Length1/Weight3;
  Length3=Length3/Weight3;
  logLengthRatio=log(Length3/Length1);
  format Species specfmt.;
  symbol = put(Species, specfmt2.);
datalines;
  1 242.0 23.2 25.4 30.0 38.4 13.4
  1 290.0 24.0 26.3 31.2 40.0 13.8
  1 340.0 23.9 26.5 31.1 39.8 15.1
  1 363.0 26.3 29.0 33.5 38.0 13.3
  ...
  [155 more records]
;
run;
```

The double trailing at sign (@@) in the INPUT statement specifies that observations are input from each line until all values are read. The variables are rescaled in order to adjust for dimensionality. Because the new variables `Weight3`–`logLengthRatio` depend on the variable `Weight`, observations with missing values for `Weight` are not added to the data set. Consequently, there are 157 observations in the SAS data set `Fish`.

Variables with larger variances exert a larger influence in calculating the clusters. In the `Fish` data set, the variables are not measured in the same units and cannot be assumed to have equal variance. Therefore, it is necessary to standardize the variables before performing the cluster analysis.

The following statements standardize the variables and perform a cluster analysis on the standardized data.
The STANDARD procedure is first used to standardize all the analytical variables to a mean of 0 and standard deviation of 1. The procedure creates the output data set Stand to contain the transformed variables.

The FASTCLUS procedure then uses the data set Stand as input and creates the data set Clust. This output data set contains the original variables and two new variables, Cluster and Distance. The variable Cluster contains the cluster number to which each observation has been assigned. The variable Distance gives the distance from the observation to its cluster seed.

It is usually desirable to try several values of the MAXCLUSTERS= option. A reasonable beginning for this example is to use MAXCLUSTERS=7, since there are seven species of fish represented in the data set Fish.

The VAR statement specifies the variables used in the cluster analysis.

The results from this analysis are displayed in the following figures.

**Figure 28.1.** Initial Seeds Used in the FASTCLUS Procedure

Figure 28.1 displays the table of initial seeds used for each variable and cluster. The first line in the figure displays the option settings for REPLACE, RADIUS, MAXCLUSTERS, and MAXITER. These options, with the exception of MAXCLUSTERS and MAXITER, are set at their respective default values (REPLACE=FULL, RADIUS=0). Both the MAXCLUSTERS= and MAXITER= options are set in the PROC FASTCLUS statement.

Next, PROC FASTCLUS produces a table of summary statistics for the clusters. Figure 28.2 displays the number of observations in the cluster (frequency) and the
root mean square standard deviation. The next two columns display the largest Euclidean distance from the cluster seed to any observation within the cluster and the number of the nearest cluster.

The last column of the table displays the distance between the centroid of the nearest cluster and the centroid of the current cluster. A centroid is the point having coordinates that are the means of all the observations in the cluster.

### Figure 28.2.  Cluster Summary Table from the FASTCLUS Procedure

Figure 28.3 displays the table of statistics for the variables. The table lists for each variable the total standard deviation, the pooled within-cluster standard deviation and the $R^2$ value for predicting the variable from the cluster. The ratio of between-cluster variance to within-cluster variance ($R^2$ to $1 - R^2$) appears in the last column.

### Figure 28.3.  Statistics for Variables Used in the FASTCLUS Procedure

The pseudo $F$ statistic, approximate expected overall $R^2$, and cubic clustering criterion are also displayed.
criterion (CCC) are listed at the bottom of the figure. You can compare values of these statistics by running PROC FASTCLUS with different values for the MAXCLUSTERS= option. The $R^2$ and CCC values are not valid for correlated variables.

Values of the cubic clustering criterion greater than 2 or 3 indicate good clusters. Values between 0 and 2 indicate potential clusters, but they should be taken with caution; large negative values may indicate outliers.

PROC FASTCLUS next produces the within-cluster means and standard deviations of the variables, displayed in Figure 28.4.

**Figure 28.4.** Cluster Means and Standard Deviations from the FASTCLUS Procedure

It is useful to study further the clusters calculated by the FASTCLUS procedure. One method is to look at a frequency tabulation of the clusters with other classification variables. The following statements invoke the FREQ procedure to crosstabulate the empirical clusters with the variable `Species`:

```plaintext
proc freq data=Clust;
tables Species*Cluster;
run;
```

These statements produce a frequency table of the variable `Cluster` versus the variable `Species`.

**Figure 28.5** displays the marked division between clusters.

**Figure 28.5.** Frequency Table of Cluster versus Species

For cases in which you have three or more clusters, you can use the CANDISC and GPLOT procedures to obtain a graphical check on the distribution of the clusters. In the following statements, the CANDISC and GPLOT procedures are used to compute canonical variables and plot the clusters.

```plaintext
proc candisc data=Clust out=Can noprint;
  class Cluster;
  var Length1 logLengthRatio Height Width Weight3;
legend1 frame cframe=ligr label=none cborder=black
position=center value=(justify=center);
axis1 label=(angle=90 rotate=0) minor=none;
axis2 minor=none;
```

```plaintext
```
First, the CANDISC procedure is invoked to perform a canonical discriminant analysis using the data set Clust and creating the output SAS data set Can. The NOPRINT option suppresses display of the output. The CLASS statement specifies the variable Cluster to define groups for the analysis. The VAR statement specifies the variables used in the analysis.

Next, the GPLOT procedure plots the two canonical variables from PROC CANDISC, Can1 and Can2. The PLOT statement specifies the variable Cluster as the identification variable.

![Plot of Canonical Variables and Cluster Value](image)
The resulting plot (Figure 28.6) illustrates the spatial separation of the clusters calculated in the FASTCLUS procedure.

**Syntax**

The following statements are available in the FASTCLUS procedure:

```
PROC FASTCLUS MAXCLUSTERS=n | RADIUS=t < options > ;
   VAR variables ;
   ID variable ;
   FREQ variable ;
   WEIGHT variable ;
   BY variables ;
```

Usually you need only the VAR statement in addition to the PROC FASTCLUS statement. The BY, FREQ, ID, VAR, and WEIGHT statements are described in alphabetical order after the PROC FASTCLUS statement.

**PROC FASTCLUS Statement**

```
PROC FASTCLUS MAXCLUSTERS= n | RADIUS=t < options > ;
```

You must specify either the MAXCLUSTERS= or the RADIUS= argument in the PROC FASTCLUS statement.

- **MAXCLUSTERS=n**
  - specifies the maximum number of clusters allowed. If you omit the MAXCLUSTERS= option, a value of 100 is assumed.

- **RADIUS=t**
  - establishes the minimum distance criterion for selecting new seeds. No observation is considered as a new seed unless its minimum distance to previous seeds exceeds the value given by the RADIUS= option. The default value is 0. If you specify the REPLACE=RANDOM option, the RADIUS= option is ignored.

You can specify the following options in the PROC FASTCLUS statement. Table 28.1 summarizes the options.

</tbody>
</table>

The following list provides details on these options. The list is in alphabetical order.

**BINS=n**

specifies the number of bins used in the bin-sort algorithm for computing medians for LEAST=1. By default, PROC FASTCLUS uses from 10 to 100 bins, depending on the amount of memory available. Larger values use more memory and make each iteration somewhat slower, but they may reduce the number of iterations. Smaller values have the opposite effect. The minimum value of \( n \) is 5.
CLUSTER=name
specifies a name for the variable in the OUTSEED= and OUT= data sets that indicates cluster membership. The default name for this variable is CLUSTER.

CONVERGE=c
CONV=c
specifies the convergence criterion. Any nonnegative value is allowed. The default value is 0.0001 for all values of \( p \) if LEAST=\( p \) is explicitly specified; otherwise, the default value is 0.02. Iterations stop when the maximum relative change in the cluster seeds is less than or equal to the convergence criterion and additional conditions on the homotopy parameter, if any, are satisfied (see the HP= option). The relative change in a cluster seed is the distance between the old seed and the new seed divided by a scaling factor. If you do not specify the LEAST= option, the scaling factor is the minimum distance between the initial seeds. If you specify the LEAST= option, the scaling factor is an \( L_1 \) scale estimate and is recomputed on each iteration. Specify the CONVERGE= option only if you specify a MAXITER= value greater than 1.

DATA=SAS-data-set
specifies the input data set containing observations to be clustered. If you omit the DATA= option, the most recently created SAS data set is used. The data must be coordinates, not distances, similarities, or correlations.

DELETE=n
deletes cluster seeds to which \( n \) or fewer observations are assigned. Deletion occurs after processing for the DRIFT option is completed and after each iteration specified by the MAXITER= option. Cluster seeds are not deleted after the final assignment of observations to clusters, so in rare cases a final cluster may not have more than \( n \) members. The DELETE= option is ineffective if you specify MAXITER=0 and do not specify the DRIFT option. By default, no cluster seeds are deleted.

DISTANCE | DIST
computes distances between the cluster means.

DRIFT
executes the second of the four steps described in the section “Background” on page 1380. After initial seed selection, each observation is assigned to the cluster with the nearest seed. After an observation is processed, the seed of the cluster to which it is assigned is recalculated as the mean of the observations currently assigned to the cluster. Thus, the cluster seeds drift about rather than remaining fixed for the duration of the pass.

HC=c
HP=p_1 < p_2>
pertains to the homotopy parameter for LEAST=\( p \), where \( 1 < p < 2 \). You should specify these options only if you encounter convergence problems using the default values.

For \( 1 < p < 2 \), PROC FASTCLUS tries to optimize a perturbed variant of the \( L_p \) clustering criterion (Gonin and Money 1989, pp. 5–6). When the homotopy parameter is 0, the optimization criterion is equivalent to the clustering criterion. For a large homotopy parameter, the optimization criterion approaches the least-squares
criterion and is, therefore, easy to optimize. Beginning with a large homotopy parameter, PROC FASTCLUS gradually decreases it by a factor in the range [0.01,0.5] over the course of the iterations. When both the homotopy parameter and the convergence measure are sufficiently small, the optimization process is declared to have converged.

If the initial homotopy parameter is too large or if it is decreased too slowly, the optimization may require many iterations. If the initial homotopy parameter is too small or if it is decreased too quickly, convergence to a local optimum is likely.

\[ HC=c \]

specifies the criterion for updating the homotopy parameter. The homotopy parameter is updated when the maximum relative change in the cluster seeds is less than or equal to \( c \). The default is the minimum of 0.01 and 100 times the value of the CONVERGE= option.

\[ HP=p_1 \]

specifies \( p_1 \) as the initial value of the homotopy parameter. The default is 0.05 if the modified Ekblom-Newton method is used; otherwise, it is 0.25.

\[ HP=p_1 p_2 \]

also specifies \( p_2 \) as the minimum value for the homotopy parameter, which must be reached for convergence. The default is the minimum of \( p_1 \) and 0.01 times the value of the CONVERGE= option.

**IMPUTE**

requests imputation of missing values after the final assignment of observations to clusters. If an observation has a missing value for a variable used in the cluster analysis, the missing value is replaced by the corresponding value in the cluster seed to which the observation is assigned. If the observation is not assigned to a cluster, missing values are not replaced. If you specify the IMPUTE option, the imputed values are not used in computing cluster statistics.

If you also request an OUT= data set, it contains the imputed values.

**INSTAT=** *SAS-data-set*

reads a SAS data set previously created by the FASTCLUS procedure using the OUTSTAT= option. If you specify the INSTAT= option, no clustering iterations are performed and no output is displayed. Only cluster assignment and imputation are performed as an OUT= data set is created.

**IRLS**

causes PROC FASTCLUS to use an iteratively reweighted least-squares method instead of the modified Ekblom-Newton method. If you specify the IRLS option, you must also specify LEAST=\( p \), where \( 1 < p < 2 \). Use the IRLS option only if you encounter convergence problems with the default method.

**LEAST=** \( p \) | **MAX**

\[ L=p \] | **MAX**

causes PROC FASTCLUS to optimize an \( L_p \) criterion, where \( 1 \leq p \leq \infty \) (Spath 1985, pp. 62–63). Infinity is indicated by LEAST=MAX. The value of this clustering criterion is displayed in the iteration history.
If you do not specify the LEAST= option, PROC FASTCLUS uses the least-squares ($L_2$) criterion. However, the default number of iterations is only 1 if you omit the LEAST= option, so the optimization of the criterion is generally not completed. If you specify the LEAST= option, the maximum number of iterations is increased to allow the optimization process a chance to converge. See the MAXITER= option on page 1393.

Specifying the LEAST= option also changes the default convergence criterion from 0.02 to 0.0001. See the CONVERGE= option on page 1390.

When LEAST=2, PROC FASTCLUS tries to minimize the root mean square difference between the data and the corresponding cluster means.

When LEAST=1, PROC FASTCLUS tries to minimize the mean absolute difference between the data and the corresponding cluster medians.

When LEAST=MAX, PROC FASTCLUS tries to minimize the maximum absolute difference between the data and the corresponding cluster midranges.

For general values of $p$, PROC FASTCLUS tries to minimize the $p$th root of the mean of the $p$th powers of the absolute differences between the data and the corresponding cluster seeds.

The divisor in the clustering criterion is either the number of nonmissing data used in the analysis or, if there is a WEIGHT statement, the sum of the weights corresponding to all the nonmissing data used in the analysis (that is, an observation with $n$ nonmissing data contributes $n$ times the observation weight to the divisor). The divisor is not adjusted for degrees of freedom.

The method for updating cluster seeds during iteration depends on the LEAST= option, as follows (Gonin and Money 1989).

<table>
<thead>
<tr>
<th>$p$</th>
<th>Algorithm for Computing Cluster Seeds</th>
</tr>
</thead>
<tbody>
<tr>
<td>$p = 1$</td>
<td>bin sort for median</td>
</tr>
<tr>
<td>$1 &lt; p &lt; 2$</td>
<td>modified Merle-Spath if you specify IRLS,\n otherwise modified Ekblom-Newton</td>
</tr>
<tr>
<td>$p = 2$</td>
<td>arithmetic mean</td>
</tr>
<tr>
<td>$2 &lt; p &lt; \infty$</td>
<td>Newton</td>
</tr>
<tr>
<td>$p = \infty$</td>
<td>midrange</td>
</tr>
</tbody>
</table>

During the final pass, a modified Merle-Spath step is taken to compute the cluster centers for $1 \leq p < 2$ or $2 < p < \infty$.

If you specify the LEAST=$p$ option with a value other than 2, PROC FASTCLUS computes pooled scale estimates analogous to the root mean square standard deviation but based on $p$th power deviations instead of squared deviations.
The divisors for computing the mean absolute deviation or the root mean $p$th-power absolute deviation are adjusted for degrees of freedom just like the divisors for computing standard deviations. This adjustment can be suppressed by the VARDEF= option.

**LIST**

lists all observations, giving the value of the ID variable (if any), the number of the cluster to which the observation is assigned, and the distance between the observation and the final cluster seed.

**MAXITER=$n$**
specifies the maximum number of iterations for recomputing cluster seeds. When the value of the MAXITER= option is greater than 0, PROC FASTCLUS executes the third of the four steps described in the “Background” section on page 1380. In each iteration, each observation is assigned to the nearest seed, and the seeds are recomputed as the means of the clusters.

The default value of the MAXITER= option depends on the LEAST=$p$ option.

<table>
<thead>
<tr>
<th>LEAST=$p$</th>
<th>MAXITER=</th>

</tr>
<tr>
<td>$1.5 \leq p &lt; 2$</td>
<td>20</td>
</tr>
<tr>
<td>$p = 2$</td>
<td>10</td>
</tr>
<tr>
<td>$2 &lt; p \leq \infty$</td>
<td>20</td>
</tr>
</tbody>
</table>

**MEAN=SAS-data-set**

creates an output data set to contain the cluster means and other statistics for each cluster. If you want to create a permanent SAS data set, you must specify a two-level name. Refer to “SAS Data Files” in *SAS Language Reference: Concepts* for more information on permanent data sets.

**NOMISS**

excludes observations with missing values from the analysis. However, if you also specify the IMPUTE option, observations with missing values are included in the final cluster assignments.
NOPRINT
suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

OUT=SAS-data-set
creates an output data set to contain all the original data, plus the new variables CLUSTER and DISTANCE. Refer to “SAS Data Files” in SAS Language Reference: Concepts for more information on permanent data sets.

OUTITER
outputs information from the iteration history to the OUTSEED= data set, including the cluster seeds at each iteration.

OUTSEED=SAS-data-set
OUTS=SAS-data-set
is another name for the MEAN= data set, provided because the data set may contain location estimates other than means. The MEAN= option is still accepted.

OUTSTAT=SAS-data-set
creates an output data set to contain various statistics, especially those not included in the OUTSEED= data set. Unlike the OUTSEED= data set, the OUTSTAT= data set is not suitable for use as a SEED= data set in a subsequent PROC FASTCLUS step.

RANDOM=n
specifies a positive integer as a starting value for the pseudo-random number generator for use with REPLACE=RANDOM. If you do not specify the RANDOM= option, the time of day is used to initialize the pseudo-random number sequence.

REPLACE=FULL | PART | NONE | RANDOM
specifies how seed replacement is performed.

FULL requests default seed replacement as described in the section “Background” on page 1380.

PART requests seed replacement only when the distance between the observation and the closest seed is greater than the minimum distance between seeds.

NONE suppresses seed replacement.

RANDOM selects a simple pseudo-random sample of complete observations as initial cluster seeds.

SEED=SAS-data-set
specifies an input data set from which initial cluster seeds are to be selected. If you do not specify the SEED= option, initial seeds are selected from the DATA= data set. The SEED= data set must contain the same variables that are used in the data analysis.
SHORT
suppresses the display of the initial cluster seeds, cluster means, and standard deviations.

STRICT
STRICT=s
prevents an observation from being assigned to a cluster if its distance to the nearest cluster seed exceeds the value of the STRICT= option. If you specify the STRICT option without a numeric value, you must also specify the RADIUS= option, and its value is used instead. In the OUT= data set, observations that are not assigned due to the STRICT= option are given a negative cluster number, the absolute value of which indicates the cluster with the nearest seed.

SUMMARY
suppresses the display of the initial cluster seeds, statistics for variables, cluster means, and standard deviations.

VARDEF=DF | N | WDF | WEIGHT | WGT
specifies the divisor to be used in the calculation of variances and covariances. The default value is VARDEF=DF. The possible values of the VARDEF= option and associated divisors are as follows.

<table>
<thead>
<tr>
<th>Value</th>
<th>Description</th>
<th>Divisor</th>
</tr>
</thead>
<tbody>
<tr>
<td>DF</td>
<td>error degrees of freedom</td>
<td>( n - c )</td>
</tr>
<tr>
<td>N</td>
<td>number of observations</td>
<td>( n )</td>
</tr>
<tr>
<td>WDF</td>
<td>sum of weights DF</td>
<td>( \sum w_i - c )</td>
</tr>
<tr>
<td>WEIGHT</td>
<td>sum of weights</td>
<td>( \sum w_i )</td>
</tr>
</tbody>
</table>

In the preceding definitions, \( c \) represents the number of clusters.

**BY Statement**

```plaintext
BY variables;
```

You can specify a BY statement with PROC FASTCLUS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the FASTCLUS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
Create an index on the BY variables using the DATASETS procedure.

If you specify the SEED= option and the SEED= data set does not contain any of the BY variables, then the entire SEED= data set is used to obtain initial cluster seeds for each BY group in the DATA= data set.

If the SEED= data set contains some but not all of the BY variables, or if some BY variables do not have the same type or length in the SEED= data set as in the DATA= data set, then PROC FASTCLUS displays an error message and stops.

If all the BY variables appear in the SEED= data set with the same type and length as in the DATA= data set, then each BY group in the SEED= data set is used to obtain initial cluster seeds for the corresponding BY group in the DATA= data set. All BY groups in the DATA= data set must also appear in the SEED= data set. The BY groups in the SEED= data set must be in the same order as in the DATA= data set. If you specify the NOTSORTED option in the BY statement, there must be exactly the same BY groups in the same order in both data sets. If you do not specify NOTSORTED, some BY groups can appear in the SEED= data set but not in the DATA= data set; such BY groups are not used in the analysis.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

**FREQ Statement**

```
FREQ variable ;
```

If a variable in the data set represents the frequency of occurrence for the other values in the observation, include the variable’s name in a FREQ statement. The procedure then treats the data set as if each observation appears \( n \) times, where \( n \) is the value of the FREQ variable for the observation.

If the value of the FREQ variable is missing or \( \leq 0 \), the observation is not used in the analysis. The exact values of the FREQ variable are used in computations: frequency values are not truncated to integers. The total number of observations is considered to be equal to the sum of the FREQ variable when the procedure determines degrees of freedom for significance probabilities.

The WEIGHT and FREQ statements have a similar effect, except in determining the number of observations for significance tests.

**ID Statement**

```
ID variable ;
```

The ID variable, which can be character or numeric, identifies observations on the output when you specify the LIST option.
Missing Values

VAR Statement

VAR variables ;

The VAR statement lists the numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not listed in other statements are used.

WEIGHT Statement

WEIGHT variable ;

The values of the WEIGHT variable are used to compute weighted cluster means. The WEIGHT and FREQ statements have a similar effect, except the WEIGHT statement does not alter the degrees of freedom or the number of observations. The WEIGHT variable can take nonintegral values. An observation is used in the analysis only if the value of the WEIGHT variable is greater than zero.

Details

Updates in the FASTCLUS Procedure

Some FASTCLUS procedure options and statements have changed from previous versions. The differences are as follows:

- Values of the FREQ variable are no longer truncated to integers. Noninteger variables specified in the FREQ statement produce results different than in previous releases.
- The IMPUTE option produces different cluster standard deviations and related statistics. When you specify the IMPUTE option, imputed values are no longer used in computing cluster statistics. This change causes the cluster standard deviations and other statistics computed from the standard deviations to be different than in previous releases.
- The INSTAT= option reads a SAS data set previously created by the FASTCLUS procedure using the OUTSTAT= option. If you specify the INSTAT= option, no clustering iterations are performed and no output is produced. Only cluster assignment and imputation are performed as an OUT= data set is created.
- The OUTSTAT= data set contains additional information used for imputation. _TYPE_ =SEED corresponds to values that are cluster seeds. Observations previously designated _TYPE_ =’SCALE’ are now _TYPE_ =’DISPERSION’.

Missing Values

Observations with all missing values are excluded from the analysis. If you specify the NOMISS option, observations with any missing values are excluded. Observations with missing values cannot be cluster seeds.
The distance between an observation with missing values and a cluster seed is obtained by computing the squared distance based on the nonmissing values, multiplying by the ratio of the number of variables, \( n \), to the number of variables having nonmissing values, \( m \), and taking the square root:

\[
\sqrt{\left(\frac{n}{m}\right) \sum (x_i - s_i)^2}
\]

where

\[
\begin{align*}
 n & = \text{number of variables} \\
 m & = \text{number of variables with nonmissing values} \\
x_i & = \text{value of the } i\text{th variable for the observation} \\
s_i & = \text{value of the } i\text{th variable for the seed}
\end{align*}
\]

If you specify the LEAST=\( p \) option with a power \( p \) other than 2 (the default), the distance is computed using:

\[
\left(\left(\frac{n}{m}\right) \sum (x_i - s_i)^p\right)^{\frac{1}{p}}
\]

The summation is taken over variables with nonmissing values.

The IMPUTE option fills in missing values in the OUT= output data set.

**Output Data Sets**

**OUT= Data Set**

The OUT= data set contains

- the original variables
- a new variable taking values from 1 to the value specified in the MAXCLUSTERS= option, indicating the cluster to which each observation has been assigned. You can specify the variable name with the CLUSTER= option; the default name is CLUSTER.
- a new variable, DISTANCE, giving the distance from the observation to its cluster seed

If you specify the IMPUTE option, the OUT= data set also contains a new variable, _IMPUTE_, giving the number of imputed values in each observation.
OUTSEED= Data Set

The OUTSEED= data set contains one observation for each cluster. The variables are as follows:

- the BY variables, if any
- a new variable giving the cluster number. You can specify the variable name with the CLUSTER= option. The default name is CLUSTER.
- either the FREQ variable or a new variable called _FREQ_ giving the number of observations in the cluster
- the WEIGHT variable, if any
- a new variable, _RADIUS_, giving the maximum distance between any observation in the cluster and the cluster seed
- a new variable, _GAP_, containing the distance between the current cluster mean and the nearest other cluster mean. The value is the centroid distance given in the output.
- a new variable, _NEAR_, specifying the cluster number of the nearest cluster
- the VAR variables giving the cluster means

If you specify the LEAST=p option with a value other than 2, the _RMSSTD_ variable is replaced by the _SCALE_ variable, which contains the pooled scale estimate analogous to the root mean square standard deviation but based on pth power deviations instead of squared deviations:

LEAST=1 mean absolute deviation
LEAST=p root mean pth-power absolute deviation
LEAST=MAX maximum absolute deviation

If you specify the OUTITER option, there is one set of observations in the OUTSEED= data set for each pass through the data set (that is, one set for initial seeds, one for each iteration, and one for the final clusters). Also, several additional variables appear:

_ITER_ is the iteration number. For the initial seeds, the value is 0. For the final cluster means or centers, the _ITER_ variable is one greater than the last iteration reported in the iteration history.
_CRIT_ is the clustering criterion as described under the LEAST= option.
_CHANGE_ is the maximum over clusters of the relative change in the cluster seed from the previous iteration. The relative change in a cluster seed is the distance between the old seed and the new seed divided by a scaling factor. If you do not specify the LEAST= option, the...
scaling factor is the minimum distance between the initial seeds. If you specify the LEAST= option, the scaling factor is an $L_1$ scale estimate and is recomputed on each iteration.

- _HOMPAR_ is the value of the homotopy parameter. This variable appears only for LEAST=$p$ with $1 < p < 2$.

- _BINSIZ_ is the maximum bin size used for estimating medians. This variable appears only for LEAST=1.

If you specify the OUTITER option, the variables _SCALE_, _RMSSTD_, _RADIUS_, _NEAR_, and _GAP_ have missing values except for the last pass.

You can use the OUTSEED= data set as a SEED= input data set for a subsequent analysis.

**OUTSTAT= Data Set**

The variables in the OUTSTAT= data set are as follows:

- BY variables, if any
- a new character variable, _TYPE_, specifying the type of statistic given by other variables (see Table 28.2 and Table 28.3)
- a new numeric variable giving the cluster number. You can specify the variable name with the CLUSTER= option. The default name is CLUSTER.
- a new numeric variable, _OVER_ALL_, containing statistics that apply over all of the VAR variables
- the VAR variables giving statistics for particular variables

The values of _TYPE_ for all LEAST= options are given in the following table.

**Table 28.2. _TYPE_ Values for all LEAST= Options**

<table>
<thead>
<tr>

**Computational Resources**

Let

\[
\begin{align*}
    n &= \text{number of observations} \\
    v &= \text{number of variables} \\
    c &= \text{number of clusters} \\
    p &= \text{number of passes over the data set}
\end{align*}
\]

**Memory**

The memory required is approximately \( 4(19v + 12cv + 10c + 2 \max(c + 1, v)) \) bytes.

If you request the DISTANCE option, an additional \( 4c(c+1) \) bytes of space is needed.

**Time**

The overall time required by PROC FASTCLUS is roughly proportional to \( nvc \) if \( c \) is small with respect to \( n \).

Initial seed selection requires one pass over the data set. If the observations are in random order, the time required is roughly proportional to

\[
    nvc + ve^2
\]

unless you specify REPLACE=NONE. In that case, a complete pass may not be necessary, and the time is roughly proportional to \( mvc \), where \( c \leq m \leq n \).

The DRIFT option, each iteration, and the final assignment of cluster seeds each require one pass, with time for each pass roughly proportional to \( nvc \).

For greatest efficiency, you should list the variables in the VAR statement in order of decreasing variance.
Before using PROC FASTCLUS, decide whether your variables should be standardized in some way, since variables with large variances tend to have more effect on the resulting clusters than those with small variances. If all variables are measured in the same units, standardization may not be necessary. Otherwise, some form of standardization is strongly recommended. The STANDARD procedure can standardize all variables to mean zero and variance one. The FACTOR or PRINCOMP procedures can compute standardized principal component scores. The ACECLUS procedure can transform the variables according to an estimated within-cluster covariance matrix.

Nonlinear transformations of the variables may change the number of population clusters and should, therefore, be approached with caution. For most applications, the variables should be transformed so that equal differences are of equal practical importance. An interval scale of measurement is required. Ordinal or ranked data are generally not appropriate.

PROC FASTCLUS produces relatively little output. In most cases you should create an output data set and use other procedures such as PRINT, PLOT, CHART, MEANS, DISCRIM, or CANDISC to study the clusters. It is usually desirable to try several values of the MAXCLUSTERS= option. Macros are useful for running PROC FASTCLUS repeatedly with other procedures.

A simple application of PROC FASTCLUS with two variables to examine the 2- and 3-cluster solutions may proceed as follows:

```sas
proc standard mean=0 std=1 out=stan;
  var v1 v2;
run;

proc fastclus data=stan out=clust maxclusters=2;
  var v1 v2;
run;

proc plot;
  plot v2*v1=cluster;
run;

proc fastclus data=stan out=clust maxclusters=3;
  var v1 v2;
run;

proc plot;
  plot v2*v1=cluster;
run;
```

If you have more than two variables, you can use the CANDISC procedure to compute canonical variables for plotting the clusters, for example,

```sas
proc standard mean=0 std=1 out=stan;
  var v1-v10;
```
run;
proc fastclus data=stan out=clust maxclusters=3;
  var v1-v10;
run;

proc candisc out=can;
  var v1-v10;
  class cluster;
run;

proc plot;
  plot can2*can1=cluster;
run;

If the data set is not too large, it may also be helpful to use

 proc sort;
   by cluster distance;
run;
proc print;
   by cluster;
run;

to list the clusters. By examining the values of DISTANCE, you can determine if any observations are unusually far from their cluster seeds.

It is often advisable, especially if the data set is large or contains outliers, to make a preliminary PROC FASTCLUS run with a large number of clusters, perhaps 20 to 100. Use MAXITER=0 and OUTSEED=SAS-data-set. You can save time on subsequent runs by selecting cluster seeds from this output data set using the SEED= option.

You should check the preliminary clusters for outliers, which often appear as clusters with only one member. Use a DATA step to delete outliers from the data set created by the OUTSEED= option before using it as a SEED= data set in later runs. If there are severe outliers, the subsequent PROC FASTCLUS runs should specify the STRICT option to prevent the outliers from distorting the clusters.

You can use the OUTSEED= data set with the PLOT procedure to plot _GAP_ by _FREQ_. An overlay of _RADIUS_ by _FREQ_ provides a baseline against which to compare the values of _GAP_. Outliers appear in the upper left area of the plot, with large values of _GAP_ and small _FREQ_ values. Good clusters appear in the upper right area, with large values of both _GAP_ and _FREQ_. Good potential cluster seeds appear in the lower right, as well as in the upper right, since large _FREQ_ values indicate high density regions. Small _FREQ_ values in the left part of the plot indicate poor cluster seeds because the points are in low density regions. It often helps to remove all clusters with small frequencies even though the clusters may not be remote enough to be considered outliers. Removing points in low density regions improves cluster separation and provides visually sharper cluster outlines in scatter plots.
Unless the SHORT or SUMMARY option is specified, PROC FASTCLUS displays

- Initial Seeds, cluster seeds selected after one pass through the data
- Change in Cluster Seeds for each iteration, if you specify MAXITER=n > 1

If you specify the LEAST=p option, with (1 < p < 2), and you omit the IRLS option, an additional column is displayed in the Iteration History table. The column contains a character to identify the method used in each iteration. PROC FASTCLUS chooses the most efficient method to cluster the data at each iterative step, given the condition of the data. Thus, the method chosen is data dependent. The possible values are described as follows:

<table>
<thead>
<tr>
<th>Value</th>
<th>Method</th>
</tr>
</thead>
<tbody>
<tr>
<td>N</td>
<td>Newton’s Method</td>
</tr>
<tr>
<td>I or L</td>
<td>iteratively weighted least squares (IRLS)</td>
</tr>
<tr>
<td>1</td>
<td>IRLS step, halved once</td>
</tr>
<tr>
<td>2</td>
<td>IRLS step, halved twice</td>
</tr>
<tr>
<td>3</td>
<td>IRLS step, halved three times</td>
</tr>
</tbody>
</table>

PROC FASTCLUS displays a Cluster Summary, giving the following for each cluster:

- Cluster number
- Frequency, the number of observations in the cluster
- Weight, the sum of the weights of the observations in the cluster, if you specify the WEIGHT statement
- RMS Std Deviation, the root mean square across variables of the cluster standard deviations, which is equal to the root mean square distance between observations in the cluster
- Maximum Distance from Seed to Observation, the maximum distance from the cluster seed to any observation in the cluster
- Nearest Cluster, the number of the cluster with mean closest to the mean of the current cluster
- Centroid Distance, the distance between the centroids (means) of the current cluster and the nearest other cluster

A table of statistics for each variable is displayed unless you specify the SUMMARY option. The table contains

- Total STD, the total standard deviation
• Within STD, the pooled within-cluster standard deviation
• R-Squared, the $R^2$ for predicting the variable from the cluster
• $\text{RSQ}/(1 - \text{RSQ})$, the ratio of between-cluster variance to within-cluster variance ($R^2/(1 - R^2)$)
• OVER-ALL, all of the previous quantities pooled across variables

PROC FASTCLUS also displays

• Pseudo $F$ Statistic,

$$\frac{R^2}{c-1} \frac{1-R^2}{n-c}$$

where $R^2$ is the observed overall $R^2$, $c$ is the number of clusters, and $n$ is the number of observations. The pseudo $F$ statistic was suggested by Calinski and Harabasz (1974). Refer to Milligan and Cooper (1985) and Cooper and Milligan (1988) regarding the use of the pseudo $F$ statistic in estimating the number of clusters. See Example 23.2 in Chapter 23, “The CLUSTER Procedure,” for a comparison of pseudo $F$ statistics.

• Observed Overall R-Squared, if you specify the SUMMARY option

• Approximate Expected Overall R-Squared, the approximate expected value of the overall $R^2$ under the uniform null hypothesis assuming that the variables are uncorrelated. The value is missing if the number of clusters is greater than one-fifth the number of observations.

• Cubic Clustering Criterion, computed under the assumption that the variables are uncorrelated. The value is missing if the number of clusters is greater than one-fifth the number of observations.

If you are interested in the approximate expected $R^2$ or the cubic clustering criterion but your variables are correlated, you should cluster principal component scores from the PRINCOMP procedure. Both of these statistics are described by Sarle (1983). The performance of the cubic clustering criterion in estimating the number of clusters is examined by Milligan and Cooper (1985) and Cooper and Milligan (1988).

• Distances Between Cluster Means, if you specify the DISTANCE option

Unless you specify the SHORT or SUMMARY option, PROC FASTCLUS displays

• Cluster Means for each variable
• Cluster Standard Deviations for each variable
PROC FASTCLUS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**Table 28.4. ODS Tables Produced in PROC FASTCLUS**

Chapter 28. The FASTCLUS Procedure

Examples

Example 28.1. Fisher’s Iris Data

The iris data published by Fisher (1936) have been widely used for examples in discriminant analysis and cluster analysis. The sepal length, sepal width, petal length, and petal width are measured in millimeters on fifty iris specimens from each of three species, *Iris setosa*, *I. versicolor*, and *I. virginica*. Mezzich and Solomon (1980) discuss a variety of cluster analyses of the iris data.

In this example, the FASTCLUS procedure is used to find two and, then, three clusters. An output data set is created, and PROC FREQ is invoked to compare the clusters with the species classification. See Output 28.1.1 and Output 28.1.2 for these results. For three clusters, you can use the CANDISC procedure to compute canonical variables for plotting the clusters. See Output 28.1.3 for the results.

Example 28.2. Outliers

The second example involves data artificially generated to contain two clusters and several severe outliers. A preliminary analysis specifies twenty clusters and outputs an OUTSEED= data set to be used for a diagnostic plot. The exact number of initial clusters is not important; similar results could be obtained with ten or fifty initial clusters. Examination of the plot suggests that clusters with more than five (again, the exact number is not important) observations may yield good seeds for the main analysis. A DATA step deletes clusters with five or fewer observations, and the remaining cluster means provide seeds for the next PROC FASTCLUS analysis.

Two clusters are requested; the LEAST= option specifies the mean absolute deviation criterion (LEAST=1). Values of the LEAST= option less than 2 reduce the effect of outliers on cluster centers.

The next analysis also requests two clusters; the STRICT= option is specified to prevent outliers from distorting the results. The STRICT= value is chosen to be close to the _GAP_ and _RADIUS_ values of the larger clusters in the diagnostic plot; the exact value is not critical.

A final PROC FASTCLUS run assigns the outliers to clusters. The results are displayed in Output 28.2.1 through Output 28.2.4.

```/* Create artificial data set with two clusters */
/* and some outliers. */
data x;
```

The FREQ procedure produces one-way to $n$-way frequency and crosstabulation (contingency) tables. For two-way tables, PROC FREQ computes tests and measures of association. For $n$-way tables, PROC FREQ does stratified analysis, computing statistics within, as well as across, strata. Frequencies and statistics can also be output to SAS data sets.

For one-way frequency tables, PROC FREQ can compute statistics to test for equal proportions, specified proportions, or the binomial proportion. For contingency tables, PROC FREQ can compute various statistics to examine the relationships between two classification variables adjusting for any stratification variables. PROC FREQ automatically displays the output in a report and can also save the output in a SAS data set.

For some pairs of variables, you may want to examine the existence or the strength of any association between the variables. To determine if an association exists, chi-square tests are computed. To estimate the strength of an association, PROC FREQ computes measures of association that tend to be close to zero when there is no association and close to the maximum (or minimum) value when there is perfect association. The statistics for contingency tables include:

- chi-square tests and measures
- measures of association
- risks (binomial proportions) and risk differences for $2 \times 2$ tables
- odds ratios and relative risks for $2 \times 2$ tables
- tests for trend
- tests and measures of agreement
- Cochran-Mantel-Haenszel statistics

PROC FREQ computes asymptotic standard errors, confidence intervals, and tests for measures of association and measures of agreement. Exact $p$-values and confidence intervals are available for various test statistics and measures. PROC FREQ also performs stratified analyses that compute statistics within, as well as across, strata for $n$-way tables. The statistics include Cochran-Mantel-Haenszel statistics and measures of agreement.

In choosing measures of association to use in analyzing a two-way table, you should consider the study design (which indicates whether the row and column variables are dependent or independent), the measurement scale of the variables (nominal, ordinal,
or interval), the type of association that each measure is designed to detect, and any assumptions required for valid interpretation of a measure. You should exercise care in selecting measures that are appropriate for your data.

Similar comments apply to the choice and interpretation of the test statistics. For example, the Mantel-Haenszel chi-square statistic requires an ordinal scale for both variables and is designed to detect a linear association. The Pearson chi-square, on the other hand, is appropriate for all variables and can detect any kind of association, but it is less powerful for detecting a linear association because its power is dispersed over a greater number of degrees of freedom (except for $2 \times 2$ tables).

Several SAS procedures produce frequency counts; only PROC FREQ computes chi-square tests for one-way to $n$-way tables and measures of association and agreement for contingency tables. Other procedures to consider for counting are TABULATE, CHART, and UNIVARIATE. When you want to fit models to categorical data, use a procedure such as CATMOD, GENMOD, LOGISTIC, PHREG, or PROBIT.

For more information on selecting the appropriate statistical analyses, refer to Agresti (1996) or Stokes, Davis, and Koch (1995).

**Getting Started**

**Frequency Tables and Statistics**

The FREQ procedure provides easy access to statistics for testing for association in a crosstabulation table.

In this example, high school students applied for courses in a summer enrichment program: these courses included journalism, art history, statistics, graphic arts, and computer programming. The students accepted were randomly assigned to classes with and without internships in local companies. The following table contains counts of the students who enrolled in the summer program by gender and whether they were assigned an internship slot.

**Table 29.1. Summer Enrichment Data**

<table>
<thead>
<tr>
<th>Gender</th>
<th>Internship</th>
<th>Enrollment</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>Yes</td>
</tr>
<tr>
<td>boys</td>
<td>yes</td>
<td>35</td>
</tr>
<tr>
<td>boys</td>
<td>no</td>
<td>14</td>
</tr>
<tr>
<td>girls</td>
<td>yes</td>
<td>32</td>
</tr>
<tr>
<td>girls</td>
<td>no</td>
<td>53</td>
</tr>
</tbody>
</table>

The SAS data set `SummerSchool` is created by inputting the summer enrichment data as cell count data, or providing the frequency count for each combination of variable values. The following DATA step statements create the SAS data set `SummerSchool`. 
The variable Gender takes the values ‘boys’ or ‘girls’, the variable Internship takes the values ‘yes’ and ‘no’, and the variable Enrollment takes the values ‘yes’ and ‘no’. The variable Count contains the number of students corresponding to each combination of data values. The double at sign (@@) indicates that more than one observation is included on a single data line. In this DATA step, two observations are included on each line.

Researchers are interested in whether there is an association between internship status and summer program enrollment. The Pearson chi-square statistic is an appropriate statistic to assess the association in the corresponding $2 \times 2$ table. The following PROC FREQ statements specify this analysis.

You specify the table for which you want to compute statistics with the TABLES statement. You specify the statistics you want to compute with options after a slash (/) in the TABLES statement.

```plaintext
proc freq data=SummerSchool order=data;
    weight count;
    tables Internship*Enrollment / chisq;
run;
```

The ORDER= option controls the order in which variable values are displayed in the rows and columns of the table. By default, the values are arranged according to the alphanumeric order of their unformatted values. If you specify ORDER=DATA, the data are displayed in the same order as they occur in the input data set. Here, since ‘yes’ appears before ‘no’ in the data, ‘yes’ appears first in any table. Other options for controlling order include ORDER=FORMATTED, which orders according to the formatted values, and ORDER=FREQUENCY, which orders by descending frequency count.

In the TABLES statement, Internship*Enrollment specifies a table where the rows are internship status and the columns are program enrollment. The CHISQ option requests chi-square statistics for assessing association between these two variables. Since the input data are in cell count form, the WEIGHT statement is required. The WEIGHT statement names the variable Count, which provides the frequency of each combination of data values.
Figure 29.1 presents the crosstabulation of Internship and Enrollment. In each cell, the values printed under the cell count are the table percentage, row percentage, and column percentage, respectively. For example, in the first cell, 63.21 percent of those offered courses with internships accepted them and 36.79 percent did not.

<table>

**Figure 29.2.** Statistics Produced with the CHISQ Option
Figure 29.2 displays the statistics produced by the CHISQ option. The Pearson chi-square statistic is labeled ‘Chi-Square’ and has a value of 0.8189 with 1 degree of freedom. The associated p-value is 0.3655, which means that there is no significant evidence of an association between internship status and program enrollment. The other chi-square statistics have similar values and are asymptotically equivalent. The other statistics (Phi Coefficient, Contingency Coefficient, and Cramer’s V) are measures of association derived from the Pearson chi-square. For Fisher’s exact test, the two-sided p-value is 0.4122, which also shows no association between internship status and program enrollment.

The analysis, so far, has ignored gender. However, it may be of interest to ask whether program enrollment is associated with internship status after adjusting for gender. You can address this question by doing an analysis of a set of tables, in this case, by analyzing the set consisting of one for boys and one for girls. The Cochran-Mantel-Haenszel statistic is appropriate for this situation: it addresses whether rows and columns are associated after controlling for the stratification variable. In this case, you would be stratifying by gender.

The FREQ statements for this analysis are very similar to those for the first analysis, except that there is a third variable, Gender, in the TABLES statement. When you cross more than two variables, the two rightmost variables construct the rows and columns of the table, respectively, and the leftmost variables determine the stratification.

```sas
proc freq data=SummerSchool;
   weight count;
   tables Gender*Internship*Enrollment / chisq cmh;
run;
```

This execution of PROC FREQ first produces two individual crosstabulation tables of Internship*Enrollment, one for boys and one for girls. Chi-square statistics are produced for each individual table. Figure 29.3 shows the results for boys. Note that the chi-square statistic for boys is significant at the $\alpha = 0.05$ level of significance. Boys offered a course with an internship are more likely to enroll than boys who are not.

If you look at the individual table for girls, displayed in Figure 29.4, you see that there is no evidence of association for girls between internship offers and program enrollment.

Figure 29.4. Crosstabulation Table and Statistics for Girls
These individual table results demonstrate the occasional problems with combining information into one table and not accounting for information in other variables such as Gender. Figure 29.5 contains the CMH results. There are three summary (CMH) statistics; which one you use depends on whether your rows and/or columns have an order in \( r \times c \) tables. However, in the case of \( 2 \times 2 \) tables, ordering does not matter and all three statistics take the same value. The CMH statistic follows the chi-square distribution under the hypothesis of no association, and here, it takes the value 4.0186 with 1 degree of freedom. The associated \( p \)-value is 0.0450, which indicates a significant association at the \( \alpha = 0.05 \) level.

Thus, when you adjust for the effect of gender in these data, there is an association between internship and program enrollment. But, if you ignore gender, no association is found. Note that the CMH option also produces other statistics, including estimates and confidence limits for relative risk and odds ratios for \( 2 \times 2 \) tables and the Breslow-Day Test. These results are not displayed here.

Figure 29.5. Test for the Hypothesis of No Association

Agreement Study Example

Medical researchers are interested in evaluating the efficacy of a new treatment for a skin condition. Dermatologists from participating clinics were trained to conduct the study and to evaluate the condition. After the training, two dermatologists examined patients with the skin condition from a pilot study and rated the same patients. The possible evaluations are terrible, poor, marginal, and clear. Table 29.2 contains the data.
The dermatologists’ evaluations of the patients are contained in the variables `derm1` and `derm2`; the variable `count` is the number of patients given a particular pair of ratings. In order to evaluate the agreement of the diagnoses (a possible contribution to measurement error in the study), the *kappa coefficient* is computed. You specify the AGREE option in the TABLES statement and use the TEST statement to request a test for the null hypothesis that their agreement is purely by chance. You specify the keyword KAPPA to perform this test for the kappa coefficient. The results are shown in Figure 29.6.

```plaintext
data SkinCondition;
  input derm1 $ derm2 $ count;
datalines;
terrible terrible 10
terrible poor 4
terrible marginal 1
terrible clear 0
poor terrible 5
poor poor 10
poor marginal 12
poor clear 2
marginal terrible 2
marginal poor 4
marginal marginal 12
marginal clear 5
clear terrible 0
clear poor 2
clear marginal 6
clear clear 13;

proc freq data=SkinCondition order=data;
  weight count;
  tables derm1*derm2 / agree noprint;
  test kappa;
run;
```
The FREQ Procedure

Statistics for Table of derm1 by derm2

Simple Kappa Coefficient

Kappa 0.3449
ASE 0.0724
95% Lower Conf Limit 0.2030
95% Upper Conf Limit 0.4868

Test of H0: Kappa = 0

ASE under H0 0.0612
Z 5.6366
One-sided Pr > Z <.0001
Two-sided Pr > |Z| <.0001

Sample Size = 88

Figure 29.6. Agreement Study

The kappa coefficient has the value 0.3449, which indicates slight agreement between the dermatologists, and the hypothesis test confirms that you can reject the null hypothesis of no agreement. This conclusion is further supported by the confidence interval of (0.2030, 0.4868), which suggests that the true kappa is greater than zero. The AGREE option also produces Bowker’s test for symmetry and the weighted kappa coefficient, but that output is not shown.

Syntax

The following statements are available in PROC FREQ.

- \texttt{PROC FREQ < options > ;}
  - \texttt{BY variables ;}
  - \texttt{EXACT statistic-options < / computation-options > ;}
  - \texttt{OUTPUT < OUT=SAS-data-set > options ;}
  - \texttt{TABLES requests < / options > ;}
  - \texttt{TEST options ;}
  - \texttt{WEIGHT variable < / option > ;}

The PROC FREQ statement is the only required statement for the FREQ procedure. If you specify the following statements, PROC FREQ produces a one-way frequency table for each variable in the most recently created data set.

- \texttt{proc freq;}
- \texttt{run;}

The rest of this section gives detailed syntax information for the BY, EXACT, OUTPUT, TABLES, TEST, and WEIGHT statements in alphabetical order after the description of the PROC FREQ statement. \texttt{Table 29.3} summarizes the basic functions of each statement.
Table 29.3. Summary of PROC FREQ Statements

</tbody>
</table>

PROC FREQ Statement

PROC FREQ <options>;

The PROC FREQ statement invokes the procedure.

The following table lists the options available in the PROC FREQ statement. Descriptions follow in alphabetical order.

Table 29.4. PROC FREQ Statement Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA=</td>
<td>specifies the input data set.</td>
</tr>
<tr>
<td>COMPRESS</td>
<td>begins the next one-way table on the current page.</td>
</tr>
<tr>
<td>FORMCHAR=</td>
<td>specifies the outline and cell divider characters for the cells of the crosstabulation table.</td>
</tr>
<tr>
<td>NLEVELS</td>
<td>displays the number of levels for all TABLES variables</td>
</tr>
<tr>
<td>NOPRINT</td>
<td>suppresses all displayed output.</td>
</tr>
<tr>
<td>ORDER=</td>
<td>specifies the order for listing variable values.</td>
</tr>
<tr>
<td>PAGE</td>
<td>displays one table per page.</td>
</tr>
</tbody>
</table>

You can specify the following options in the PROC FREQ statement.

COMPRESS

begins display of the next one-way frequency table on the same page as the preceding one-way table if there is enough space to begin the table. By default, the next one-way table begins on the current page only if the entire table fits on that page. The COMPRESS option is not valid with the PAGE option.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC FREQ. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

FORMCHAR(1,2,7) = 'formchar-string'

defines the characters to be used for constructing the outlines and dividers for the cells of contingency tables. The FORMCHAR= option can specify 20 different SAS formatting characters used to display output; however, PROC FREQ uses only the first, second, and seventh formatting characters. Therefore, the proper specification for PROC FREQ is FORMCHAR(1,2,7) = 'formchar-string'. The formchar-string
should be three characters long. The characters are used to denote (1) vertical separator, (2) horizontal separator, and (7) vertical-horizontal intersection. You can use any character in `formchar-string`, including hexadecimal characters. If you use hexadecimal characters, you must put an `x` after the closing quote. For information on which hexadecimal codes to use for which characters, consult the documentation for your hardware.

Specifying all blanks for `formchar-string` produces tables with no outlines or dividers:

```
formchar (1,2,7)='  
```

If you do not specify the FORMCHAR= option, PROC FREQ uses the default

```
formchar (1,2,7)='|+-'
```

Refer to the CALENDAR, PLOT, and TABULATE procedures in the Base SAS 9.1 Procedures Guide for more information on form characters.

Table 29.5. Formatting Characters Used by PROC FREQ

<table>
<thead>
<tr>
<th>Position</th>
<th>Default</th>
<th>Used to Draw</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td></td>
<td>vertical separators</td>
</tr>
<tr>
<td>2</td>
<td>-</td>
<td>horizontal separators</td>
</tr>
<tr>
<td>7</td>
<td>+</td>
<td>intersections of vertical and horizontal separators</td>
</tr>
</tbody>
</table>

NLEVELS

displays the “Number of Variable Levels” table. This table provides the number of levels for each variable named in the TABLES statements. See the section “Number of Variable Levels Table” on page 1517 for more information. PROC FREQ determines the variable levels from the formatted variable values, as described in the section “Grouping with Formats” on page 1465.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”.

Note: A NOPRINT option is also available in the TABLES statement. It suppresses display of the crosstabulation tables but allows display of the requested statistics.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order in which the values of the frequency and crosstabulation table variables are to be reported. The following table shows how PROC FREQ interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>ORDER Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>orders values according to their order in the input data set.</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>orders values by their formatted values. This order is operating-environment dependent. By default, the order is ascending.</td>
</tr>
<tr>
<td>FREQ</td>
<td>orders values by descending frequency count.</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>orders values by their unformatted values, which yields the same order that the SORT procedure does. This order is operating-environment dependent.</td>
</tr>
</tbody>
</table>

By default, ORDER=INTERNAL. The ORDER= option does not apply to missing values, which are always ordered first.
**PAGE**

Displays only one table per page. Otherwise, PROC FREQ displays multiple tables per page as space permits. The PAGE option is not valid with the COMPRESS option.

**BY Statement**

```sql
BY variables ;
```

You can specify a BY statement with PROC FREQ to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the FREQ procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *Base SAS 9.1 Procedures Guide*.

**EXACT Statement**

```sql
EXACT statistic-options < / computation-options > ;
```

The EXACT statement requests exact tests or confidence limits for the specified statistics. Optionally, PROC FREQ computes Monte Carlo estimates of the exact p-values. The `statistic-options` specify the statistics for which to provide exact tests or confidence limits. The `computation-options` specify options for the computation of exact statistics.

**CAUTION:** PROC FREQ computes exact tests with fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests may require a large amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods may not be sufficient for such large problems, consider using Monte Carlo estimation of exact p-values. See the section “Computational Resources” on page 1511 for more information.
Statistic-Options

The statistic-options specify the statistics for which exact tests or confidence limits are computed. PROC FREQ can compute exact \( p \)-values for the following hypothesis tests: chi-square goodness-of-fit test for one-way tables; Pearson chi-square, likelihood-ratio chi-square, Mantel-Haenszel chi-square, Fisher’s exact test, Jonckheere-Terpstra test, Cochran-Armitage test for trend, and McNemar’s test for two-way tables. PROC FREQ can also compute exact \( p \)-values for tests of the following statistics: Pearson correlation coefficient, Spearman correlation coefficient, simple kappa coefficient, weighted kappa coefficient, and common odds ratio. PROC FREQ can compute exact \( p \)-values for the binomial proportion test for one-way tables, as well as exact confidence limits for the binomial proportion. Additionally, PROC FREQ can compute exact confidence limits for the odds ratio for \( 2 \times 2 \) tables, as well as exact confidence limits for the common odds ratio for stratified \( 2 \times 2 \) tables.

Table 29.6 lists the available statistic-options and the exact statistics computed. Most of the option names are identical to the corresponding options in the TABLES statement and the OUTPUT statement. You can request exact computations for groups of statistics by using options that are identical to the following TABLES statement options: CHISQ, MEASURES, and AGREE. For example, when you specify the CHISQ option in the EXACT statement, PROC FREQ computes exact \( p \)-values for the Pearson chi-square, likelihood-ratio chi-square, and Mantel-Haenszel chi-square tests. You request exact \( p \)-values for an individual test by specifying one of the statistic-options shown in Table 29.6.

Table 29.6. EXACT Statement Statistic-Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Exact Statistics Computed</th>
</tr>
</thead>
<tbody>
<tr>
<td>AGREE</td>
<td>McNemar’s test for ( 2 \times 2 ) tables, simple kappa coefficient, and weighted kappa coefficient</td>
</tr>
<tr>
<td>BINOMIAL</td>
<td>binomial proportion test for one-way tables</td>
</tr>
<tr>
<td>CHISQ</td>
<td>chi-square goodness-of-fit test for one-way tables; Pearson chi-square, likelihood-ratio chi-square, and Mantel-Haenszel chi-square tests for two-way tables</td>
</tr>
<tr>
<td>COMOR</td>
<td>confidence limits for the common odds ratio for ( h \times 2 \times 2 ) tables; common odds ratio test</td>
</tr>
<tr>
<td>FISHER</td>
<td>Fisher’s exact test</td>
</tr>
<tr>
<td>JT</td>
<td>Jonckheere-Terpstra test</td>

<td>test for the Spearman correlation coefficient</td>
</tr>
<tr>
<td>TREND</td>
<td>Cochran-Armitage test for trend</td>
</tr>
<tr>
<td>WTKAP</td>
<td>test for the weighted kappa coefficient</td>
</tr>
</tbody>
</table>
**Computation-Options**

The *computation-options* specify options for computation of exact statistics. You can specify the following *computation-options* in the EXACT statement:

- **ALPHA=** \( \alpha \) specifies the level of the confidence limits for Monte Carlo \( p \)-value estimates. The value of the ALPHA= option must be between 0 and 1, and the default is 0.01. A confidence level of \( \alpha \) produces \( 100(1 - \alpha) \)% confidence limits. The default of ALPHA=.01 produces 99% confidence limits for the Monte Carlo estimates. The ALPHA= option invokes the MC option.

- **MAXTIME=** \( \text{value} \) specifies the maximum clock time (in seconds) that PROC FREQ can use to compute an exact \( p \)-value. If the procedure does not complete the computation within the specified time, the computation terminates. The value of the MAXTIME= option must be a positive number. The MAXTIME= option is valid for Monte Carlo estimation of exact \( p \)-values, as well as for direct exact \( p \)-value computation.

See the section “**Computational Resources**” on page 1511 for more information.

- **MC** requests Monte Carlo estimation of exact \( p \)-values instead of direct exact \( p \)-value computation. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations may not be sufficient. See the section “**Monte Carlo Estimation**” on page 1512 for more information.

The MC option is available for all EXACT statistic-options except BINOMIAL, COMOR, MCNEM, and OR. PROC FREQ computes only exact tests or confidence limits for those statistics.

The ALPHA=, N=, and SEED= options also invoke the MC option.

- **N=** \( n \) specifies the number of samples for Monte Carlo estimation. The value of the N= option must be a positive integer, and the default is 10000 samples. Larger values of \( n \) produce more precise estimates of exact \( p \)-values. Because larger values of \( n \) generate more samples, the computation time increases. The N= option invokes the MC option.

- **POINT** requests exact point probabilities for the test statistics.

  The POINT option is available for all the EXACT statement statistic-options except the OR option, which provides exact confidence limits as opposed to an exact test. The POINT option is not available with the MC option.

- **SEED=** \( \text{number} \) specifies the initial seed for random number generation for Monte Carlo estimation. The value of the SEED= option must be an integer. If you do not specify the SEED= option, or if the SEED= value is negative or zero, PROC FREQ uses the time of day from the computer’s clock to obtain the initial seed. The SEED= option invokes the MC option.
Using TABLES Statement Options with the EXACT Statement

If you use only one TABLES statement, you do not need to specify options in the TABLES statement that are identical to options appearing in the EXACT statement. PROC FREQ automatically invokes the corresponding TABLES statement option when you specify the option in the EXACT statement. However, when you use multiple TABLES statements and want exact computations, you must specify options in the TABLES statement to compute the desired statistics. PROC FREQ then performs exact computations for all statistics that are also specified in the EXACT statement.

OUTPUT Statement

```
OUTPUT < OUT= SAS-data-set > options ;
```

The OUTPUT statement creates a SAS data set containing statistics computed by PROC FREQ. The variables contain statistics for each two-way table or stratum, as well as summary statistics across all strata.

Only one OUTPUT statement is allowed for each execution of PROC FREQ. You must specify a TABLES statement with the OUTPUT statement. If you use multiple TABLES statements, the contents of the OUTPUT data set correspond to the last TABLES statement. If you use multiple table requests in a TABLES statement, the contents of the OUTPUT data set correspond to the last table request.

For more information, see the section “Output Data Sets” on page 1514.

Note that you can use the Output Delivery System (ODS) to create a SAS data set from any piece of PROC FREQ output. For more information, see Table 29.11 on page 1525 and Chapter 14, “Using the Output Delivery System.”

You can specify the following options in an OUTPUT statement.

**OUT=SAS-data-set**

names the output data set. If you omit the OUT= option, the data set is named DATA\textit{n}, where \textit{n} is the smallest integer that makes the name unique.

**options**

specify the statistics that you want in the output data set. Available statistics are those produced by PROC FREQ for each one-way or two-way table, as well as the summary statistics across all strata. When you request a statistic, the OUTPUT data set contains that estimate or test statistic plus any associated standard error, confidence limits, \textit{p}-values, and degrees of freedom. You can output statistics by using group options identical to those specified in the TABLES statement: AGREE, ALL, CHISQ, CMH, and MEASURES. Alternatively, you can request an individual statistic by specifying one of the options shown in the following table.
<table>
<thead>
<tr>
<th>Option</th>
<th>Output Data Set Statistics</th>
<th>Required TABLES Statement Option</th>
</tr>
</thead>
<tbody>
<tr>
<td>AGREE</td>
<td>McNemar’s test for $2 \times 2$ tables, simple kappa coefficient, and weighted kappa coefficient; for square tables with more than two response categories, Bowker’s test of symmetry; for multiple strata, overall simple and weighted kappa statistics, and tests for equal kappas among strata; for multiple strata with two response categories, Cochran’s $Q$ test</td>
<td>AGREE</td>
</tr>
<tr>
<td>AJCHI</td>
<td>continuity-adjusted chi-square for $2 \times 2$ tables</td>

### Using the TABLES Statement with the OUTPUT Statement

In order to specify that the OUTPUT data set contain a particular statistic, you must have PROC FREQ compute the statistic by using the corresponding option in the TABLES statement or the EXACT statement. For example, you cannot specify the option PCHI (Pearson chi-square) in the OUTPUT statement without also specifying a TABLES statement option or an EXACT statement option to compute the Pearson chi-square. The TABLES statement option ALL or CHISQ computes the Pearson chi-square. Additionally, if you have only one TABLES statement, the EXACT statement option CHISQ or PCHI computes the Pearson chi-square.
The TABLES statement requests one-way to \(n\)-way frequency and crosstabulation tables and statistics for those tables.

If you omit the TABLES statement, PROC FREQ generates one-way frequency tables for all data set variables that are not listed in the other statements.

The following argument is required in the TABLES statement.

**requests**

specify the frequency and crosstabulation tables to produce. A request is composed of one variable name or several variable names separated by asterisks. To request a one-way frequency table, use a single variable. To request a two-way crosstabulation table, use an asterisk between two variables. To request a multiway table (an \(n\)-way table, where \(n>2\)), separate the desired variables with asterisks. The unique values of these variables form the rows, columns, and strata of the table.

For two-way to multiway tables, the values of the last variable form the crosstabulation table columns, while the values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum. PROC FREQ produces a separate crosstabulation table for each stratum. For example, a specification of \(A*B*C*D\) in a TABLES statement produces \(k\) tables, where \(k\) is the number of different combinations of values for \(A\) and \(B\). Each table lists the values for \(C\) down the side and the values for \(D\) across the top.

You can use multiple TABLES statements in the PROC FREQ step. PROC FREQ builds all the table requests in one pass of the data, so that there is essentially no loss of efficiency. You can also specify any number of table requests in a single TABLES statement. To specify multiple table requests quickly, use a grouping syntax by placing parentheses around several variables and joining other variables or variable combinations. For example, the following statements illustrate grouping syntax.

<table>
<thead>
<tr>
<th>Request</th>
<th>Equivalent to</th>
</tr>
</thead>
<tbody>
<tr>
<td>(A*(B*C));</td>
<td>tables (A<em>B) (A</em>C);</td>
</tr>
<tr>
<td>((A \ B)*(C \ D));</td>
<td>tables (A<em>C) (B</em>C) (A<em>D) (B</em>D);</td>
</tr>
<tr>
<td>((A \ B \ C)*D);</td>
<td>tables (A<em>D) (B</em>D) (C*D);</td>
</tr>
<tr>
<td>(A -- C);</td>
<td>tables (A) (B) (C);</td>
</tr>
<tr>
<td>((A -- C)*D);</td>
<td>tables (A<em>D) (B</em>D) (C*D);</td>
</tr>
</tbody>
</table>

**Without Options**

If you request a one-way frequency table for a variable without specifying options, PROC FREQ produces frequencies, cumulative frequencies, percentages of the total frequency, and cumulative percentages for each value of the variable. If you request a two-way or an \(n\)-way crosstabulation table without specifying options, PROC FREQ produces crosstabulation tables that include cell frequencies, cell percentages of row frequencies, and cell percentages of column
frequencies. The procedure excludes observations with missing values from the table but displays the total frequency of missing observations below each table.

**Options**

The following table lists the options available with the TABLES statement. Descriptions follow in alphabetical order.

**Table 29.9.** TABLES Statement Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Control Statistical Analysis</strong></td>
<td></td>

</tbody>
</table>
You can specify the following options in a TABLES statement.

**AGREE < (WT=FC) >**
requests tests and measures of classification agreement for square tables. The AGREE option provides McNemar’s test for $2 \times 2$ tables and Bowker’s test of symmetry for tables with more than two response categories. The AGREE option also produces the simple kappa coefficient, the weighted kappa coefficient, the asymptotic standard errors for the simple and weighted kappas, and the corresponding confidence limits. When there are multiple strata, the AGREE option provides overall simple and weighted kappas as well as tests for equal kappas among strata. When there are multiple strata and two response categories, PROC FREQ computes Cochran’s $Q$ test. For more information, see the section “Tests and Measures of Agreement” on page 1493.

The (WT=FC) specification requests that PROC FREQ use Fleiss-Cohen weights to compute the weighted kappa coefficient. By default, PROC FREQ uses Cicchetti-Allison weights. See the section “Weighted Kappa Coefficient” on page 1496 for more information. You can specify the PRINTKWT option to display the kappa coefficient weights.

AGREE statistics are computed only for square tables, where the number of rows equals the number of columns. If your table is not square due to observations with zero weights, you can use the ZEROS option in the WEIGHT statement to include these observations. For more details, see the section “Tables with Zero Rows and Columns” on page 1499.

**ALL**
requests all of the tests and measures that are computed by the CHISQ, MEASURES, and CMH options. The number of CMH statistics computed can be controlled by the CMH1 and CMH2 options.

**ALPHA=\alpha**
specifies the level of confidence limits. The value of the ALPHA= option must be between 0 and 1, and the default is 0.05. A confidence level of $\alpha$ produces $100(1 - \alpha)$% confidence limits. The default of ALPHA=0.05 produces 95% confidence limits.

ALPHA= applies to confidence limits requested by TABLES statement options. There is a separate ALPHA= option in the EXACT statement that sets the level of confidence limits for Monte Carlo estimates of exact $p$-values, which are requested in the EXACT statement.

**BDT**
requests Tarone’s adjustment in the Breslow-Day test for homogeneity of odds ratios. (You must specify the CMH option to compute the Breslow-Day test.) See the section “Breslow-Day Test for Homogeneity of the Odds Ratios” on page 1508 for more information.

**BINOMIAL < (P= value) | (LEVEL= level-number | level-value) >**
requests the binomial proportion for one-way tables. The BINOMIAL option also provides the asymptotic standard error, asymptotic and exact confidence intervals,
and the asymptotic test for the binomial proportion. To request an exact test for the binomial proportion, use the BINOMIAL option in the EXACT statement.

To specify the null hypothesis proportion for the test, use P=. If you omit P=value, PROC FREQ uses 0.5 as the default for the test. By default, BINOMIAL computes the proportion of observations for the first variable level that appears in the output. To specify a different level, use LEVEL=level-number or LEVEL=level-value, where level-number is the variable level’s number or order in the output, and level-value is the formatted value of the variable level.

To include a continuity correction in the asymptotic confidence interval and test, use the BINOMIALC option instead of the BINOMIAL option.

See the section “Binomial Proportion” on page 1484 for more information.

BINOMIALC < (P= value) | (LEVEL= level-number | level-value) > requests the BINOMIAL option statistics for one-way tables, and includes a continuity correction in the asymptotic confidence interval and the asymptotic test. The BINOMIAL option statistics include the binomial proportion, the asymptotic standard error, asymptotic and exact confidence intervals, and the asymptotic test for the binomial proportion. To request an exact test for the binomial proportion, use the BINOMIAL option in the EXACT statement.

To specify the null hypothesis proportion for the test, use P=. If you omit P=value, PROC FREQ uses 0.5 as the default for the test. By default BINOMIALC computes the proportion of observations for the first variable level that appears in the output. To specify a different level, use LEVEL=level-number or LEVEL=level-value, where level-number is the variable level’s number or order in the output, and level-value is the formatted value of the variable level.

See the section “Binomial Proportion” on page 1484 for more information.

CELLCHI2 displays each crosstabulation table cell’s contribution to the total Pearson chi-square statistic, which is computed as

\[
\frac{(frequency - expected)^2}{expected}
\]

The CELLCHI2 option has no effect for one-way tables or for tables that are displayed with the LIST option.

CHISQ requests chi-square tests of homogeneity or independence and measures of association based on chi-square. The tests include the Pearson chi-square, likelihood-ratio chi-square, and Mantel-Haenszel chi-square. The measures include the phi coefficient, the contingency coefficient, and Cramer’s V. For 2 × 2 tables, the CHISQ option includes Fisher’s exact test and the continuity-adjusted chi-square. For one-way tables, the CHISQ option requests a chi-square goodness-of-fit test for equal proportions. If you specify the null hypothesis proportions with the TESTP= option, then PROC FREQ computes a chi-square goodness-of-fit test for the specified proportions. If you specify null hypothesis frequencies with the TESTF= option, PROC
FREQ computes a chi-square goodness-of-fit test for the specified frequencies. See the section “Chi-Square Tests and Statistics” on page 1469 for more information.

**CL**
requests confidence limits for the **MEASURES** statistics. If you omit the **MEASURES** option, the **CL** option invokes **MEASURES**. The FREQ procedure determines the confidence coefficient using the **ALPHA=** option, which, by default, equals 0.05 and produces 95% confidence limits.

For more information, see the section “Confidence Limits” on page 1475.

**CMH**
requests Cochran-Mantel-Haenszel statistics, which test for association between the row and column variables after adjusting for the remaining variables in a multiway table. In addition, for $2 \times 2$ tables, PROC FREQ computes the adjusted Mantel-Haenszel and logit estimates of the odds ratios and relative risks and the corresponding confidence limits. For the stratified $2 \times 2$ case, PROC FREQ computes the Breslow-Day test for homogeneity of odds ratios. (To request Tarone’s adjustment for the Breslow-Day test, use the **BDT** option.) The **CMH1** and **CMH2** options control the number of CMH statistics that PROC FREQ computes. For more information, see the section “Cochran-Mantel-Haenszel Statistics” on page 1500.

**CMH1**
requests the Cochran-Mantel-Haenszel correlation statistic and, for $2 \times 2$ tables, the adjusted Mantel-Haenszel and logit estimates of the odds ratios and relative risks and the corresponding confidence limits. For the stratified $2 \times 2$ case, PROC FREQ computes the Breslow-Day test for homogeneity of odds ratios. Except for $2 \times 2$ tables, the CMH1 option requires less memory than the CMH option, which can require an enormous amount for large tables.

**CMH2**
requests the Cochran-Mantel-Haenszel correlation statistic, row mean scores (ANOVA) statistic, and, for $2 \times 2$ tables, the adjusted Mantel-Haenszel and logit estimates of the odds ratios and relative risks and the corresponding confidence limits. For the stratified $2 \times 2$ case, PROC FREQ computes the Breslow-Day test for homogeneity of odds ratios. Except for tables with two columns, the CMH2 option requires less memory than the CMH option, which can require an enormous amount for large tables.

**CONTENTS=link-text**
specifies the text for the HTML contents file links to crosstabulation tables. For information on HTML output, refer to the *SAS Output Delivery System User’s Guide*. The **CONTENTS=** option affects only the HTML contents file, and not the HTML body file.

If you omit the **CONTENTS=** option, by default, the HTML link text for crosstabulation tables is “Cross-Tabular Freq Table.”

Note that links to all crosstabulation tables produced by a single **TABLES** statement use the same text. To specify different text for different crosstabulation table links,
request the tables in separate TABLES statements and use the CONTENTS= option in each TABLES statement.

The CONTENTS= option affects only links to crosstabulation tables. It does not affect links to other PROC FREQ tables. To specify link text for any other PROC FREQ table, you can use PROC TEMPLATE to create a customized table definition. The CONTENTS_LABEL attribute in the DEFINE TABLE statement of PROC TEMPLATE specifies the contents file link for the table. For detailed information, refer to the chapter titled “The TEMPLATE Procedure” in the SAS Output Delivery System User’s Guide.

CONVERGE=value

specifies the convergence criterion for computing the polychoric correlation when you specify the PLCORR option. The value of the CONVERGE= option must be a positive number; by default, CONVERGE=0.0001. Iterative computation of the polychoric correlation stops when the convergence measure falls below the value of the CONVERGE= option or when the number of iterations exceeds the value specified in the MAXITER= option, whichever happens first.

See the section “Polychoric Correlation” on page 1482 for more information.

CROSSLIST

displays crosstabulation tables in ODS column format, instead of the default crosstabulation cell format. In a CROSSLIST table display, the rows correspond to the crosstabulation table cells, and the columns correspond to descriptive statistics such as Frequency, Percent, and so on. See the section “Multiway Tables” on page 1518 for details on the contents of the CROSSLIST table.

The CROSSLIST table displays the same information as the default crosstabulation table, but uses an ODS column format instead of the table cell format. Unlike the default crosstabulation table, the CROSSLIST table has a table definition that you can customize with PROC TEMPLATE. For more information, refer to the chapter titled “The TEMPLATE Procedure” in the SAS Output Delivery System User’s Guide.

You can control the contents of a CROSSLIST table with the same options available for the default crosstabulation table. These include the NOFREQ, NOPERCENT, NOROW, and NOCOL options. You can request additional information in a CROSSLIST table with the CELLCHI2, DEVIATION, EXPECTED, MISSPRINT, and TOTPCT options.

The FORMAT= option and the CUMCOL option have no effect for CROSSLIST tables. You cannot specify both the LIST option and the CROSSLIST option in the same TABLES statement.

You can use the NOSPARSE option to suppress display of variable levels with zero frequency in CROSSLIST tables. By default for CROSSLIST tables, PROC FREQ displays all levels of the column variable within each level of the row variable, including any column variable levels with zero frequency for that row. And for multiway tables displayed with the CROSSLIST option, the procedure displays all levels of the row variable for each stratum of the table by default, including any row variable levels with zero frequency for the stratum.
CUMCOL

displays the cumulative column percentages in the cells of the crosstabulation table.

DEVIATION

displays the deviation of the cell frequency from the expected frequency for each cell of the crosstabulation table. The DEVIATION option is valid for contingency tables but has no effect on tables produced with the LIST option.

EXPECTED

displays the expected table cell frequencies under the hypothesis of independence (or homogeneity). The EXPECTED option is valid for crosstabulation tables but has no effect on tables produced with the LIST option.

FISHER | EXACT

requests Fisher’s exact test for tables that are larger than $2 \times 2$. This test is also known as the Freeman-Halton test. For more information, see the section “Fisher’s Exact Test” on page 1472 and the “EXACT Statement” section on page 1443.

CAUTION: For tables with many rows or columns or with large total frequency, PROC FREQ may require a large amount of time or memory to compute exact $p$-values. See the section “Computational Resources” on page 1511 for more information.

FORMAT=format-name

specifies a format for the following crosstabulation table cell values: frequency, expected frequency, and deviation. PROC FREQ also uses this format to display the total row and column frequencies for crosstabulation tables.

You can specify any standard SAS numeric format or a numeric format defined with the FORMAT procedure. The format length must not exceed 24. If you omit FORMAT=, by default, PROC FREQ uses the BEST6. format to display frequencies less than 1E6, and the BEST7. format otherwise.

To change formats for all other FREQ tables, you can use PROC TEMPLATE. For information on this procedure, refer to the chapter titled “The TEMPLATE Procedure” in the SAS Output Delivery System User’s Guide.

JT

performs the Jonckheere-Terpstra test. For more information, see the section “Jonckheere-Terpstra Test” on page 1491.

LIST

displays two-way to $n$-way tables in a list format rather than as crosstabulation tables. PROC FREQ ignores the LIST option when you request statistical tests or measures of association.
**MAXITER=** <number>
specifies the maximum number of iterations for computing the polychoric correlation when you specify the **PLCORR** option. The value of the **MAXITER=** option must be a positive integer; by default, **MAXITER=20**. Iterative computation of the polychoric correlation stops when the number of iterations exceeds the value of the **MAXITER=** option, or when the convergence measure falls below the value of the **CONVERGE=** option, whichever happens first. For more information see the section “Polychoric Correlation” on page 1482.

**MEASURES**
requests several measures of association and their asymptotic standard errors (ASE). The measures include gamma, Kendall’s tau-b, Stuart’s tau-c, Somers’ $D(C|R)$, Somers’ $D(R|C)$, the Pearson and Spearman correlation coefficients, lambda (symmetric and asymmetric), uncertainty coefficients (symmetric and asymmetric). To request confidence limits for these measures of association, you can specify the **CL** option.

For $2 \times 2$ tables, the **MEASURES** option also provides the odds ratio, column 1 relative risk, column 2 relative risk, and the corresponding confidence limits. Alternatively, you can obtain the odds ratio and relative risks, without the other measures of association, by specifying the **RELRISK** option.

For more information, see the section “Measures of Association” on page 1474.

**MISSING**
treats missing values as nonmissing and includes them in calculations of percentages and other statistics.

For more information, see the section “Missing Values” on page 1466.

**MISSPRINT**
displays missing value frequencies for all tables, even though PROC FREQ does not use the frequencies in the calculation of statistics. For more information, see the section “Missing Values” on page 1466.

**NOCOL**
suppresses the display of column percentages in cells of the crosstabulation table.

**NOCUM**
suppresses the display of cumulative frequencies and cumulative percentages for one-way frequency tables and for crosstabulation tables in list format.

**NOFREQ**
suppresses the display of cell frequencies for crosstabulation tables. This also suppresses frequencies for row totals.

**NOPERCENT**
suppresses the display of cell percentages, row total percentages, and column total percentages for crosstabulation tables. For one-way frequency tables and crosstabulation tables in list format, the **NOPERCENT** option suppresses the display of percentages and cumulative percentages.
NOPRINT
suppresses the display of frequency and crosstabulation tables but displays all requested tests and statistics. Use the NOPRINT option in the PROC FREQ statement to suppress the display of all tables.

NOROW
suppresses the display of row percentages in cells of the crosstabulation table.

NOSPARSE requests that PROC FREQ not invoke the SPARSE option when you specify the ZEROS option in the WEIGHT statement. The NOSPARSE option suppresses the display of cells with a zero frequency count in the list output, and it also omits them from the OUT= data set. By default, the ZEROS option invokes the SPARSE option, which displays table cells with a zero frequency count in the LIST output and includes them in the OUT= data set. For more information, see the description of the ZEROS option.

For CROSSLIST tables, the NOSPARSE option suppresses display of variable levels with zero frequency. By default for CROSSLIST tables, PROC FREQ displays all levels of the column variable within each level of the row variable, including any column variable levels with zero frequency for that row. And for multiway tables displayed with the CROSSLIST option, the procedure displays all levels of the row variable for each stratum of the table by default, including any row variable levels with zero frequency for the stratum.

NOWARN suppresses the log warning message that the asymptotic chi-square test may not be valid. By default, PROC FREQ displays this log message when more than 20 percent of the table cells have expected frequencies less than five.

OUT=SAS-data-set
names the output data set that contains variable values and frequency counts. The variable COUNT contains the frequencies and the variable PERCENT contains the percentages. If more than one table request appears in the TABLES statement, the contents of the data set correspond to the last table request in the TABLES statement. For more information, see the section “Output Data Sets” on page 1514 and see the following descriptions for the options OUTCUM, OUTEXPECT, and OUTPCT.

OUTCUM includes the cumulative frequency and the cumulative percentage for one-way tables in the output data set when you specify the OUT= option in the TABLES statement. The variable CUM_FREQ contains the cumulative frequency for each level of the analysis variable, and the variable CUM_PCT contains the cumulative percentage for each level. The OUTCUM option has no effect for two-way or multiway tables.

For more information, see the section “Output Data Sets” on page 1514.

OUTEXPECT includes the expected frequency in the output data set for crosstabulation tables when you specify the OUT= option in the TABLES statement. The variable EXPECTED
contains the expected frequency for each table cell. The EXPECTED option is valid for two-way or multiway tables, and has no effect for one-way tables.

For more information, see the section “Output Data Sets” on page 1514.

**OUTPCT**
includes the following additional variables in the output data set when you specify the OUT= option in the TABLES statement for crosstabulation tables:

- **PCT_COL**: the percentage of column frequency
- **PCT_ROW**: the percentage of row frequency
- **PCT_TABL**: the percentage of stratum frequency, for \( n \)-way tables where \( n > 2 \)

The OUTPCT option is valid for two-way or multiway tables, and has no effect for one-way tables.

For more information, see the section “Output Data Sets” on page 1514.

**PLCORR**
requests the polychoric correlation coefficient. For \( 2 \times 2 \) tables, this statistic is more commonly known as the tetrachoric correlation coefficient, and it is labeled as such in the displayed output. If you omit the MEASURES option, the PLCORR option invokes MEASURES. For more information, see the section “Polychoric Correlation” on page 1482 and the descriptions for the CONVERGE= and MAXITER= options in this list.

**PRINTKWT**
displays the weights PROC FREQ uses to compute the weighted kappa coefficient. You must also specify the AGREE option, which requests the weighted kappa coefficient. You can specify (WT=FC) with the AGREE option to request Fleiss-Cohen weights. By default, PROC FREQ uses Cicchetti-Allison weights.

See the section “Weighted Kappa Coefficient” on page 1496 for more information.

**RELRISK**
requests relative risk measures and their confidence limits for \( 2 \times 2 \) tables. These measures include the odds ratio and the column 1 and 2 relative risks. For more information, see the section “Odds Ratio and Relative Risks for \( 2 \times 2 \) Tables” on page 1488. You can also obtain the RELRISK measures by specifying the MEASURES option, which produces other measures of association in addition to the relative risks.

**RISKDIFF**
requests column 1 and 2 risks (or binomial proportions), risk differences, and their confidence limits for \( 2 \times 2 \) tables. See the section “Risks and Risk Differences” on page 1486 for more information.

**RISKDIFFC**
requests the RISKDIFF option statistics for \( 2 \times 2 \) tables, and includes a continuity correction in the asymptotic confidence limits. The RISKDIFF option statistics include the column 1 and 2 risks (or binomial proportions), risk differences, and their
confidence limits. See the section “Risks and Risk Differences” on page 1486 for more information.

SCORES=\textit{type}

specifies the type of row and column scores that PROC FREQ uses with the Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics, where \textit{type} is one of the following (the default is \textit{SCORE=TABLE}):

- MODRIDIT
- RANK
- RIDIT
- TABLE

By default, the row or column scores are the integers 1,2,... for character variables and the actual variable values for numeric variables. Using other types of scores yields nonparametric analyses. For more information, see the section “Scores” on page 1468.

To display the row and column scores, you can use the \textit{SCOROUT} option.

\textbf{SCOROUT}

displays the row and the column scores. You specify the score type with the \textit{SCORES=} option. PROC FREQ uses the scores when it calculates the Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, or Cochran-Mantel-Haenszel statistics. The SCOROUT option displays the row and column scores only when statistics are computed for two-way tables. To store the scores in an output data set, use the Output Delivery System.

For more information, see the section “Scores” on page 1468.

\textbf{SPARSE}

lists all possible combinations of the variable values for an \(n\)-way table when \(n > 1\), even if a combination does not occur in the data. The SPARSE option applies only to crosstabulation tables displayed in list format and to the OUT= output data set. Otherwise, if you do not use the LIST option or the OUT= option, the SPARSE option has no effect.

When you specify the SPARSE and LIST options, PROC FREQ displays all combinations of variable variables in the table listing, including those values with a frequency count of zero. By default, without the SPARSE option, PROC FREQ does not display zero-frequency values in list output. When you use the SPARSE and OUT= options, PROC FREQ includes empty crosstabulation table cells in the output data set. By default, PROC FREQ does not include zero-frequency table cells in the output data set.

For more information, see the section “Missing Values” on page 1466.
TESTF=(values)
specifies the null hypothesis frequencies for a one-way chi-square test for specified frequencies. You can separate values with blanks or commas. The sum of the frequency values must equal the total frequency for the one-way table. The number of TESTF= values must equal the number of variable levels in the one-way table. List these values in the order in which the corresponding variable levels appear in the output. If you omit the CHISQ option, the TESTF= option invokes CHISQ.

For more information, see the section “Chi-Square Test for One-Way Tables” on page 1470.

TESTP=(values)
specifies the null hypothesis proportions for a one-way chi-square test for specified proportions. You can separate values with blanks or commas. Specify values in probability form as numbers between 0 and 1, where the proportions sum to 1. Or specify values in percentage form as numbers between 0 and 100, where the percentages sum to 100. The number of TESTP= values must equal the number of variable levels in the one-way table. List these values in the order in which the corresponding variable levels appear in the output. If you omit the CHISQ option, the TESTP= option invokes CHISQ.

For more information, see the section “Chi-Square Test for One-Way Tables” on page 1470.

TOTPCT
displays the percentage of total frequency in crosstabulation tables, for n-way tables where n > 2. This percentage is also available with the LIST option or as the PERCENT variable in the OUT= output data set.

TREND
performs the Cochran-Armitage test for trend. The table must be 2 × C or R × 2. For more information, see the section “Cochran-Armitage Test for Trend” on page 1490.

TEST Statement

TEST  options ;

The TEST statement requests asymptotic tests for the specified measures of association and measures of agreement. You must use a TABLES statement with the TEST statement.

options
specify the statistics for which to provide asymptotic tests. The available statistics are those measures of association and agreement listed in Table 29.10. The option names are identical to those in the TABLES statement and the OUTPUT statement. You can request all available tests for groups of statistics by using group options MEASURES or AGREE. Or you can request tests individually by using one of the options shown in Table 29.10.

For each measure of association or agreement that you specify, the TEST statement provides an asymptotic test that the measure equals zero. When you request an asymptotic test, PROC FREQ gives the asymptotic standard error under the null
hypothesis, the test statistic, and the p-values. Additionally, PROC FREQ reports the confidence limits for that measure. The ALPHA= option in the TABLES statement determines the confidence level, which, by default, equals 0.05 and provides 95% confidence limits. For more information, see the sections “Asymptotic Tests” on page 1475 and “Confidence Limits” on page 1475, and see “Statistical Computations” beginning on page 1468 for sections describing the individual measures.

In addition to these asymptotic tests, exact tests for selected measures of association and agreement are available with the EXACT statement. See the section “EXACT Statement” on page 1443 for more information.

**WEIGHT Statement**

```
WEIGHT variable < / option > ;
```

The WEIGHT statement specifies a numeric variable with a value that represents the frequency of the observation. The WEIGHT statement is most commonly used to input cell count data. See the “Inputting Frequency Counts” section on page 1464 for more information. If you use the WEIGHT statement, PROC FREQ assumes that an observation represents \( n \) observations, where \( n \) is the value of variable. The value of the weight variable need not be an integer. When a weight value is missing, PROC FREQ ignores the corresponding observation. When a weight value is zero, PROC FREQ ignores the corresponding observation unless you specify the ZEROS option, which includes observations with zero weights. If a WEIGHT statement does not appear, each observation has a default weight of 1. The sum of the weight variable values represents the total number of observations.

If any value of the weight variable is negative, PROC FREQ displays the frequencies (as measured by the weighted values) but does not compute percentages and other statistics. If you create an output data set using the OUT= option in the TABLES
statement, PROC FREQ creates the PERCENT variable and assigns a missing value for each observation. PROC FREQ also assigns missing values to the variables that the OUTEXPECT and OUTPCT options create. You cannot create an output data set using the OUTPUT statement since statistics are not computed when there are negative weights.

**Option**

**ZEROS**

includes observations with zero weight values. By default, PROC FREQ ignores observations with zero weights.

If you specify the ZEROS option, frequency and and crosstabulation tables display any levels corresponding to observations with zero weights. Without the ZEROS option, PROC FREQ does not process observations with zero weights, and so does not display levels that contain only observations with zero weights.

With the ZEROS option, PROC FREQ includes levels with zero weights in the chi-square goodness-of-fit test for one-way tables. Also, PROC FREQ includes any levels with zero weights in binomial computations for one-way tables. This enables computation of binomial estimates and tests when there are no observations with positive weights in the specified level.

For two-way tables, the ZEROS option enables computation of kappa statistics when there are levels containing no observations with positive weight. For more information, see the section “Tables with Zero Rows and Columns” on page 1499.

Note that even with the ZEROS option, PROC FREQ does not compute the CHISQ or MEASURES statistics for two-way tables when the table has a zero row or zero column, because most of these statistics are undefined in this case.

The ZEROS option invokes the SPARSE option in the TABLES statement, which includes table cells with a zero frequency count in the list output and the OUT= data set. By default, without the SPARSE option, PROC FREQ does not include zero frequency cells in the list output or in the OUT= data set. If you specify the ZEROS option in the WEIGHT statement but do not want the SPARSE option, you can specify the NOSPARSE option in the TABLES statement.

**Details**

**Inputting Frequency Counts**

PROC FREQ can use either raw data or cell count data to produce frequency and crosstabulation tables. *Raw data*, also known as case-record data, report the data as one record for each subject or sample member. *Cell count data* report the data as a table, listing all possible combinations of data values along with the frequency counts. This way of presenting data often appears in published results.
The following DATA step statements store raw data in a SAS data set:

```sas
data Raw;
  input Subject $ R C @@;
datalines;
  01 1 1 02 1 1 03 1 1 04 1 1 05 1 1
  06 1 2 07 1 2 08 1 2 09 2 1 10 2 1
  11 2 1 12 2 1 13 2 2 14 2 2 14 2 2
;
```

You can store the same data as cell counts using the following DATA step statements:

```sas
data CellCounts;
  input R C Count @@;
datalines;
  1 1 5 1 2 3
  2 1 4 2 2 3
;
```

The variable `R` contains the values for the rows, and the variable `C` contains the values for the columns. The `Count` variable contains the cell count for each row and column combination.

Both the `Raw` data set and the `CellCounts` data set produce identical frequency counts, two-way tables, and statistics. With the `CellCounts` data set, you must use a WEIGHT statement to specify that the `Count` variable contains cell counts. For example, to create a two-way crosstabulation table, submit the following statements:

```sas
proc freq data=CellCounts;
  weight Count;
  tables R*C;
run;
```

### Grouping with Formats

PROC FREQ groups a variable’s values according to its formatted values. If you assign a format to a variable with a FORMAT statement, PROC FREQ formats the variable values before dividing observations into the levels of a frequency or crosstabulation table.

For example, suppose that a variable `X` has the values 1.1, 1.4, 1.7, 2.1, and 2.3. Each of these values appears as a level in the frequency table. If you decide to round each value to a single digit, include the following statement in the PROC FREQ step:

```sas
format X 1.;
```

Now the table lists the frequency count for formatted level 1 as two and formatted level 2 as three.
PROC FREQ treats formatted character variables in the same way. The formatted values are used to group the observations into the levels of a frequency table or crosstabulation table. PROC FREQ uses the entire value of a character format to classify an observation.

You can also use the FORMAT statement to assign formats that were created with the FORMAT procedure to the variables. User-written formats determine the number of levels for a variable and provide labels for a table. If you use the same data with different formats, then you can produce frequency counts and statistics for different classifications of the variable values.

When you use PROC FORMAT to create a user-written format that combines missing and nonmissing values into one category, PROC FREQ treats the entire category of formatted values as missing. For example, a questionnaire codes 1 as yes, 2 as no, and 8 as a no answer. The following PROC FORMAT step creates a user-written format:

```sas
proc format;
  value Questfmt 1 = 'Yes'
                   2 = 'No'
                   8, = 'Missing';
run;
```

When you use a FORMAT statement to assign `Questfmt.` to a variable, the variable’s frequency table no longer includes a frequency count for the response of 8. You must use the MISSING or MISSPRINT option in the TABLES statement to list the frequency for no answer. The frequency count for this level includes observations with either a value of 8 or a missing value (.).

The frequency or crosstabulation table lists the values of both character and numeric variables in ascending order based on internal (unformatted) variable values unless you change the order with the ORDER= option. To list the values in ascending order by formatted values, use ORDER=FORMATTED in the PROC FREQ statement.

For more information on the FORMAT statement, refer to SAS Language Reference: Concepts.

**Missing Values**

By default, PROC FREQ excludes missing values before it constructs the frequency and crosstabulation tables. PROC FREQ also excludes missing values before computing statistics. However, the total frequency of observations with missing values is displayed below each table. The following options change the way in which PROC FREQ handles missing values:

- **MISSPRINT** includes missing value frequencies in frequency or crosstabulation tables.
- **MISSING** includes missing values in percentage and statistical calculations.
The OUT= option in the TABLES statement includes an observation in the output data set that contains the frequency of missing values. The NMISS option in the OUTPUT statement creates a variable in the output data set that contains the number of missing values.

Figure 29.7 shows three ways in which PROC FREQ handles missing values. The first table uses the default method; the second table uses the MISSPRINT option; and the third table uses the MISSING option.

**Figure 29.7. Missing Values in Frequency Tables**

When a combination of variable values for a crosstabulation is missing, PROC FREQ assigns zero to the frequency count for the table cell. By default, PROC FREQ omits missing combinations in list format and in the output data set that is created in a TABLES statement. To include the missing combinations, use the SPARSE option with the LIST or OUT= option in the TABLES statement.

PROC FREQ treats missing BY variable values like any other BY variable value. The missing values form a separate BY group. When the value of a WEIGHT variable is missing, PROC FREQ excludes the observation from the analysis.
Statistical Computations

Definitions and Notation

In this chapter, a two-way table represents the crosstabulation of variables $X$ and $Y$. Let the rows of the table be labeled by the values $X_i, i = 1, 2, \ldots, R$, and the columns by $Y_j, j = 1, 2, \ldots, C$. Let $n_{ij}$ denote the cell frequency in the $i$th row and the $j$th column and define the following:

$$n_{i.} = \sum_j n_{ij} \quad \text{(row totals)}$$

$$n_{.j} = \sum_i n_{ij} \quad \text{(column totals)}$$

$$n = \sum_i \sum_j n_{ij} \quad \text{(overall total)}$$

$$p_{ij} = \frac{n_{ij}}{n} \quad \text{(cell percentages)}$$

$$p_{i.} = \frac{n_{i.}}{n} \quad \text{(row percentages)}$$

$$p_{.j} = \frac{n_{.j}}{n} \quad \text{(column percentages)}$$

$$R_i = \text{score for row } i$$

$$C_j = \text{score for column } j$$

$$\bar{R} = \sum_i n_{i.} R_i / n \quad \text{(average row score)}$$

$$\bar{C} = \sum_j n_{.j} C_j / n \quad \text{(average column score)}$$

$$A_{ij} = \sum_{k>i} \sum_{l>j} n_{kl} + \sum_{k<i} \sum_{l<j} n_{kl}$$

$$D_{ij} = \sum_{k>i} \sum_{l<j} n_{kl} + \sum_{k<i} \sum_{l>j} n_{kl}$$

$$P = \sum_i \sum_j n_{ij} A_{ij} \quad \text{(twice the number of concordances)}$$

$$Q = \sum_i \sum_j n_{ij} D_{ij} \quad \text{(twice the number of discordances)}$$

Scores

PROC FREQ uses scores for the variable values when computing the Mantel-Haenszel chi-square, Pearson correlation, Cochran-Armitage test for trend, weighted kappa coefficient, and Cochran-Mantel-Haenszel statistics. The SCORES= option in the TABLES statement specifies the score type that PROC FREQ uses. The available score types are TABLE, RANK, RIDIT, and MODRIDIT scores. The default score type is TABLE.
For numeric variables, table scores are the values of the row and column levels. If the row or column variables are formatted, then the table score is the internal numeric value corresponding to that level. If two or more numeric values are classified into the same formatted level, then the internal numeric value for that level is the smallest of these values. For character variables, table scores are defined as the row numbers and column numbers (that is, 1 for the first row, 2 for the second row, and so on).

Rank scores, which you can use to obtain nonparametric analyses, are defined by

\[
R_1 = \frac{1}{2} \left( \sum_{k<i} n_k + (n_i + 1) \right) + \frac{n_i}{2} + 1 \quad i = 1, 2, \ldots, R
\]

\[
C_1 = \frac{1}{2} \left( \sum_{l<j} n_l + (n_j + 1) \right) + \frac{n_j}{2} + 1 \quad j = 1, 2, \ldots, C
\]

Note that rank scores yield midranks for tied values.

Ridit scores (Bross 1958; Mack and Skillings 1980) also yield nonparametric analyses, but they are standardized by the sample size. Ridit scores are derived from rank scores as

\[
R_2 = \frac{R_1}{n}
\]

\[
C_2 = \frac{C_1}{n}
\]

Modified ridit (MODRIDIT) scores (van Elteren 1960; Lehmann 1975), which also yield nonparametric analyses, represent the expected values of the order statistics for the uniform distribution on (0,1). Modified ridit scores are derived from rank scores as

\[
R_3 = \frac{R_1}{n + 1}
\]

\[
C_3 = \frac{C_1}{n + 1}
\]

**Chi-Square Tests and Statistics**

When you specify the CHISQ option in the TABLES statement, PROC FREQ performs the following chi-square tests for each two-way table: Pearson chi-square, continuity-adjusted chi-square for 2 × 2 tables, likelihood-ratio chi-square, Mantel-Haenszel chi-square, and Fisher’s exact test for 2 × 2 tables. Also, PROC FREQ computes the following statistics derived from the Pearson chi-square: the phi coefficient, the contingency coefficient, and Cramer’s V. PROC FREQ computes Fisher’s exact test for general R × C tables when you specify the FISHER (or EXACT) option in the TABLES statement, or, equivalently, when you specify the FISHER option in the EXACT statement.
For one-way frequency tables, PROC FREQ performs a chi-square goodness-of-fit test when you specify the CHISQ option. The other chi-square tests and statistics described in this section are defined only for two-way tables and so are not computed for one-way frequency tables.

All the two-way test statistics described in this section test the null hypothesis of no association between the row variable and the column variable. When the sample size \( n \) is large, these test statistics are distributed approximately as chi-square when the null hypothesis is true. When the sample size is not large, exact tests may be useful. PROC FREQ computes exact tests for the following chi-square statistics when you specify the corresponding option in the EXACT statement: Pearson chi-square, likelihood-ratio chi-square, and Mantel-Haenszel chi-square. See the section “Exact Statistics” beginning on page 1508 for more information.

Note that the Mantel-Haenszel chi-square statistic is appropriate only when both variables lie on an ordinal scale. The other chi-square tests and statistics in this section are appropriate for either nominal or ordinal variables. The following sections give the formulas that PROC FREQ uses to compute the chi-square tests and statistics. For further information on the formulas and on the applicability of each statistic, refer to Agresti (1996), Stokes, Davis, and Koch (1995), and the other references cited for each statistic.

**Chi-Square Test for One-Way Tables**

For one-way frequency tables, the CHISQ option in the TABLES statement computes a chi-square goodness-of-fit test. Let \( C \) denote the number of classes, or levels, in the one-way table. Let \( f_i \) denote the frequency of class \( i \) (or the number of observations in class \( i \)) for \( i = 1, 2, \ldots, C \). Then PROC FREQ computes the chi-square statistic as

\[
Q^\chi = \sum_{i=1}^{C} \frac{(f_i - e_i)^2}{e_i}
\]

where \( e_i \) is the expected frequency for class \( i \) under the null hypothesis.

In the test for equal proportions, which is the default for the CHISQ option, the null hypothesis specifies equal proportions of the total sample size for each class. Under this null hypothesis, the expected frequency for each class equals the total sample size divided by the number of classes,

\[
e_i = \frac{n}{C} \quad \text{for } i = 1, 2, \ldots, C
\]

In the test for specified frequencies, which PROC FREQ computes when you input null hypothesis frequencies using the TESTF= option, the expected frequencies are those TESTF= values. In the test for specified proportions, which PROC FREQ computes when you input null hypothesis proportions using the TESTP= option, the expected frequencies are determined from the TESTP= proportions \( p_i \), as

\[
e_i = p_i \times n \quad \text{for } i = 1, 2, \ldots, C
\]
Under the null hypothesis (of equal proportions, specified frequencies, or specified proportions), this test statistic has an asymptotic chi-square distribution, with \( C - 1 \) degrees of freedom. In addition to the asymptotic test, PROC FREQ computes the exact one-way chi-square test when you specify the CHISQ option in the EXACT statement.

**Chi-Square Test for Two-Way Tables**

The Pearson chi-square statistic for two-way tables involves the differences between the observed and expected frequencies, where the expected frequencies are computed under the null hypothesis of independence. The chi-square statistic is computed as

\[
Q_P = \sum_i \sum_j \frac{(n_{ij} - e_{ij})^2}{e_{ij}}
\]

where

\[
e_{ij} = \frac{n_i \cdot n_j}{n}
\]

When the row and column variables are independent, \( Q_P \) has an asymptotic chi-square distribution with \((R - 1)(C - 1)\) degrees of freedom. For large values of \( Q_P \), this test rejects the null hypothesis in favor of the alternative hypothesis of general association. In addition to the asymptotic test, PROC FREQ computes the exact chi-square test when you specify the PCHI or CHISQ option in the EXACT statement.

For a \( 2 \times 2 \) table, the Pearson chi-square is also appropriate for testing the equality of two binomial proportions or, for \( R \times 2 \) and \( 2 \times C \) tables, the homogeneity of proportions. Refer to Fienberg (1980).

**Likelihood-Ratio Chi-Square Test**

The likelihood-ratio chi-square statistic involves the ratios between the observed and expected frequencies. The statistic is computed as

\[
G^2 = 2 \sum_i \sum_j n_{ij} \ln \left( \frac{n_{ij}}{e_{ij}} \right)
\]

When the row and column variables are independent, \( G^2 \) has an asymptotic chi-square distribution with \((R - 1)(C - 1)\) degrees of freedom. In addition to the asymptotic test, PROC FREQ computes the exact test when you specify the LRCHI or CHISQ option in the EXACT statement.

**Continuity-Adjusted Chi-Square Test**

The continuity-adjusted chi-square statistic for \( 2 \times 2 \) tables is similar to the Pearson chi-square, except that it is adjusted for the continuity of the chi-square distribution. The continuity-adjusted chi-square is most useful for small sample sizes. The use of the continuity adjustment is controversial; this chi-square test is more conservative, and more like Fisher’s exact test, when your sample size is small. As the sample size increases, the statistic becomes more and more like the Pearson chi-square.
The statistic is computed as
\[ Q_C = \sum_i \sum_j \left[ \max(0, |n_{ij} - e_{ij}| - 0.5) \right]^2 \]

Under the null hypothesis of independence, \( Q_C \) has an asymptotic chi-square distribution with \((R - 1)(C - 1)\) degrees of freedom.

**Mantel-Haenszel Chi-Square Test**

The Mantel-Haenszel chi-square statistic tests the alternative hypothesis that there is a linear association between the row variable and the column variable. Both variables must lie on an ordinal scale. The statistic is computed as
\[ Q_{MH} = (n - 1)r^2 \]

where \( r^2 \) is the Pearson correlation between the row variable and the column variable. For a description of the Pearson correlation, see the “Pearson Correlation Coefficient” section on page 1479. The Pearson correlation and, thus, the Mantel-Haenszel chi-square statistic use the scores that you specify in the SCORES= option in the TABLES statement.

Under the null hypothesis of no association, \( Q_{MH} \) has an asymptotic chi-square distribution with one degree of freedom. In addition to the asymptotic test, PROC FREQ computes the exact test when you specify the MHCHI or CHISQ option in the EXACT statement.

Refer to Mantel and Haenszel (1959) and Landis, Heyman, and Koch (1978).

**Fisher's Exact Test**

Fisher’s exact test is another test of association between the row and column variables. This test assumes that the row and column totals are fixed, and then uses the hypergeometric distribution to compute probabilities of possible tables with these observed row and column totals. Fisher’s exact test does not depend on any large-sample distribution assumptions, and so it is appropriate even for small sample sizes and for sparse tables.

**2 \times 2 Tables**

For 2 \times 2 tables, PROC FREQ gives the following information for Fisher’s exact test: table probability, two-sided \( p \)-value, left-sided \( p \)-value, and right-sided \( p \)-value. The table probability equals the hypergeometric probability of the observed table, and is in fact the value of the test statistic for Fisher’s exact test.

Where \( p \) is the hypergeometric probability of a specific table with the observed row and column totals, Fisher’s exact \( p \)-values are computed by summing probabilities \( p \) over defined sets of tables,
\[ PROB = \sum_A p \]
The two-sided $p$-value is the sum of all possible table probabilities (for tables having the observed row and column totals) that are less than or equal to the observed table probability. So, for the two-sided $p$-value, the set $A$ includes all possible tables with hypergeometric probabilities less than or equal to the probability of the observed table. A small two-sided $p$-value supports the alternative hypothesis of association between the row and column variables.

One-sided tests are defined in terms of the frequency of the cell in the first row and first column of the table, the (1,1) cell. Denoting the observed (1,1) cell frequency by $F$, the left-sided $p$-value for Fisher’s exact test is probability that the (1,1) cell frequency is less than or equal to $F$. So, for the left-sided $p$-value, the set $A$ includes those tables with a (1,1) cell frequency less than or equal to $F$. A small left-sided $p$-value supports the alternative hypothesis that the probability of an observation being in the first cell is less than expected under the null hypothesis of independent row and column variables.

Similarly, for a right-sided alternative hypothesis, $A$ is the set of tables where the frequency of the (1,1) cell is greater than or equal to that in the observed table. A small right-sided $p$-value supports the alternative that the probability of the first cell is greater than that expected under the null hypothesis.

Because the (1,1) cell frequency completely determines the $2 \times 2$ table when the marginal row and column sums are fixed, these one-sided alternatives can be equivalently stated in terms of other cell probabilities or ratios of cell probabilities. The left-sided alternative is equivalent to an odds ratio greater than 1, where the odds ratio equals $(n_{11} n_{22} / n_{12} n_{21})$. Additionally, the left-sided alternative is equivalent to the column 1 risk for row 1 being less than the column 1 risk for row 2, $p_{1|1} < p_{1|2}$. Similarly, the right-sided alternative is equivalent to the column 1 risk for row 1 being greater than the column 1 risk for row 2, $p_{1|1} > p_{1|2}$. Refer to Agresti (1996).

**$R \times C$ Tables**

Fisher’s exact test was extended to general $R \times C$ tables by Freeman and Halton (1951), and this test is also known as the Freeman-Halton test. For $R \times C$ tables, the two-sided $p$-value is defined the same as it is for $2 \times 2$ tables. The set $A$ contains all tables with $p$ less than or equal to the probability of the observed table. A small $p$-value supports the alternative hypothesis of association between the row and column variables. For $R \times C$ tables, Fisher’s exact test is inherently two-sided. The alternative hypothesis is defined only in terms of general, and not linear, association. Therefore, PROC FREQ does not provide right-sided or left-sided $p$-values for general $R \times C$ tables.

For $R \times C$ tables, PROC FREQ computes Fisher’s exact test using the network algorithm of Mehta and Patel (1983), which provides a faster and more efficient solution than direct enumeration. See the section “Exact Statistics” beginning on page 1508 for more details.
Phi Coefficient

The phi coefficient is a measure of association derived from the Pearson chi-square statistic. It has the range $-1 \leq \phi \leq 1$ for $2 \times 2$ tables. Otherwise, the range is $0 \leq \phi \leq \min(\sqrt{R-1}, \sqrt{C-1})$ (Liebetrau 1983). The phi coefficient is computed as

$$\phi = \frac{n_{11}n_{22} - n_{12}n_{21}}{\sqrt{n_{11}n_{22}n_{12}n_{21}}} \quad \text{for } 2 \times 2 \text{ tables}$$

$$\phi = \sqrt{\frac{Q_P}{P+n}} \quad \text{otherwise}$$

Contingency Coefficient

The contingency coefficient is a measure of association derived from the Pearson chi-square. It has the range $0 \leq P \leq \sqrt{\frac{m-1}{m}}$, where $m = \min(R, C)$ (Liebetrau 1983). The contingency coefficient is computed as

$$P = \sqrt{\frac{Q_P}{Q_P+n}}$$

Refer to Kendall and Stuart (1979, pp. 587–588).

Cramer’s $V$

Cramer’s $V$ is a measure of association derived from the Pearson chi-square. It is designed so that the attainable upper bound is always 1. It has the range $-1 \leq V \leq 1$ for $2 \times 2$ tables; otherwise, the range is $0 \leq V \leq 1$. Cramer’s $V$ is computed as

$$V = \phi \quad \text{for } 2 \times 2 \text{ tables}$$

$$V = \sqrt{\frac{Q_P}{\min(R-1, C-1)}} \quad \text{otherwise}$$

Refer to Kendall and Stuart (1979, p. 588).

Measures of Association

When you specify the MEASURES option in the TABLES statement, PROC FREQ computes several statistics that describe the association between the two variables of the contingency table. The following are measures of ordinal association that consider whether the variable $Y$ tends to increase as $X$ increases: gamma, Kendall’s tau-$b$, Stuart’s tau-$c$, and Somers’ $D$. These measures are appropriate for ordinal variables, and they classify pairs of observations as concordant or discordant. A pair is concordant if the observation with the larger value of $X$ also has the larger value of $Y$. A pair is discordant if the observation with the larger value of $X$ has the smaller
value of Y. Refer to Agresti (1996) and the other references cited in the discussion of each measure of association.

The Pearson correlation coefficient and the Spearman rank correlation coefficient are also appropriate for ordinal variables. The Pearson correlation describes the strength of the linear association between the row and column variables, and it is computed using the row and column scores specified by the SCORES= option in the TABLES statement. The Spearman correlation is computed with rank scores. The polychoric correlation (requested by the PLCORR option) also requires ordinal variables and assumes that the variables have an underlying bivariate normal distribution. The following measures of association do not require ordinal variables: lambda asymmetric, lambda symmetric, and uncertainty coefficients.

PROC FREQ computes estimates of the measures according to the formulas given in the discussion of each measure of association. For each measure, PROC FREQ computes an asymptotic standard error (ASE), which is the square root of the asymptotic variance denoted by \( \text{var} \) in the following sections.

**Confidence Limits**

If you specify the CL option in the TABLES statement, PROC FREQ computes asymptotic confidence limits for all MEASURES statistics. The confidence coefficient is determined according to the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

The confidence limits are computed as

\[
\text{est} \pm \left( z_{\alpha/2} \times \text{ASE} \right)
\]

where \( \text{est} \) is the estimate of the measure, \( z_{\alpha/2} \) is the \( 100(1 - \alpha/2) \) percentile of the standard normal distribution, and ASE is the asymptotic standard error of the estimate.

**Asymptotic Tests**

For each measure that you specify in the TEST statement, PROC FREQ computes an asymptotic test of the null hypothesis that the measure equals zero. Asymptotic tests are available for the following measures of association: gamma, Kendall’s tau-b, Stuart’s tau-c, Somers’ \( D(R|C) \), Somers’ \( D(C|R) \), the Pearson correlation coefficient, and the Spearman rank correlation coefficient. To compute an asymptotic test, PROC FREQ uses a standardized test statistic \( z \), which has an asymptotic standard normal distribution under the null hypothesis. The standardized test statistic is computed as

\[
z = \frac{\text{est}}{\sqrt{\text{var}_0(\text{est})}}
\]

where \( \text{est} \) is the estimate of the measure and \( \text{var}_0(\text{est}) \) is the variance of the estimate under the null hypothesis. Formulas for \( \text{var}_0(\text{est}) \) are given in the discussion of each measure of association.
Note that the ratio of $est$ to $\sqrt{\text{var}_0(est)}$ is the same for the following measures: gamma, Kendall’s tau-b, Stuart’s tau-c, Somers’ $D(R\mid C)$, and Somers’ $D(C\mid R)$. Therefore, the tests for these measures are identical. For example, the $p$-values for the test of $H_0$: gamma $= 0$ equal the $p$-values for the test of $H_0$: tau-b $= 0$.

PROC FREQ computes one-sided and two-sided $p$-values for each of these tests. When the test statistic $z$ is greater than its null hypothesis expected value of zero, PROC FREQ computes the right-sided $p$-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided $p$-value supports the alternative hypothesis that the true value of the measure is greater than zero. When the test statistic is less than or equal to zero, PROC FREQ computes the left-sided $p$-value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. A small left-sided $p$-value supports the alternative hypothesis that the true value of the measure is less than zero. The one-sided $p$-value $P_1$ can be expressed as

$$P_1 = \text{Prob} \left( Z > z \right) \quad \text{if} \quad z > 0$$
$$P_1 = \text{Prob} \left( Z < z \right) \quad \text{if} \quad z \leq 0$$

where $Z$ has a standard normal distribution. The two-sided $p$-value $P_2$ is computed as

$$P_2 = \text{Prob} \left( |Z| > |z| \right)$$

**Exact Tests**

Exact tests are available for two measures of association, the Pearson correlation coefficient and the Spearman rank correlation coefficient. If you specify the PCORR option in the EXACT statement, PROC FREQ computes the exact test of the hypothesis that the Pearson correlation equals zero. If you specify the SCORR option in the EXACT statement, PROC FREQ computes the exact test of the hypothesis that the Spearman correlation equals zero. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

**Gamma**

The estimator of gamma is based only on the number of concordant and discordant pairs of observations. It ignores tied pairs (that is, pairs of observations that have equal values of $X$ or equal values of $Y$). Gamma is appropriate only when both variables lie on an ordinal scale. It has the range $-1 \leq \Gamma \leq 1$. If the two variables are independent, then the estimator of gamma tends to be close to zero. Gamma is estimated by

$$G = \frac{P - Q}{P + Q}$$

with asymptotic variance

$$\text{var} = \frac{16}{(P + Q)^4} \sum_i \sum_j n_{ij} (QA_{ij} - PD_{ij})^2$$
The variance of the estimator under the null hypothesis that gamma equals zero is computed as

\[
\text{var}_0(G) = \frac{4}{(P + Q)^2} \left( \sum_{i} \sum_{j} n_{ij}(A_{ij} - D_{ij})^2 - (P - Q)^2/n \right)
\]

For 2 x 2 tables, gamma is equivalent to Yule’s $Q$. Refer to Goodman and Kruskal (1979), Agresti (1990), and Brown and Benedetti (1977).

**Kendall’s Tau-b**

Kendall’s tau-$b$ is similar to gamma except that tau-$b$ uses a correction for ties. Tau-$b$ is appropriate only when both variables lie on an ordinal scale. Tau-$b$ has the range $-1 \leq \tau_b \leq 1$. It is estimated by

\[
t_b = \frac{P - Q}{\sqrt{w_r w_c}}
\]

with

\[
\text{var} = \frac{1}{w^4} \left( \sum_{i} \sum_{j} n_{ij}(2wd_{ij} + t_b v_{ij})^2 - n^3 t_b^2 (w_r + w_c)^2 \right)
\]

where

\[
\begin{align*}
w &= \sqrt{w_r w_c} \\
w_r &= n^2 - \sum_{i} n_{i}^2 \\
w_c &= n^2 - \sum_{j} n_{j}^2 \\
d_{ij} &= A_{ij} - D_{ij} \\
v_{ij} &= n_i w_c + n_j w_r
\end{align*}
\]

The variance of the estimator under the null hypothesis that tau-$b$ equals zero is computed as

\[
\text{var}_0(t_b) = \frac{4}{w_r w_c} \left( \sum_{i} \sum_{j} n_{ij}(A_{ij} - D_{ij})^2 - (P - Q)^2/n \right)
\]

Refer to Kendall (1955) and Brown and Benedetti (1977).
**Stuart’s Tau-c**

Stuart’s tau-c makes an adjustment for table size in addition to a correction for ties. Tau-c is appropriate only when both variables lie on an ordinal scale. Tau-c has the range $-1 \leq \tau_c \leq 1$. It is estimated by

$$t_c = \frac{m(P - Q)}{n^2(m - 1)}$$

with

$$\text{var} = 4m^2 \left( \frac{\sum \sum n_{ij} d_{ij}^2 - (P - Q)^2 / n}{(m - 1)^2 n^4} \right)$$

where

$$m = \min(R, C)$$

$$d_{ij} = A_{ij} - D_{ij}$$

The variance of the estimator under the null hypothesis that tau-c equals zero is

$$\text{var}_0(t_c) = \text{var}$$

Refer to Brown and Benedetti (1977).

**Somers’ D(C|R) and D(R|C)**

Somers’ $D(C|R)$ and Somers’ $D(R|C)$ are asymmetric modifications of tau-b. $C|R$ denotes that the row variable X is regarded as an independent variable, while the column variable Y is regarded as dependent. Similarly, $R|C$ denotes that the column variable Y is regarded as an independent variable, while the row variable X is regarded as dependent. Somers’ $D$ differs from tau-b in that it uses a correction only for pairs that are tied on the independent variable. Somers’ $D$ is appropriate only when both variables lie on an ordinal scale. It has the range $-1 \leq D \leq 1$. Formulas for Somers’ $D(R|C)$ are obtained by interchanging the indices.

$$D(C|R) = \frac{P - Q}{w_r}$$

with

$$\text{var} = \frac{4}{w_r} \sum_i \sum_j n_{ij} \left( w_r d_{ij} - (P - Q)(n - n_i) \right)^2$$
where
\[
\begin{align*}
w_r &= n^2 - \sum_i n_i^2, \\
d_{ij} &= A_{ij} - D_{ij}
\end{align*}
\]

The variance of the estimator under the null hypothesis that \(D(C|R)\) equals zero is computed as
\[
\text{var}_0(D(C|R)) = \frac{4}{w_r^2} \left( \sum_i \sum_j n_{ij} (A_{ij} - D_{ij})^2 - (P - Q)^2/n \right)
\]

Refer to Somers (1962), Goodman and Kruskal (1979), and Liebetrau (1983).

**Pearson Correlation Coefficient**

PROC FREQ computes the Pearson correlation coefficient using the scores specified in the SCORES= option. The Pearson correlation is appropriate only when both variables lie on an ordinal scale. It has the range \(-1 \leq \rho \leq 1\). The Pearson correlation coefficient is computed as
\[
r = \frac{v}{w} = \frac{ss_{rc}}{\sqrt{ss_r ss_c}}
\]

with
\[
\text{var} = \frac{1}{w_r^4} \sum_i \sum_j n_{ij} \left( w(R_i - \bar{R})(C_j - \bar{C}) - \frac{b_{ij}v}{2w} \right)^2
\]

The row scores \(R_i\) and the column scores \(C_j\) are determined by the SCORES= option in the TABLES statement, and
\[
\begin{align*}
ss_r &= \sum_i \sum_j n_{ij}(R_i - \bar{R})^2 \\
ss_c &= \sum_i \sum_j n_{ij}(C_j - \bar{C})^2 \\
ss_{rc} &= \sum_i \sum_j n_{ij}(R_i - \bar{R})(C_j - \bar{C}) \\
b_{ij} &= (R_i - \bar{R})^2 ss_c + (C_j - \bar{C})^2 ss_r \\
v &= ss_{rc} \\
w &= \sqrt{ss_r ss_c}
\end{align*}
\]
Refer to Snedecor and Cochran (1989) and Brown and Benedetti (1977).

To compute an asymptotic test for the Pearson correlation, PROC FREQ uses a standardized test statistic \( r^* \), which has an asymptotic standard normal distribution under the null hypothesis that the correlation equals zero. The standardized test statistic is computed as

\[
r^* = \frac{r}{\sqrt{\text{var}_0(r)}}
\]

where \( \text{var}_0(r) \) is the variance of the correlation under the null hypothesis.

\[
\text{var}_0(r) = \frac{\sum_i \sum_j n_{ij}(R_i - \bar{R})(C_j - \bar{C})^2 - ss_{rc}^2/n}{ss_r ss_c}
\]

The asymptotic variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. Refer to Brown and Benedetti (1977).

PROC FREQ also computes the exact test for the hypothesis that the Pearson correlation equals zero when you specify the PCORR option in the EXACT statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

**Spearman Rank Correlation Coefficient**

The Spearman correlation coefficient is computed using rank scores \( R_{1i} \) and \( C_{1j} \), defined in the section “Scores” beginning on page 1468. It is appropriate only when both variables lie on an ordinal scale. It has the range \(-1 \leq \rho_s \leq 1\). The Spearman correlation coefficient is computed as

\[
\rho_s = \frac{v}{w}
\]

with

\[
\text{var} = \frac{1}{n^2 w^3} \sum_i \sum_j n_{ij}(z_{ij} - \bar{z})^2
\]

where

\[
v = \sum_i \sum_j n_{ij}R(i)C(j)
\]

\[
w = \frac{1}{12} \sqrt{FG}
\]

\[
F = n^3 - \sum_i n_i^3.
\]
Refer to Snedecor and Cochran (1989) and Brown and Benedetti (1977).

To compute an asymptotic test for the Spearman correlation, PROC FREQ uses a standardized test statistic \( r_s^* \), which has an asymptotic standard normal distribution under the null hypothesis that the correlation equals zero. The standardized test statistic is computed as

\[
r_s^* = \frac{r_s}{\sqrt{\text{var}_0(r_s)}}
\]

where \( \text{var}_0(r_s) \) is the variance of the correlation under the null hypothesis.

\[
\text{var}_0(r_s) = \frac{1}{n^2w^2} \sum_i \sum_j n_{ij} (v_{ij} - \bar{v})^2
\]

where

\[
\bar{v} = \sum_i \sum_j n_{ij} v_{ij} / n
\]

The asymptotic variance is derived for multinomial sampling in a contingency table framework, and it differs from the form obtained under the assumption that both variables are continuous and normally distributed. Refer to Brown and Benedetti (1977).

PROC FREQ also computes the exact test for the hypothesis that the Spearman rank correlation equals zero when you specify the SCORR option in the EXACT statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.
Polychoric Correlation

When you specify the PLCORR option in the TABLES statement, PROC FREQ computes the polychoric correlation. This measure of association is based on the assumption that the ordered, categorical variables of the frequency table have an underlying bivariate normal distribution. For $2 \times 2$ tables, the polychoric correlation is also known as the tetrachoric correlation. Refer to Drasgow (1986) for an overview of polychoric correlation. The polychoric correlation coefficient is the maximum likelihood estimate of the product-moment correlation between the normal variables, estimating thresholds from the observed table frequencies. The range of the polychoric correlation is from -1 to 1. Olsson (1979) gives the likelihood equations and an asymptotic covariance matrix for the estimates.

To estimate the polychoric correlation, PROC FREQ iteratively solves the likelihood equations by a Newton-Raphson algorithm using the Pearson correlation coefficient as the initial approximation. Iteration stops when the convergence measure falls below the convergence criterion or when the maximum number of iterations is reached, whichever occurs first. The CONVERGE= option sets the convergence criterion, and the default value is 0.0001. The MAXITER= option sets the maximum number of iterations, and the default value is 20.

Lambda Asymmetric

Asymmetric lambda, $\lambda(C|R)$, is interpreted as the probable improvement in predicting the column variable $Y$ given knowledge of the row variable $X$. Asymmetric lambda has the range $0 \leq \lambda(C|R) \leq 1$. It is computed as

$$\lambda(C|R) = \frac{\sum_i r_i - r}{n - r}$$

with

$$\text{var} = \frac{n - \sum_i r_i}{(n - r)^3} \left( \sum_i r_i + r - 2 \sum_i (r_i | l_i = l) \right)$$

where

$$r_i = \max_j (n_{ij})$$

$$r = \max_j (n_{..j})$$

Also, let $l_i$ be the unique value of $j$ such that $r_i = n_{ij}$, and let $l$ be the unique value of $j$ such that $r = n_{..j}$.

Because of the uniqueness assumptions, ties in the frequencies or in the marginal totals must be broken in an arbitrary but consistent manner. In case of ties, $l$ is defined here as the smallest value of $j$ such that $r = n_{..j}$. For a given $i$, if there is at least one value $j$ such that $n_{ij} = r_i = c_j$, then $l_i$ is defined here to be the smallest such value.
of \( j \). Otherwise, if \( n_{i} = r_{i} \), then \( l_{i} \) is defined to be equal to \( l \). If neither condition is true, then \( l_{i} \) is taken to be the smallest value of \( j \) such that \( n_{ij} = r_{i} \). The formulas for lambda asymmetric \((R|C)\) can be obtained by interchanging the indices.

Refer to Goodman and Kruskal (1979).

**Lambda Symmetric**

The nondirectional lambda is the average of the two asymmetric lambdas, \( \lambda(C|R) \) and \( \lambda(R|C) \). Lambda symmetric has the range \( 0 \leq \lambda \leq 1 \). Lambda symmetric is defined as

\[
\lambda = \frac{\sum_{i} r_{i} + \sum_{j} c_{j} - r - c}{2n - r - c} = \frac{w - v}{w}
\]

with

\[
\text{var} = \frac{1}{w^4} \left( wvy - 2w^2 \left[ n - \sum_{i} \sum_{j} (n_{ij} \mid j = l_{i}, i = k_{j}) \right] - 2v^2(n - nk_{l}) \right)
\]

where

\[
\begin{align*}
c_{j} &= \max_{i}(n_{ij}) \\
c &= \max_{i}(n_{i}) \\
w &= 2n - r - c \\
v &= 2n - \sum_{i} r_{i} - \sum_{j} c_{j} \\
x &= \sum_{i} (r_{i} \mid l_{i} = l) + \sum_{j} (c_{j} \mid k_{j} = k) + r_{k} + c_{l} \\
y &= 8n - w - v - 2x
\end{align*}
\]

Refer to Goodman and Kruskal (1979).

**Uncertainty Coefficients \((C|R)\) and \((R|C)\)**

The uncertainty coefficient, \( U(C|R) \), is the proportion of uncertainty (entropy) in the column variable \( Y \) that is explained by the row variable \( X \). It has the range \( 0 \leq U(C|R) \leq 1 \). The formulas for \( U(R|C) \) can be obtained by interchanging the indices.
\[
U(C|R) = \frac{H(X) + H(Y) - H(XY)}{H(Y)} = \frac{v}{w}
\]
with

\[
var = \frac{1}{n^2 w^4} \sum_i \sum_j n_{ij} \left( H(Y) \ln \left( \frac{n_{ij}}{n_i} \right) + (H(X) - H(XY)) \ln \left( \frac{n_{ij}}{n} \right) \right)^2
\]
where

\[
v = H(X) + H(Y) - H(XY)
\]
\[
w = H(Y)
\]
\[
H(X) = -\sum_i \left( \frac{n_{i.}}{n} \right) \ln \left( \frac{n_{i.}}{n} \right)
\]
\[
H(Y) = -\sum_j \left( \frac{n_{.j}}{n} \right) \ln \left( \frac{n_{.j}}{n} \right)
\]
\[
H(XY) = -\sum_i \sum_j \left( \frac{n_{ij}}{n} \right) \ln \left( \frac{n_{ij}}{n} \right)
\]

Refer to Theil (1972, pp. 115–120) and Goodman and Kruskal (1979).

**Uncertainty Coefficient (U)**

The uncertainty coefficient, \(U\), is the symmetric version of the two asymmetric coefficients. It has the range \(0 \leq U \leq 1\). It is defined as

\[
U = \frac{2(H(X) + H(Y) - H(XY))}{H(X) + H(Y)}
\]
with

\[
var = 4 \sum_i \sum_j n_{ij} \left( H(XY) \ln \left( \frac{n_{ij} n_{i.}}{n^2} \right) - (H(X) + H(Y)) \ln \left( \frac{n_{ij}}{n} \right) \right)^2
\]

Refer to Goodman and Kruskal (1979).

**Binomial Proportion**

When you specify the BINOMIAL option in the TABLES statement, PROC FREQ computes a binomial proportion for one-way tables. By default this is the proportion of observations in the first variable level, or class, that appears in the output. To specify a different level, use the LEVEL= option.

\[
\hat{p} = \frac{n_1}{n}
\]
where $n_1$ is the frequency for the first level and $n$ is the total frequency for the one-way table. The standard error for the binomial proportion is computed as

$$se(\hat{p}) = \sqrt{\hat{p}(1-\hat{p})/n}$$

Using the normal approximation to the binomial distribution, PROC FREQ constructs asymptotic confidence limits for $p$ according to

$$\hat{p} \pm \left(z_{\alpha/2} \times se(\hat{p})\right)$$

where $z_{\alpha/2}$ is the $100(1-\alpha/2)$ percentile of the standard normal distribution. The confidence level $\alpha$ is determined by the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

If you specify the BINOMIALC option, PROC FREQ includes a continuity correction of $1/2n$ in the asymptotic confidence limits for $p$. The purpose of this correction is to adjust for the difference between the normal approximation and the binomial distribution, which is a discrete distribution. Refer to Fleiss (1981). With the continuity correction, the asymptotic confidence limits for $p$ are

$$\hat{p} \pm \left(z_{\alpha/2} \times se(\hat{p}) + (1/2n)\right)$$

Additionally, PROC FREQ computes exact confidence limits for the binomial proportion using the $F$ distribution method given in Collett (1991) and also described by Leemis and Trivedi (1996).

PROC FREQ computes an asymptotic test of the hypothesis that the binomial proportion equals $p_0$, where the value of $p_0$ is specified by the P= option in the TABLES statement. If you do not specify a value for the P= option, PROC FREQ uses $p_0 = 0.5$ by default. The asymptotic test statistic is

$$z = \frac{\hat{p} - p_0}{\sqrt{p_0(1-p_0)/n}}$$

If you specify the BINOMIALC option, PROC FREQ includes a continuity correction in the asymptotic test statistic, towards adjusting for the difference between the normal approximation and the discrete binomial distribution. Refer to Fleiss (1981). The continuity correction of $(1/2n)$ is subtracted from $(\hat{p} - p_0)$ in the numerator of the test statistic $z$ if $(\hat{p} - p_0)$ is positive; otherwise, the continuity correction is added to the numerator.

PROC FREQ computes one-sided and two-sided $p$-values for this test. When the test statistic $z$ is greater than zero, its expected value under the null hypothesis, PROC FREQ computes the right-sided $p$-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided $p$-value supports the alternative hypothesis that the true value of the proportion is greater than $p_0$. When the test statistic is less than or equal to zero, PROC FREQ computes the left-sided $p$-value, which is the probability of a smaller value of the statistic occurring
under the null hypothesis. A small left-sided $p$-value supports the alternative hypothesis that the true value of the proportion is less than $p_0$. The one-sided $p$-value $P_1$ can be expressed as

$$P_1 = \Pr(Z > z) \quad \text{if } z > 0$$

$$P_1 = \Pr(Z < z) \quad \text{if } z \leq 0$$

where $Z$ has a standard normal distribution. The two-sided $p$-value $P_2$ is computed as

$$P_2 = \Pr(|Z| > |z|)$$

When you specify the BINOMIAL option in the EXACT statement, PROC FREQ also computes an exact test of the null hypothesis $H_0: p = p_0$. To compute this exact test, PROC FREQ uses the binomial probability function

$$\Pr(X = x | p_0) = \binom{n}{x} p_0^x (1 - p_0)^{n-x} \quad x = 0, 1, 2, \ldots, n$$

where the variable $X$ has a binomial distribution with parameters $n$ and $p_0$. To compute $\Pr(X \leq n_1)$, PROC FREQ sums these binomial probabilities over $x$ from zero to $n_1$. To compute $\Pr(X \geq n_1)$, PROC FREQ sums these binomial probabilities over $x$ from $n_1$ to $n$. Then the exact one-sided $p$-value is

$$P_1 = \min \left( \Pr(X \leq n_1 | p_0), \Pr(X \geq n_1 | p_0) \right)$$

and the exact two-sided $p$-value is

$$P_2 = 2 \times P_1$$

**Risks and Risk Differences**

The RISKDIFF option in the TABLES statement provides estimates of risks (or binomial proportions) and risk differences for $2 \times 2$ tables. This analysis may be appropriate when comparing the proportion of some characteristic for two groups, where row 1 and row 2 correspond to the two groups, and the columns correspond to two possible characteristics or outcomes. For example, the row variable might be a treatment or dose, and the column variable might be the response. Refer to Collett (1991), Fleiss (1981), and Stokes, Davis, and Koch (1995).

Let the frequencies of the $2 \times 2$ table be represented as follows.

<table>
<thead>
<tr>
<th></th>
<th>Column 1</th>
<th>Column 2</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Row 1</td>
<td>$n_{11}$</td>
<td>$n_{12}$</td>
<td>$n_1$</td>
</tr>
<tr>
<td>Row 2</td>
<td>$n_{21}$</td>
<td>$n_{22}$</td>
<td>$n_2$</td>
</tr>
<tr>
<td>Total</td>
<td>$n_1$</td>
<td>$n_2$</td>
<td>$n$</td>
</tr>
</tbody>
</table>
The column 1 risk for row 1 is the proportion of row 1 observations classified in column 1,

\[ p_{1|1} = \frac{n_{11}}{n_1}. \]

This estimates the conditional probability of the column 1 response, given the first level of the row variable.

The column 1 risk for row 2 is the proportion of row 2 observations classified in column 1,

\[ p_{1|2} = \frac{n_{21}}{n_2}. \]

and the overall column 1 risk is the proportion of all observations classified in column 1,

\[ p_1 = \frac{n_{-1}}{n}. \]

The column 1 risk difference compares the risks for the two rows, and it is computed as the column 1 risk for row 1 minus the column 1 risk for row 2,

\[ (pdiff)_1 = p_{1|1} - p_{1|2} \]

The risks and risk difference are defined similarly for column 2.

The standard error of the column 1 risk estimate for row \( i \) is computed as

\[ se(p_{1|i}) = \sqrt{p_{1|i} (1 - p_{1|i}) / n_i}. \]

The standard error of the overall column 1 risk estimate is computed as

\[ se(p_1) = \sqrt{p_1 (1 - p_1) / n}. \]

If the two rows represent independent binomial samples, the standard error for the column 1 risk difference is computed as

\[ se((pdiff)_1) = \sqrt{var(p_{1|1}) + var(p_{1|2})} \]

The standard errors are computed in a similar manner for the column 2 risks and risk difference.

Using the normal approximation to the binomial distribution, PROC FREQ constructs asymptotic confidence limits for the risks and risk differences according to

\[ est \pm \left( z_{\alpha/2} \times se(est) \right) \]
where \( est \) is the estimate, \( z_{\alpha/2} \) is the \( 100(1 - \alpha/2) \) percentile of the standard normal distribution, and \( se(est) \) is the standard error of the estimate. The confidence level \( \alpha \) is determined from the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

If you specify the RISKDIFFC option, PROC FREQ includes continuity corrections in the asymptotic confidence limits for the risks and risk differences. Continuity corrections adjust for the difference between the normal approximation and the discrete binomial distribution. Refer to Fleiss (1981). Including a continuity correction, the asymptotic confidence limits become

\[
est \pm (z_{\alpha/2} \times se(est) + cc)
\]

where \( cc \) is the continuity correction. For the column 1 risk for row 1, \( cc = (1/2n_1) \); for the column 1 risk for row 2, \( cc = (1/2n_2) \); for the overall column 1 risk, \( cc = (1/2n) \); and for the column 1 risk difference, \( cc = ((1/n_1 + 1/n_2)/2) \). Continuity corrections are computed similarly for the column 2 risks and risk difference.

PROC FREQ computes exact confidence limits for the column 1, column 2, and overall risks using the \( F \) distribution method given in Collett (1991) and also described by Leemis and Trivedi (1996). PROC FREQ does not provide exact confidence limits for the risk differences. Refer to Agresti (1992) for a discussion of issues involved in constructing exact confidence limits for differences of proportions.

**Odds Ratio and Relative Risks for 2 x 2 Tables**

**Odds Ratio (Case-Control Studies)**

The odds ratio is a useful measure of association for a variety of study designs. For a retrospective design called a case-control study, the odds ratio can be used to estimate the relative risk when the probability of positive response is small (Agresti 1990). In a case-control study, two independent samples are identified based on a binary (yes-no) response variable, and the conditional distribution of a binary explanatory variable is examined, within fixed levels of the response variable. Refer to Stokes, Davis, and Koch (1995) and Agresti (1996).

The odds of a positive response (column 1) in row 1 is \( n_{11}/n_{12} \). Similarly, the odds of a positive response in row 2 is \( n_{21}/n_{22} \). The odds ratio is formed as the ratio of the row 1 odds to the row 2 odds. The odds ratio for 2 \( \times \) 2 tables is defined as

\[
OR = \frac{n_{11}/n_{12}}{n_{21}/n_{22}} = \frac{n_{11}n_{22}}{n_{12}n_{21}}
\]

The odds ratio can be any nonnegative number. When the row and column variables are independent, the true value of the odds ratio equals 1. An odds ratio greater than 1 indicates that the odds of a positive response are higher in row 1 than in row 2. Values less than 1 indicate the odds of positive response are higher in row 2. The strength of association increases with the deviation from 1.

The transformation \( G = (OR - 1)/(OR + 1) \) transforms the odds ratio to the range \((-1, 1)\) with \( G = 0 \) when \( OR = 1 \); \( G = -1 \) when \( OR = 0 \); and \( G \) approaches 1.
as OR approaches infinity. \( G \) is the gamma statistic, which PROC FREQ computes when you specify the MEASURES option.

The asymptotic 100\((1 - \alpha)\)% confidence limits for the odds ratio are

\[
( OR \cdot \exp(-z\sqrt{v}), \ OR \cdot \exp(z\sqrt{v}) )
\]

where

\[
v = \text{var}(\ln OR) = \frac{1}{n_{11}} + \frac{1}{n_{12}} + \frac{1}{n_{21}} + \frac{1}{n_{22}}
\]

and \( z \) is the 100\((1 - \alpha/2)\) percentile of the standard normal distribution. If any of the four cell frequencies are zero, the estimates are not computed.

When you specify option OR in the EXACT statement, PROC FREQ computes exact confidence limits for the odds ratio. Because this is a discrete problem, the confidence coefficient for these exact confidence limits is not exactly \( 1 - \alpha \) but is at least \( 1 - \alpha \). Thus, these confidence limits are conservative. Refer to Agresti (1992).

PROC FREQ computes exact confidence limits for the odds ratio with an algorithm based on that presented by Thomas (1971). Refer also to Gart (1971). The following two equations are solved iteratively for the lower and upper confidence limits, \( \phi_1 \) and \( \phi_2 \).

\[
\sum_{i=n_{11}}^{n_{11}} \binom{n_{11}}{i} \binom{n_{21}-i}{n_{11}-i} \phi_1^i / \sum_{i=0}^{n_{11}} \binom{n_{11}}{i} \binom{n_{21}-i}{n_{11}-i} \phi_1^i = \frac{\alpha}{2}
\]

\[
\sum_{i=0}^{n_{11}} \binom{n_{11}}{i} \binom{n_{21}-i}{n_{11}-i} \phi_2^i / \sum_{i=0}^{n_{11}} \binom{n_{11}}{i} \binom{n_{21}-i}{n_{11}-i} \phi_2^i = \frac{\alpha}{2}
\]

When the odds ratio equals zero, which occurs when either \( n_{11} = 0 \) or \( n_{22} = 0 \), then PROC FREQ sets the lower exact confidence limit to zero and determines the upper limit with level \( \alpha \). Similarly, when the odds ratio equals infinity, which occurs when either \( n_{12} = 0 \) or \( n_{21} = 0 \), then PROC FREQ sets the upper exact confidence limit to infinity and determines the lower limit with level \( \alpha \).

**Relative Risks (Cohort Studies)**

These measures of relative risk are useful in cohort (prospective) study designs, where two samples are identified based on the presence or absence of an explanatory factor. The two samples are observed in future time for the binary (yes-no) response variable under study. Relative risk measures are also useful in cross-sectional studies, where two variable are observed simultaneously. Refer to Stokes, Davis, and Koch (1995) and Agresti (1996).

The column 1 relative risk is the ratio of the column 1 risks for row 1 to row 2. The column 1 risk for row 1 is the proportion of the row 1 observations classified in column 1,

\[
p_{1|1} = n_{11} / n_1.
\]
Similarly, the column 1 risk for row 2 is

\[ p_{1|2} = \frac{n_{21}}{n_2}. \]

The column 1 relative risk is then computed as

\[ RR_1 = \frac{p_{1|1}}{p_{1|2}}. \]

A relative risk greater than 1 indicates that the probability of positive response is greater in row 1 than in row 2. Similarly, a relative risk less than 1 indicates that the probability of positive response is less in row 1 than in row 2. The strength of association increases with the deviation from 1.

The asymptotic 100(1 − α)% confidence limits for the column 1 relative risk are

\[ (RR_1 \cdot \exp(-z\sqrt{v}), RR_1 \cdot \exp(z\sqrt{v})) \]

where

\[ v = \text{var}(\ln RR_1) = \frac{1 - p_{1|1}}{n_{11}} + \frac{1 - p_{1|2}}{n_{21}}. \]

and \( z \) is the 100(1 − α/2) percentile of the standard normal distribution. If either \( n_{11} \) or \( n_{21} \) is zero, the estimates are not computed.

PROC FREQ computes the column 2 relative risks in a similar manner.

**Cochran-Armitage Test for Trend**

The TREND option in the TABLES statement requests the Cochran-Armitage test for trend, which tests for trend in binomial proportions across levels of a single factor or covariate. This test is appropriate for a contingency table where one variable has two levels and the other variable is ordinal. The two-level variable represents the response, and the other variable represents an explanatory variable with ordered levels. When the contingency table has two columns and \( R \) rows, PROC FREQ tests for trend across the \( R \) levels of the row variable, and the binomial proportion is computed as the proportion of observations in the first column. When the table has two rows and \( C \) columns, PROC FREQ tests for trend across the \( C \) levels of the column variable, and the binomial proportion is computed as the proportion of observations in the first row.

The trend test is based upon the regression coefficient for the weighted linear regression of the binomial proportions on the scores of the levels of the explanatory variable. Refer to Margolin (1988) and Agresti (1990). If the contingency table has two columns and \( R \) rows, the trend test statistic is computed as

\[ T = \frac{\sum_{i=1}^{R} n_{i1}(R_i - \bar{R})}{\sqrt{p_{1}(1 - p_{1})s^2}}. \]
where

\[ s^2 = \sum_{i=1}^{R} n_i \cdot (R_i - \bar{R})^2 \]

The row scores \( R_i \) are determined by the value of the \texttt{SCORES=} option in the \texttt{TABLES} statement. By default, \texttt{PROC FREQ} uses table scores. For character variables, the table scores for the row variable are the row numbers (for example, 1 for the first row, 2 for the second row, and so on). For numeric variables, the table score for each row is the numeric value of the row level. When you perform the trend test, the explanatory variable may be numeric (for example, dose of a test substance), and these variable values may be appropriate scores. If the explanatory variable has ordinal levels that are not numeric, you can assign meaningful scores to the variable levels. Sometimes equidistant scores, such as the table scores for a character variable, may be appropriate. For more information on choosing scores for the trend test, refer to Margolin (1988).

The null hypothesis for the Cochran-Armitage test is no trend, which means that the binomial proportion \( p_{i1} = n_{i1}/n_i \) is the same for all levels of the explanatory variable. Under this null hypothesis, the trend test statistic is asymptotically distributed as a standard normal random variable. In addition to this asymptotic test, \texttt{PROC FREQ} can compute the exact trend test, which you request by specifying the \texttt{TREND} option in the \texttt{EXACT} statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

\texttt{PROC FREQ} computes one-sided and two-sided \( p \)-values for the trend test. When the test statistic is greater than its null hypothesis expected value of zero, \texttt{PROC FREQ} computes the right-sided \( p \)-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided \( p \)-value supports the alternative hypothesis of increasing trend in binomial proportions from row 1 to row \( R \). When the test statistic is less than or equal to zero, \texttt{PROC FREQ} outputs the left-sided \( p \)-value. A small left-sided \( p \)-value supports the alternative of decreasing trend.

The one-sided \( p \)-value \( P_1 \) can be expressed as

\[ P_1 = \text{Prob} ( \text{Trend Statistic} > T ) \quad \text{if} \quad T > 0 \]

\[ P_1 = \text{Prob} ( \text{Trend Statistic} < T ) \quad \text{if} \quad T \leq 0 \]

The two-sided \( p \)-value \( P_2 \) is computed as

\[ P_2 = \text{Prob} ( |\text{Trend Statistic}| > |T| ) \]

\textbf{Jonckheere-Terpstra Test}

The \texttt{JT} option in the \texttt{TABLES} statement requests the Jonckheere-Terpstra test, which is a nonparametric test for ordered differences among classes. It tests the null hypothesis that the distribution of the response variable does not differ among classes. It is
designed to detect alternatives of ordered class differences, which can be expressed as \( \tau_1 \leq \tau_2 \leq \cdots \leq \tau_R \) (or \( \tau_1 \geq \tau_2 \geq \cdots \geq \tau_R \)), with at least one of the inequalities being strict, where \( \tau_i \) denotes the effect of class \( i \). For such ordered alternatives, the Jonckheere-Terpstra test can be preferable to tests of more general class difference alternatives, such as the Kruskal–Wallis test (requested by the option WILCOXON in the NPAR1WAY procedure). Refer to Pirie (1983) and Hollander and Wolfe (1973) for more information about the Jonckheere-Terpstra test.

The Jonckheere-Terpstra test is appropriate for a contingency table in which an ordinal column variable represents the response. The row variable, which can be nominal or ordinal, represents the classification variable. The levels of the row variable should be ordered according to the ordering you want the test to detect. The order of variable levels is determined by the ORDER= option in the PROC FREQ statement. The default is ORDER=INTERNAL, which orders by unformatted values. If you specify ORDER=DATA, PROC FREQ orders values according to their order in the input data set. For more information on how to order variable levels, see the ORDER= option on page 1442.

The Jonckheere-Terpstra test statistic is computed by first forming \( R(R-1)/2 \) Mann-Whitney counts \( M_{i,i'} \), where \( i < i' \), for pairs of rows in the contingency table,

\[
M_{i,i'} = \begin{cases} 
\text{number of times } X_{i,j} < X_{i',j'}, \\
\quad j = 1, \ldots, n_i; \quad j' = 1, \ldots, n_{i'} 
\end{cases} + \frac{1}{2} \begin{cases} 
\text{number of times } X_{i,j} = X_{i',j'}, \\
\quad j = 1, \ldots, n_i; \quad j' = 1, \ldots, n_{i'} 
\end{cases}
\]

where \( X_{i,j} \) is response \( j \) in row \( i \). Then the Jonckheere-Terpstra test statistic is computed as

\[
J = \sum_{1 \leq i < i' \leq R} M_{i,i'}
\]

This test rejects the null hypothesis of no difference among classes for large values of \( J \). Asymptotic \( p \)-values for the Jonckheere-Terpstra test are obtained by using the normal approximation for the distribution of the standardized test statistic. The standardized test statistic is computed as

\[
J^* = \frac{J - E_0(J)}{\sqrt{\text{var}_0(J)}}
\]

where \( E_0(J) \) and \( \text{var}_0(J) \) are the expected value and variance of the test statistic under the null hypothesis.

\[
E_0(J) = \left( n^2 - \sum_i n_i^2 \right) / 4
\]

\[
\text{var}_0(J) = A/72 + B/\left[36n(n-1)(n-2)\right] + C/\left[8n(n-1)\right]
\]
where

\[ A = n(n - 1)(2n + 5) - \sum_{i} n_i(n_i - 1)(2n_i + 5) - \sum_{j} n_j(n_j - 1)(2n_j + 5) \]

\[ B = \left[ \sum_{i} n_i(n_i - 1)(n_i - 2) \right] \left[ \sum_{j} n_j(n_j - 1)(n_j - 2) \right] \]

\[ C = \left[ \sum_{i} n_i(n_i - 1) \right] \left[ \sum_{j} n_j(n_j - 1) \right] \]

In addition to this asymptotic test, PROC FREQ can compute the exact Jonckheere-Terpstra test, which you request by specifying the JT option in the EXACT statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

PROC FREQ computes one-sided and two-sided \( p \)-values for the Jonckheere-Terpstra test. When the standardized test statistic is greater than its null hypothesis expected value of zero, PROC FREQ computes the right-sided \( p \)-value, which is the probability of a larger value of the statistic occurring under the null hypothesis. A small right-sided \( p \)-value supports the alternative hypothesis of increasing order from row 1 to row \( R \). When the standardized test statistic is less than or equal to zero, PROC FREQ computes the left-sided \( p \)-value. A small left-sided \( p \)-value supports the alternative of decreasing order from row 1 to row \( R \).

The one-sided \( p \)-value \( P_1 \) can be expressed as

\[ P_1 = \text{Prob} ( \text{Std JT Statistic} > J^* ) \quad \text{if} \quad J^* > 0 \]

\[ P_1 = \text{Prob} ( \text{Std JT Statistic} < J^* ) \quad \text{if} \quad J^* \leq 0 \]

The two-sided \( p \)-value \( P_2 \) is computed as

\[ P_2 = \text{Prob} ( |\text{Std JT Statistic}| > |J^*| ) \]

**Tests and Measures of Agreement**

When you specify the AGREE option in the TABLES statement, PROC FREQ computes tests and measures of agreement for square tables (that is, for tables where the number of rows equals the number of columns). For two-way tables, these tests and measures include McNemar’s test for \( 2 \times 2 \) tables, Bowker’s test of symmetry, the simple kappa coefficient, and the weighted kappa coefficient. For multiple strata (\( n \)-way tables, where \( n > 2 \)), PROC FREQ computes the overall simple kappa coefficient and the overall weighted kappa coefficient, as well as tests for equal kappas (simple and weighted) among strata. Cochran’s \( Q \) is computed for multi-way tables when each variable has two levels, that is, for \( 2 \times 2 \times \cdots \times 2 \) tables.
PROC FREQ computes the kappa coefficients (simple and weighted), their asymptotic standard errors, and their confidence limits when you specify the AGREE option in the TABLES statement. If you also specify the KAPPA option in the TEST statement, then PROC FREQ computes the asymptotic test of the hypothesis that simple kappa equals zero. Similarly, if you specify the WTKAP option in the TEST statement, PROC FREQ computes the asymptotic test for weighted kappa.

In addition to the asymptotic tests described in this section, PROC FREQ computes the exact p-value for McNemar’s test when you specify the option MCNEM in the EXACT statement. For the kappa statistics, PROC FREQ computes the exact test of the hypothesis that kappa (or weighted kappa) equals zero when you specify the option KAPPA (or WTKAP) in the EXACT statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

The discussion of each test and measures of agreement provides the formulas that PROC FREQ uses to compute the AGREE statistics. For information on the use and interpretation of these statistics, refer to Agresti (1990), Agresti (1996), Fleiss (1981), and the other references cited for each statistic.

**McNemar’s Test**

PROC FREQ computes McNemar’s test for $2 \times 2$ tables when you specify the AGREE option. McNemar’s test is appropriate when you are analyzing data from matched pairs of subjects with a dichotomous (yes-no) response. It tests the null hypothesis of marginal homogeneity, or $p_{1} = p_{1}$. McNemar’s test is computed as

$$Q_M = \frac{(n_{12} - n_{21})^2}{n_{12} + n_{21}}$$

Under the null hypothesis, $Q_M$ has an asymptotic chi-square distribution with one degree of freedom. Refer to McNemar (1947), as well as the references cited in the preceding section. In addition to the asymptotic test, PROC FREQ also computes the exact p-value for McNemar’s test when you specify the MCNEM option in the EXACT statement.

**Bowker’s Test of Symmetry**

For Bowker’s test of symmetry, the null hypothesis is that the probabilities in the square table satisfy symmetry or that $p_{ij} = p_{ji}$ for all pairs of table cells. When there are more than two categories, Bowker’s test of symmetry is calculated as

$$Q_B = \sum_{i<j} (n_{ij} - n_{ji})^2 / n_{ij} + n_{ji}$$

For large samples, $Q_B$ has an asymptotic chi-square distribution with $R(R - 1)/2$ degrees of freedom under the null hypothesis of symmetry of the expected counts. Refer to Bowker (1948). For two categories, this test of symmetry is identical to McNemar’s test.
Simple Kappa Coefficient

The simple kappa coefficient, introduced by Cohen (1960), is a measure of interrater agreement:

\[ \hat{\kappa} = \frac{P_o - P_e}{1 - P_e} \]

where \( P_o = \sum_i p_{ii} \) and \( P_e = \sum_i p_i p_{.i} \). If the two response variables are viewed as two independent ratings of the \( n \) subjects, the kappa coefficient equals +1 when there is complete agreement of the raters. When the observed agreement exceeds chance agreement, kappa is positive, with its magnitude reflecting the strength of agreement. Although this is unusual in practice, kappa is negative when the observed agreement is less than chance agreement. The minimum value of kappa is between \(-1\) and \(0\), depending on the marginal proportions.

The asymptotic variance of the simple kappa coefficient can be estimated by the following, according to Fleiss, Cohen, and Everitt (1969):

\[ var = \frac{A + B - C}{(1 - P_e)^2 n} \]

where

\[ A = \sum_i p_{ii} \left[ 1 - (p_i + p_{.i})(1 - \hat{\kappa}) \right]^2 \]

\[ B = (1 - \hat{\kappa})^2 \sum_{i \neq j} p_{ij} (p_i + p_{.j})^2 \]

and

\[ C = \left( \hat{\kappa} - P_e (1 - \hat{\kappa}) \right)^2 \]

PROC FREQ computes confidence limits for the simple kappa coefficient according to

\[ \hat{\kappa} \pm \left( z_{\alpha/2} \times \sqrt{var} \right) \]

where \( z_{\alpha/2} \) is the 100(1 - \( \alpha \)/2) percentile of the standard normal distribution. The value of \( \alpha \) is determined by the value of the ALPHA= option, which, by default, equals 0.05 and produces 95% confidence limits.

To compute an asymptotic test for the kappa coefficient, PROC FREQ uses a standardized test statistic \( \hat{\kappa}^* \), which has an asymptotic standard normal distribution under
the null hypothesis that kappa equals zero. The standardized test statistic is computed as
\[
\hat{\kappa}^* = \frac{\hat{\kappa}}{\sqrt{\text{var}_0(\hat{\kappa})}}
\]
where \(\text{var}_0(\hat{\kappa})\) is the variance of the kappa coefficient under the null hypothesis.

\[
\text{var}_0(\hat{\kappa}) = \frac{P_e + P_e^2 - \sum_i p_i p_i (p_i + p_i)}{(1 - P_e)^2 n}
\]

Refer to Fleiss (1981).

In addition to the asymptotic test for kappa, PROC FREQ computes the exact test when you specify the KAPPA or AGREE option in the EXACT statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

### Weighted Kappa Coefficient

The weighted kappa coefficient is a generalization of the simple kappa coefficient, using weights to quantify the relative difference between categories. For \(2 \times 2\) tables, the weighted kappa coefficient equals the simple kappa coefficient. PROC FREQ displays the weighted kappa coefficient only for tables larger than \(2 \times 2\). PROC FREQ computes the weights from the column scores, using either the Cicchetti-Allison weight type or the Fleiss-Cohen weight type, both of which are described in the following section. The weights \(w_{ij}\) are constructed so that \(0 \leq w_{ij} < 1\) for all \(i \neq j\), \(w_{ii} = 1\) for all \(i\), and \(w_{ij} = w_{ji}\). The weighted kappa coefficient is defined as

\[
\hat{\kappa}_w = \frac{P_{o(w)} - P_{e(w)}}{1 - P_{e(w)}}
\]

where

\[
P_{o(w)} = \sum_i \sum_j w_{ij} p_{ij}
\]

and

\[
P_{e(w)} = \sum_i \sum_j w_{ij} p_i p_j
\]

The asymptotic variance of the weighted kappa coefficient can be estimated by the following, according to Fleiss, Cohen, and Everitt (1969):

\[
\text{var} = \frac{\sum_i \sum_j p_{ij} [w_{ij} - (w_i + w_j)(1 - \hat{\kappa}_w)]^2 - \left[\hat{\kappa}_w - P_{e(w)}(1 - \hat{\kappa}_w)\right]^2}{(1 - P_{e(w)})^2 n}
\]
where

\[ \overline{w}_i \cdot = \sum_j p_{i,j} w_{ij} \]

and

\[ \overline{w}_j \cdot = \sum_i p_{i,j} w_{ij} \]

PROC FREQ computes confidence limits for the weighted kappa coefficient according to

\[ \hat{\kappa}_w \pm \left( z_{\alpha/2} \times \sqrt{var} \right) \]

where \( z_{\alpha/2} \) is the 100(1 – \( \alpha/2 \)) percentile of the standard normal distribution. The value of \( \alpha \) is determined by the value of the \text{ALPHA=} option, which, by default, equals 0.05 and produces 95% confidence limits.

To compute an asymptotic test for the weighted kappa coefficient, PROC FREQ uses a standardized test statistic \( \hat{\kappa}^*_w \), which has an asymptotic standard normal distribution under the null hypothesis that weighted kappa equals zero. The standardized test statistic is computed as

\[ \hat{\kappa}^*_w = \frac{\hat{\kappa}_w}{\sqrt{\text{var}_0(\hat{\kappa}_w)}} \]

where \( \text{var}_0(\hat{\kappa}_w) \) is the variance of the weighted kappa coefficient under the null hypothesis.

\[ \text{var}_0(\hat{\kappa}_w) = \sum_i \sum_j p_{i,j} \left[ w_{ij} - (\overline{w}_i \cdot + \overline{w}_j \cdot) \right]^2 - P_e(w)^2 \]

(1 – \( P_e(w) \))^2 \( n \)

Refer to Fleiss (1981).

In addition to the asymptotic test for weighted kappa, PROC FREQ computes the exact test when you specify the \text{WTKAP} or \text{AGREE} option in the \text{EXACT} statement. See the section “Exact Statistics” beginning on page 1508 for information on exact tests.

**Weights**

PROC FREQ computes kappa coefficient weights using the column scores and one of two available weight types. The column scores are determined by the \text{SCORES=} option in the \text{TABLES} statement. The two available weight types are Cicchetti-Allison and Fleiss-Cohen, and PROC FREQ uses the Cicchetti-Allison type by default. If you specify (\text{WT=}\text{FC}) with the \text{AGREE} option, then PROC FREQ uses the Fleiss-Cohen weight type to construct kappa weights.
PROC FREQ computes Cicchetti-Allison kappa coefficient weights using a form similar to that given by Cicchetti and Allison (1971).

\[ w_{ij} = 1 - \frac{|C_i - C_j|}{C_C - C_1} \]

where \( C_i \) is the score for column \( i \), and \( C \) is the number of categories or columns.

You can specify the score type using the SCORES= option in the TABLES statement; if you do not specify the SCORES= option, PROC FREQ uses table scores. For numeric variables, table scores are the values of the numeric row and column headings. You can assign numeric values to the categories in a way that reflects their level of similarity. For example, suppose you have four categories and order them according to similarity. If you assign them values of 0, 2, 4, and 10, the following weights are used for computing the weighted kappa coefficient:

\[ w_{12} = 0.8, \quad w_{13} = 0.6, \quad w_{14} = 0, \quad w_{23} = 0.8, \quad w_{24} = 0.2, \quad \text{and} \quad w_{34} = 0.4. \]

Note that when there are only two categories (that is, \( C = 2 \)), the weighted kappa coefficient is identical to the simple kappa coefficient.

If you specify (WT=FC) with the AGREE option in the TABLES statement, PROC FREQ computes Fleiss-Cohen kappa coefficient weights using a form similar to that given by Fleiss and Cohen (1973).

\[ w_{ij} = 1 - \frac{(C_i - C_j)^2}{(C_C - C_1)^2} \]

For the preceding example, the weights used for computing the weighted kappa coefficient are:

\[ w_{12} = 0.96, \quad w_{13} = 0.84, \quad w_{14} = 0, \quad w_{23} = 0.96, \quad w_{24} = 0.36, \quad \text{and} \quad w_{34} = 0.64. \]

**Overall Kappa Coefficient**

When there are multiple strata, PROC FREQ combines the stratum-level estimates of kappa into an overall estimate of the supposed common value of kappa. Assume there are \( q \) strata, indexed by \( h = 1, 2, \ldots, q \), and let \( \text{var}(\hat{\kappa}_h) \) denote the squared standard error of \( \hat{\kappa}_h \). Then the estimate of the overall kappa, according to Fleiss (1981), is computed as

\[ \hat{\kappa}_{\text{overall}} = \sum_{h=1}^{q} \frac{\hat{\kappa}_h}{\text{var}(\hat{\kappa}_h)} / \sum_{h=1}^{q} \frac{1}{\text{var}(\hat{\kappa}_h)} \]

PROC FREQ computes an estimate of the overall weighted kappa in a similar manner.

**Tests for Equal Kappa Coefficients**

When there are multiple strata, the following chi-square statistic tests whether the stratum-level values of kappa are equal.

\[ Q_K = \sum_{h=1}^{q} \frac{(\hat{\kappa}_h - \hat{\kappa}_{\text{overall}})^2}{\text{var}(\hat{\kappa}_h)} \]
Under the null hypothesis of equal kappas over the $q$ strata, $Q_K$ has an asymptotic chi-square distribution with $q - 1$ degrees of freedom. PROC FREQ computes a test for equal weighted kappa coefficients in a similar manner.

**Cochran’s Q Test**

Cochran’s $Q$ is computed for multi-way tables when each variable has two levels, that is, for $2 \times 2 \cdot \cdot \cdot \times 2$ tables. Cochran’s $Q$ statistic is used to test the homogeneity of the one-dimensional margins. Let $m$ denote the number of variables and $N$ denote the total number of subjects. Then Cochran’s $Q$ statistic is computed as

$$Q_C = (m - 1) \frac{\sum_{j=1}^{m} T_j^2 - T^2}{mT - \sum_{k=1}^{N} S_k^2}$$

where $T_j$ is the number of positive responses for variable $j$, $T$ is the total number of positive responses over all variables, and $S_k$ is the number of positive responses for subject $k$. Under the null hypothesis, Cochran’s $Q$ is an approximate chi-square statistic with $m - 1$ degrees of freedom. Refer to Cochran (1950). When there are only two binary response variables ($m = 2$), Cochran’s $Q$ simplifies to McNemar’s test. When there are more than two response categories, you can test for marginal homogeneity using the repeated measures capabilities of the CATMOD procedure.

**Tables with Zero Rows and Columns**

The AGREE statistics are defined only for square tables, where the number of rows equals the number of columns. If the table is not square, PROC FREQ does not compute AGREE statistics. In the kappa statistic framework, where two independent raters assign ratings to each of $n$ subjects, suppose one of the raters does not use all possible $r$ rating levels. If the corresponding table has $r$ rows but only $r - 1$ columns, then the table is not square, and PROC FREQ does not compute the AGREE statistics. To create a square table in this situation, use the ZEROS option in the WEIGHT statement, which requests that PROC FREQ include observations with zero weights in the analysis. And input zero-weight observations to represent any rating levels that are not used by a rater, so that the input data set has at least one observation for each possible rater and rating combination. This includes all rating levels in the analysis, whether or not not all levels are actually assigned by both raters. The resulting table is a square table, $r \times r$, and so all AGREE statistics can be computed.

For more information, see the description of the ZEROS option. By default, PROC FREQ does not process observations that have zero weights, because these observations do not contribute to the total frequency count, and because any resulting zero-weight row or column causes many of the tests and measures of association to be undefined. However, kappa statistics are defined for tables with a zero-weight row or column, and the ZEROS option allows input of zero-weight observations so you can construct the tables needed to compute kappas.
**Cochran-Mantel-Haenszel Statistics**

For $n$-way crosstabulation tables, consider the following example:

```plaintext
proc freq;
  tables A*B*C*D / cmh;
run;
```

The CMH option in the TABLES statement gives a stratified statistical analysis of the relationship between $C$ and $D$, after controlling for $A$ and $B$. The stratified analysis provides a way to adjust for the possible confounding effects of $A$ and $B$ without being forced to estimate parameters for them. The analysis produces Cochran-Mantel-Haenszel statistics, and for $2 \times 2$ tables, it includes estimation of the common odds ratio, common relative risks, and the Breslow-Day test for homogeneity of the odds ratios.

Let the number of strata be denoted by $q$, indexing the strata by $h = 1, 2, \ldots, q$. Each stratum contains a contingency table with $X$ representing the row variable and $Y$ representing the column variable. For table $h$, denote the cell frequency in row $i$ and column $j$ by $n_{hij}$, with corresponding row and column marginal totals denoted by $n_{hi}$ and $n_{hj}$, and the overall stratum total by $n_h$.

Because the formulas for the Cochran-Mantel-Haenszel statistics are more easily defined in terms of matrices, the following notation is used. Vectors are presumed to be column vectors unless they are transposed ($'$).

- $n_{hi}' = (n_{h1i}, n_{h2i}, \ldots, n_{hc_i})$ (1 x $C$)
- $n_h' = (n_{h1}', n_{h2}', \ldots, n_{hR}')$ (1 x $RC$)
- $p_{hi} = \frac{n_{hi}}{n_h}$ (1 x 1)
- $p_{hj} = \frac{n_{hj}}{n_h}$ (1 x 1)
- $P_{h*} = (p_{h1}, p_{h2}, \ldots, p_{hR})$ (1 x $R$)
- $P_{h*}' = (p_{h1}', p_{h2}', \ldots, p_{hC}')$ (1 x $C$)

Assume that the strata are independent and that the marginal totals of each stratum are fixed. The null hypothesis, $H_0$, is that there is no association between $X$ and $Y$ in any of the strata. The corresponding model is the multiple hypergeometric; this implies that, under $H_0$, the expected value and covariance matrix of the frequencies are, respectively,

$$m_h = E[n_h | H_0] = n_h (P_{h*} \otimes P_{h*})$$

and

$$\text{var}[n_h | H_0] = c \left( (DP_{h*} - P_{h*}P_{h*}') \otimes (DP_{h*} - P_{h*}P_{h*}') \right)$$
where
\[ c = \frac{n_h^2}{n_h - 1} \]
and where \( \otimes \) denotes Kronecker product multiplication and \( D_a \) is a diagonal matrix with elements of \( a \) on the main diagonal.

The generalized CMH statistic (Landis, Heyman, and Koch 1978) is defined as
\[ Q_{\text{CMH}} = G^t V_G^{-1} G \]
where
\[ G = \sum_h B_h (n_h - m_h) \]
\[ V_G = \sum_h B_h \left( \text{Var}(n_h | H_0) \right) B'_h \]
and where
\[ B_h = C_h \otimes R_h \]
is a matrix of fixed constants based on column scores \( C_h \) and row scores \( R_h \). When the null hypothesis is true, the CMH statistic has an asymptotic chi-square distribution with degrees of freedom equal to the rank of \( B_h \). If \( V_G \) is found to be singular, PROC FREQ prints a message and sets the value of the CMH statistic to missing.

PROC FREQ computes three CMH statistics using this formula for the generalized CMH statistic, with different row and column score definitions for each statistic. The CMH statistics that PROC FREQ computes are the correlation statistic, the ANOVA (row mean scores) statistic, and the general association statistic. These statistics test the null hypothesis of no association against different alternative hypotheses. The following sections describe the computation of these CMH statistics.

**CAUTION:** The CMH statistics have low power for detecting an association in which the patterns of association for some of the strata are in the opposite direction of the patterns displayed by other strata. Thus, a nonsignificant CMH statistic suggests either that there is no association or that no pattern of association has enough strength or consistency to dominate any other pattern.

**Correlation Statistic**

The correlation statistic, popularized by Mantel and Haenszel (1959) and Mantel (1963), has one degree of freedom and is known as the Mantel-Haenszel statistic.

The alternative hypothesis for the correlation statistic is that there is a linear association between \( X \) and \( Y \) in at least one stratum. If either \( X \) or \( Y \) does not lie on an ordinal (or interval) scale, then this statistic is not meaningful.
To compute the correlation statistic, PROC FREQ uses the formula for the generalized CMH statistic with the row and column scores determined by the SCORES= option in the TABLES statement. See the section “Scores” on page 1468 for more information on the available score types. The matrix of row scores $R_h$ has dimension $1 \times R$, and the matrix of column scores $C_h$ has dimension $1 \times C$.

When there is only one stratum, this CMH statistic reduces to $(n - 1)r^2$, where $r$ is the Pearson correlation coefficient between $X$ and $Y$. When nonparametric (RANK or RIDIT) scores are specified, then the statistic reduces to $(n - 1)r_s^2$, where $r_s$ is the Spearman rank correlation coefficient between $X$ and $Y$. When there is more than one stratum, then this CMH statistic becomes a stratum-adjusted correlation statistic.

**ANOVA (Row Mean Scores) Statistic**

The ANOVA statistic can be used only when the column variable $Y$ lies on an ordinal (or interval) scale so that the mean score of $Y$ is meaningful. For the ANOVA statistic, the mean score is computed for each row of the table, and the alternative hypothesis is that, for at least one stratum, the mean scores of the $R$ rows are unequal. In other words, the statistic is sensitive to location differences among the $R$ distributions of $Y$.

The matrix of column scores $C_h$ has dimension $1 \times C$, the column scores are determined by the SCORES= option.

The matrix of row scores $R_h$ has dimension $(R - 1) \times R$ and is created internally by PROC FREQ as

$$R_h = [I_{R-1}, -J_{R-1}]$$

where $I_{R-1}$ is an identity matrix of rank $R - 1$, and $J_{R-1}$ is an $(R - 1) \times 1$ vector of ones. This matrix has the effect of forming $R - 1$ independent contrasts of the $R$ mean scores.

When there is only one stratum, this CMH statistic is essentially an analysis of variance (ANOVA) statistic in the sense that it is a function of the variance ratio $F$ statistic that would be obtained from a one-way ANOVA on the dependent variable $Y$. If nonparametric scores are specified in this case, then the ANOVA statistic is a Kruskal-Wallis test.

If there is more than one stratum, then this CMH statistic corresponds to a stratum-adjusted ANOVA or Kruskal-Wallis test. In the special case where there is one subject per row and one subject per column in the contingency table of each stratum, this CMH statistic is identical to Friedman’s chi-square. See Example 29.8 on page 1546 for an illustration.

**General Association Statistic**

The alternative hypothesis for the general association statistic is that, for at least one stratum, there is some kind of association between $X$ and $Y$. This statistic is always interpretable because it does not require an ordinal scale for either $X$ or $Y$. 
For the general association statistic, the matrix $R_h$ is the same as the one used for the ANOVA statistic. The matrix $C_h$ is defined similarly as

$$C_h = [I_{C-1}, -J_{C-1}]$$

PROC FREQ generates both score matrices internally. When there is only one stratum, then the general association CMH statistic reduces to $Q_P(n - 1)/n$, where $Q_P$ is the Pearson chi-square statistic. When there is more than one stratum, then the CMH statistic becomes a stratum-adjusted Pearson chi-square statistic. Note that a similar adjustment can be made by summing the Pearson chi-squares across the strata. However, the latter statistic requires a large sample size in each stratum to support the resulting chi-square distribution with $q(R - 1)(C - 1)$ degrees of freedom. The CMH statistic requires only a large overall sample size since it has only $(R - 1)(C - 1)$ degrees of freedom.

Refer to Cochran (1954); Mantel and Haenszel (1959); Mantel (1963); Birch (1965); Landis, Heyman, and Koch (1978).

**Adjusted Odds Ratio and Relative Risk Estimates**

The CMH option provides adjusted odds ratio and relative risk estimates for stratified $2 \times 2$ tables. For each of these measures, PROC FREQ computes the Mantel-Haenszel estimate and the logit estimate. These estimates apply to $n$-way table requests in the TABLES statement, when the row and column variables both have only two levels.

For example,

```plaintext
proc freq;
  tables A*B*C*D / cmh;
run;
```

In this example, if the row and columns variables $C$ and $D$ both have two levels, PROC FREQ provides odds ratio and relative risk estimates, adjusting for the confounding variables $A$ and $B$.

The choice of an appropriate measure depends on the study design. For case-control (retrospective) studies, the odds ratio is appropriate. For cohort (prospective) or cross-sectional studies, the relative risk is appropriate. See the section “Odds Ratio and Relative Risks for 2 x 2 Tables” beginning on page 1488 for more information on these measures.

Throughout this section, $z$ denotes the $100(1 - \alpha/2)$ percentile of the standard normal distribution.

**Odds Ratio, Case-Control Studies**

**Mantel-Haenszel Estimator**

The Mantel-Haenszel estimate of the common odds ratio is computed as

$$OR_{MH} = \frac{\sum_h n_{h11} n_{h22}/n_h}{\sum_h n_{h12} n_{h21}/n_h}$$
It is always computed unless the denominator is zero. Refer to Mantel and Haenszel (1959) and Agresti (1990).

Using the estimated variance for $\log(OR_{MH})$ given by Robins, Breslow, and Greenland (1986), PROC FREQ computes the corresponding $100(1 - \alpha)$% confidence limits for the odds ratio as

$$
( OR_{MH} \cdot \exp(-z\hat{\sigma}), OR_{MH} \cdot \exp(z\hat{\sigma}) )
$$

where

$$
\hat{\sigma}^2 = \text{var} [ \ln(OR_{MH}) ]
$$

$$
= \frac{\sum_h (n_{h11} + n_{h22})(n_{h11} n_{h22})/n_h^2}{2 \left( \sum_h n_{h11} n_{h22}/n_h \right)^2}
+ \frac{\sum_h [(n_{h11} + n_{h22})(n_{h12} n_{h21}) + (n_{h12} + n_{h21})(n_{h11} n_{h22})]/n_h^2}{2 \left( \sum_h n_{h11} n_{h22}/n_h \right) \left( \sum_h n_{h12} n_{h21}/n_h \right)}
+ \frac{\sum_h (n_{h12} + n_{h21})(n_{h12} n_{h21})/n_h^2}{2 \left( \sum_h n_{h12} n_{h21}/n_h \right)^2}
$$

Note that the Mantel-Haenszel odds ratio estimator is less sensitive to small $n_h$ than the logit estimator.

**Logit Estimator**

The adjusted logit estimate of the odds ratio (Woolf 1955) is computed as

$$
OR_L = \exp \left( \frac{\sum_h w_h \ln(OR_h)}{\sum_h w_h} \right)
$$

and the corresponding $100(1 - \alpha)$% confidence limits are

$$
\left( OR_L \cdot \exp \left( \frac{-z}{\sqrt{\sum_h w_h}} \right), OR_L \cdot \exp \left( \frac{z}{\sqrt{\sum_h w_h}} \right) \right)
$$

where $OR_h$ is the odds ratio for stratum $h$, and

$$
w_h = \frac{1}{\text{var}(\ln OR_h)}
$$

If any cell frequency in a stratum $h$ is zero, then PROC FREQ adds 0.5 to each cell of the stratum before computing $OR_h$ and $w_h$ (Haldane 1955), and prints a warning.

**Exact Confidence Limits for the Common Odds Ratio**

When you specify the COMOR option in the EXACT statement, PROC FREQ computes exact confidence limits for the common odds ratio for stratified $2 \times 2$ tables.
This computation assumes that the odds ratio is constant over all the $2 \times 2$ tables. Exact confidence limits are constructed from the distribution of $S = \sum_h n_{h11}$, conditional on the marginal totals of the $2 \times 2$ tables.

Because this is a discrete problem, the confidence coefficient for these exact confidence limits is not exactly $1 - \alpha$ but is at least $1 - \alpha$. Thus, these confidence limits are conservative. Refer to Agresti (1992).

PROC FREQ computes exact confidence limits for the common odds ratio with an algorithm based on that presented by Vollset, Hirji, and Elashoff (1991). Refer also to Mehta, Patel, and Gray (1985).

Conditional on the marginal totals of $2 \times 2$ table $h$, let the random variable $S_h$ denote the frequency of table cell $(1,1)$. Given the row totals $n_{h1}$ and $n_{h2}$ and column totals $n_{h1}$ and $n_{h2}$, the lower and upper bounds for $S_h$ are $l_h$ and $u_h$,

$$l_h = \max \left( 0, n_{h1} - n_{h2} \right)$$

$$u_h = \min \left( n_{h1}, n_{h1} \right)$$

Let $C_{sh}$ denote the hypergeometric coefficient,

$$C_{sh} = \binom{n_{h1}}{s_h} \binom{n_{h2}}{n_{h1} - s_h}$$

and let $\phi$ denote the common odds ratio. Then the conditional distribution of $S_h$ is

$$P( S_h = s_h \mid n_{11}, n_{12}, n_{21}, n_{22} ) = \frac{C_{sh} \phi^{s_h}}{\sum_{x = l_h}^{u_h} C_x \phi^x}$$

Summing over all the $2 \times 2$ tables, $S = \sum_h S_h$, and the lower and upper bounds of $S$ are $l$ and $u$,

$$l = \sum_h l_h \quad \text{and} \quad u = \sum_h u_h$$

The conditional distribution of the sum $S$ is

$$P( S = s \mid n_{h1}, n_{h1}, n_{h2}; h = 1, \ldots, q ) = \frac{C_s \phi^s}{\sum_{x = l}^{u} C_x \phi^x}$$

where

$$C_s = \sum_{s_1 + \ldots + s_q = s} \left( \prod_h C_{sh} \right)$$
Let $s_0$ denote the observed sum of cell (1,1) frequencies over the $q$ tables. The following two equations are solved iteratively for lower and upper confidence limits for the common odds ratio, $\phi_1$ and $\phi_2$,

$$\sum_{x = s_0}^{x = u} C_x \frac{\phi_1^x}{\sum_{x = l}^{x = u} C_x \phi_1^x} = \alpha/2$$

$$\sum_{x = l}^{x = s_0} C_x \frac{\phi_2^x}{\sum_{x = l}^{x = u} C_x \phi_2^x} = \alpha/2$$

When the observed sum $s_0$ equals the lower bound $l$, then PROC FREQ sets the lower exact confidence limit to zero and determines the upper limit with level $\alpha$. Similarly, when the observed sum $s_0$ equals the upper bound $u$, then PROC FREQ sets the upper exact confidence limit to infinity and determines the lower limit with level $\alpha$.

When you specify the COMOR option in the EXACT statement, PROC FREQ also computes the exact test that the common odds ratio equals one. Setting $\phi = 1$, the conditional distribution of the sum $S$ under the null hypothesis becomes

$$P_0(S = s \mid n_{h1,1}, n_{h1,2}, n_{h2,1}, \ldots, n_{h2,q}; h = 1, \ldots, q) = \frac{C_s}{\sum_{x = l}^{x = u} C_x}$$

The point probability for this exact test is the probability of the observed sum $s_0$ under the null hypothesis, conditional on the marginals of the stratified $2 \times 2$ tables, and is denoted by $P_0(s_0)$. The expected value of $S$ under the null hypothesis is

$$E_0(S) = \frac{\sum_{x = l}^{x = u} x C_x}{\sum_{x = l}^{x = u} C_x}$$

The one-sided exact $p$-value is computed from the conditional distribution as $P_0(S \geq s_0)$ or $P_0(S \leq s_0)$, depending on whether the observed sum $s_0$ is greater or less than $E_0(S)$.

$$P_1 = P_0(S \geq s_0) = \frac{\sum_{x = s_0}^{x = u} C_x}{\sum_{x = l}^{x = u} C_x} \quad \text{if } s_0 > E_0(S)$$

$$P_1 = P_0(S \leq s_0) = \frac{\sum_{x = l}^{x = s_0} C_x}{\sum_{x = l}^{x = u} C_x} \quad \text{if } s_0 \leq E_0(S)$$

PROC FREQ computes two-sided $p$-values for this test according to three different definitions. A two-sided $p$-value is computed as twice the one-sided $p$-value, setting the result equal to one if it exceeds one.

$$P_2 = 2 \times P_1$$
Additionally, a two-sided $p$-value is computed as the sum of all probabilities less than or equal to the point probability of the observed sum $s_0$, summing over all possible values of $s$, $l \leq s \leq u$.

$$P^b_2 = \sum_{l \leq s \leq u: P_0(s) \leq P_0(s_0)} P_0(s)$$

Also, a two-sided $p$-value is computed as the sum of the one-sided $p$-value and the corresponding area in the opposite tail of the distribution, equidistant from the expected value.

$$P^c_2 = P_0 (|S - E_0(S)| \geq |s_0 - E_0(S)|)$$

**Relative Risks, Cohort Studies**

**Mantel-Haenszel Estimator**

The Mantel-Haenszel estimate of the common relative risk for column 1 is computed as

$$RR_{MH} = \frac{\sum_h n_{h11} n_{h21} / n_h}{\sum_h n_{h21} n_{h11} / n_h}$$

It is always computed unless the denominator is zero. Refer to Mantel and Haenszel (1959) and Agresti (1990).

Using the estimated variance for $\log(RR_{MH})$ given by Greenland and Robins (1985), PROC FREQ computes the corresponding 100$(1 - \alpha)$% confidence limits for the relative risk as

$$\left( RR_{MH} \cdot \exp(-z\hat{\sigma}), RR_{MH} \cdot \exp(z\hat{\sigma}) \right)$$

where

$$\hat{\sigma}^2 = \text{var} [\ln(RR_{MH})]$$

$$= \frac{\sum_h (n_{h11} n_{h21} n_{h1} - n_{h11} n_{h21} n_h)/n_h^2}{\left(\sum_h n_{h11} n_{h21}/n_h\right) \left(\sum_h n_{h21} n_{h11}/n_h\right)}$$

**Logit Estimator**

The adjusted logit estimate of the common relative risk for column 1 is computed as

$$RR_L = \exp\left(\frac{\sum_h w_h \ln RR_h}{\sum w_h}\right)$$

and the corresponding 100$(1 - \alpha)$% confidence limits are

$$\left( RR_L \exp\left(\frac{-z}{\sqrt{\sum h w_h}}\right), RR_L \exp\left(\frac{z}{\sqrt{\sum h w_h}}\right) \right)$$
where \( RR_h \) is the column 1 relative risk estimate for stratum \( h \), and

\[
wh = \frac{1}{var(\ln RR_h)}
\]

If \( n_{h11} \) or \( n_{h21} \) is zero, then PROC FREQ adds 0.5 to each cell of the stratum before computing \( RR_h \) and \( w_h \), and prints a warning. Refer to Kleinbaum, Kupper, and Morgenstern (1982, Sections 17.4 and 17.5).

**Breslow-Day Test for Homogeneity of the Odds Ratios**

When you specify the CMH option, PROC FREQ computes the Breslow-Day test for stratified analysis of \( 2 \times 2 \) tables. It tests the null hypothesis that the odds ratios for the \( q \) strata are all equal. When the null hypothesis is true, the statistic has approximately a chi-square distribution with \( q - 1 \) degrees of freedom. Refer to Breslow and Day (1980) and Agresti (1996).

The Breslow-Day statistic is computed as

\[
Q_{BD} = \sum_h \frac{(n_{h11} - E(n_{h11} | OR_{MH}))^2}{var(n_{h11} | OR_{MH})}
\]

where \( E \) and \( var \) denote expected value and variance, respectively. The summation does not include any table with a zero row or column. If \( OR_{MH} \) equals zero or if it is undefined, then PROC FREQ does not compute the statistic and prints a warning message.

For the Breslow-Day test to be valid, the sample size should be relatively large in each stratum, and at least 80% of the expected cell counts should be greater than 5. Note that this is a stricter sample size requirement than the requirement for the Cochran-Mantel-Haenszel test for \( q \times 2 \times 2 \) tables, in that each stratum sample size (not just the overall sample size) must be relatively large. Even when the Breslow-Day test is valid, it may not be very powerful against certain alternatives, as discussed in Breslow and Day (1980).

If you specify the BDT option, PROC FREQ computes the Breslow-Day test with Tarone’s adjustment, which subtracts an adjustment factor from \( Q_{BD} \) to make the resulting statistic asymptotically chi-square.

\[
Q_{BDT} = Q_{BD} - \frac{\left( \sum_h (n_{h11} - E(n_{h11} | OR_{MH})) \right)^2}{\sum_h var(n_{h11} | OR_{MH})}
\]

Refer to Tarone (1985), Jones et al. (1989), and Breslow (1996).

**Exact Statistics**

Exact statistics can be useful in situations where the asymptotic assumptions are not met, and so the asymptotic \( p \)-values are not close approximations for the true \( p \)-values. Standard asymptotic methods involve the assumption that the test statistic follows a particular distribution when the sample size is sufficiently large. When the
sample size is not large, asymptotic results may not be valid, with the asymptotic $p$-values differing perhaps substantially from the exact $p$-values. Asymptotic results may also be unreliable when the distribution of the data is sparse, skewed, or heavily tied. Refer to Agresti (1996) and Bishop, Fienberg, and Holland (1975). Exact computations are based on the statistical theory of exact conditional inference for contingency tables, reviewed by Agresti (1992).

In addition to computation of exact $p$-values, PROC FREQ provides the option of estimating exact $p$-values by Monte Carlo simulation. This can be useful for problems that are so large that exact computations require a great amount of time and memory, but for which asymptotic approximations may not be sufficient.

PROC FREQ provides exact $p$-values for the following tests for two-way tables: Pearson chi-square, likelihood-ratio chi-square, Mantel-Haenszel chi-square, Fisher’s exact test, Jonckheere-Terpstra test, Cochran-Armitage test for trend, and McNemar’s test. PROC FREQ also computes exact $p$-values for tests of hypotheses that the following statistics equal zero: Pearson correlation coefficient, Spearman correlation coefficient, simple kappa coefficient, and weighted kappa coefficient. Additionally, PROC FREQ computes exact confidence limits for the odds ratio for $2 \times 2$ tables. For stratified $2 \times 2$ tables, PROC FREQ computes exact confidence limits for the common odds ratio, as well as an exact test that the common odds ratio equals one. For one-way frequency tables, PROC FREQ provides the exact chi-square goodness-of-fit test (for equal proportions or for proportions or frequencies that you specify). Also for one-way tables, PROC FREQ provides exact confidence limits for the binomial proportion and an exact test for the binomial proportion value.

The following sections summarize the exact computational algorithms, define the exact $p$-values that PROC FREQ computes, discuss the computational resource requirements, and describe the Monte Carlo estimation option.

**Computational Algorithms**

PROC FREQ computes exact $p$-values for general $R \times C$ tables using the network algorithm developed by Mehta and Patel (1983). This algorithm provides a substantial advantage over direct enumeration, which can be very time-consuming and feasible only for small problems. Refer to Agresti (1992) for a review of algorithms for computation of exact $p$-values, and refer to Mehta, Patel, and Tsiatis (1984) and Mehta, Patel, and Senchaudhuri (1991) for information on the performance of the network algorithm.

The reference set for a given contingency table is the set of all contingency tables with the observed marginal row and column sums. Corresponding to this reference set, the network algorithm forms a directed acyclic network consisting of nodes in a number of stages. A path through the network corresponds to a distinct table in the reference set. The distances between nodes are defined so that the total distance of a path through the network is the corresponding value of the test statistic. At each node, the algorithm computes the shortest and longest path distances for all the paths that pass through that node. For statistics that can be expressed as a linear combination of cell frequencies multiplied by increasing row and column scores, PROC FREQ computes shortest and longest path distances using the algorithm given in Agresti, Mehta, and Patel (1990). For statistics of other forms, PROC FREQ computes an
upper bound for the longest path and a lower bound for the shortest path, following
the approach of Valz and Thompson (1994).

The longest and shortest path distances or bounds for a node are compared to the
value of the test statistic to determine whether all paths through the node contribute
to the $p$-value, none of the paths through the node contribute to the $p$-value, or neither
of these situations occur. If all paths through the node contribute, the $p$-value is incre-
mented accordingly, and these paths are eliminated from further analysis. If no paths
contribute, these paths are eliminated from the analysis. Otherwise, the algorithm
continues, still processing this node and the associated paths. The algorithm finishes
when all nodes have been accounted for, incrementing the $p$-value accordingly, or
eliminated.

In applying the network algorithm, PROC FREQ uses full precision to represent all
statistics, row and column scores, and other quantities involved in the computations.
Although it is possible to use rounding to improve the speed and memory require-
ments of the algorithm, PROC FREQ does not do this since it can result in reduced
accuracy of the $p$-values.

For one-way tables, PROC FREQ computes the exact chi-square goodness-of-fit test
by the method of Radlow and Alf (1975). PROC FREQ generates all possible one-
way tables with the observed total sample size and number of categories. For each
possible table, PROC FREQ compares its chi-square value with the value for the ob-
served table. If the table’s chi-square value is greater than or equal to the observed
chi-square, PROC FREQ increments the exact $p$-value by the probability of that ta-
ble, which is calculated under the null hypothesis using the multinomial frequency
distribution. By default, the null hypothesis states that all categories have equal pro-
portions. If you specify null hypothesis proportions or frequencies using the TESTP=
or TESTF= option in the TABLES statement, then PROC FREQ calculates the exact
chi-square test based on that null hypothesis.

For binomial proportions in one-way tables, PROC FREQ computes exact confidence
limits using the $F$ distribution method given in Collett (1991) and also described by
Leemis and Trivedi (1996). PROC FREQ computes the exact test for a binomial
proportion ($H_0: p = p_0$) by summing binomial probabilities over all alternatives. See
the section “Binomial Proportion” on page 1484 for details. By default, PROC FREQ
uses $p_0 = 0.5$ as the null hypothesis proportion. Alternatively, you can specify the
null hypothesis proportion with the P= option in the TABLES statement.

See the section “Odds Ratio and Relative Risks for 2 x 2 Tables” on page 1488 for
details on computation of exact confidence limits for the odds ratio for $2 \times 2$ tables.
See the section “Exact Confidence Limits for the Common Odds Ratio” on page
1504 for details on computation of exact confidence limits for the common odds ratio
for stratified $2 \times 2$ tables.

**Definition of $p$-Values**

For several tests in PROC FREQ, the test statistic is nonnegative, and large values of
the test statistic indicate a departure from the null hypothesis. Such tests include the
Pearson chi-square, the likelihood-ratio chi-square, the Mantel-Haenszel chi-square,
Fisher’s exact test for tables larger than $2 \times 2$ tables, McNemar’s test, and the one-
way chi-square goodness-of-fit test. The exact $p$-value for these nondirectional tests is the sum of probabilities for those tables having a test statistic greater than or equal to the value of the observed test statistic.

There are other tests where it may be appropriate to test against either a one-sided or a two-sided alternative hypothesis. For example, when you test the null hypothesis that the true parameter value equals 0 ($T = 0$), the alternative of interest may be one-sided ($T \leq 0$, or $T \geq 0$) or two-sided ($T \neq 0$). Such tests include the Pearson correlation coefficient, Spearman correlation coefficient, Jonckheere-Terpstra test, Cochran-Armitage test for trend, simple kappa coefficient, and weighted kappa coefficient. For these tests, PROC FREQ outputs the right-sided $p$-value when the observed value of the test statistic is greater than its expected value. The right-sided $p$-value is the sum of probabilities for those tables having a test statistic greater than or equal to the observed test statistic. Otherwise, when the test statistic is less than or equal to its expected value, PROC FREQ outputs the left-sided $p$-value. The left-sided $p$-value is the sum of probabilities for those tables having a test statistic less than or equal to the one observed. The one-sided $p$-value $P_1$ can be expressed as

$$P_1 = \text{Prob} \left( \text{Test Statistic} \geq t \right) \quad \text{if} \quad t > E_0(T)$$

$$P_1 = \text{Prob} \left( \text{Test Statistic} \leq t \right) \quad \text{if} \quad t \leq E_0(T)$$

where $t$ is the observed value of the test statistic and $E_0(T)$ is the expected value of the test statistic under the null hypothesis. PROC FREQ computes the two-sided $p$-value as the sum of the one-sided $p$-value and the corresponding area in the opposite tail of the distribution of the statistic, equidistant from the expected value. The two-sided $p$-value $P_2$ can be expressed as

$$P_2 = \text{Prob} \left( | \text{Test Statistic} - E_0(T) | \geq | t - E_0(T) | \right)$$

If you specify the POINT option in the EXACT statement, PROC FREQ also displays exact point probabilities for the test statistics. The exact point probability is the exact probability that the test statistic equals the observed value.

**Computational Resources**

PROC FREQ uses relatively fast and efficient algorithms for exact computations. These recently developed algorithms, together with improvements in computer power, make it feasible now to perform exact computations for data sets where previously only asymptotic methods could be applied. Nevertheless, there are still large problems that may require a prohibitive amount of time and memory for exact computations, depending on the speed and memory available on your computer. For large problems, consider whether exact methods are really needed or whether asymptotic methods might give results quite close to the exact results, while requiring much less computer time and memory. When asymptotic methods may not be sufficient for such large problems, consider using Monte Carlo estimation of exact $p$-values, as described in the section “Monte Carlo Estimation” on page 1512.
A formula does not exist that can predict in advance how much time and memory are needed to compute an exact \( p \)-value for a certain problem. The time and memory required depend on several factors, including which test is being performed, the total sample size, the number of rows and columns, and the specific arrangement of the observations into table cells. Generally, larger problems (in terms of total sample size, number of rows, and number of columns) tend to require more time and memory. Additionally, for a fixed total sample size, time and memory requirements tend to increase as the number of rows and columns increases, since this corresponds to an increase in the number of tables in the reference set. Also for a fixed sample size, time and memory requirements increase as the marginal row and column totals become more homogeneous. Refer to Agresti, Mehta, and Patel (1990) and Gail and Mantel (1977).

At any time while PROC FREQ is computing exact \( p \)-values, you can terminate the computations by pressing the system interrupt key sequence (refer to the SAS Companion for your system) and choosing to stop computations. After you terminate exact computations, PROC FREQ completes all other remaining tasks. The procedure produces the requested output and reports missing values for any exact \( p \)-values that were not computed by the time of termination.

You can also use the MAXTIME= option in the EXACT statement to limit the amount of time PROC FREQ uses for exact computations. You specify a MAXTIME= value that is the maximum amount of clock time (in seconds) that PROC FREQ can use to compute an exact \( p \)-value. If PROC FREQ does not finish computing an exact \( p \)-value within that time, it terminates the computation and completes all other remaining tasks.

**Monte Carlo Estimation**

If you specify the option MC in the EXACT statement, PROC FREQ computes Monte Carlo estimates of the exact \( p \)-values instead of directly computing the exact \( p \)-values. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations may not be sufficient. To describe the precision of each Monte Carlo estimate, PROC FREQ provides the asymptotic standard error and \( 100(1-\alpha)\% \) confidence limits. The confidence level \( \alpha \) is determined by the ALPHA= option in the EXACT statement, which, by default, equals 0.01, and produces 99% confidence limits. The N=n option in the EXACT statement specifies the number of samples that PROC FREQ uses for Monte Carlo estimation; the default is 10000 samples. You can specify a larger value for \( n \) to improve the precision of the Monte Carlo estimates. Because larger values of \( n \) generate more samples, the computation time increases. Alternatively, you can specify a smaller value of \( n \) to reduce the computation time.

To compute a Monte Carlo estimate of an exact \( p \)-value, PROC FREQ generates a random sample of tables with the same total sample size, row totals, and column totals as the observed table. PROC FREQ uses the algorithm of Agresti, Wackerly, and Boyett (1979), which generates tables in proportion to their hypergeometric probabilities conditional on the marginal frequencies. For each sample table, PROC FREQ computes the value of the test statistic and compares it to the value for the observed table. When estimating a right-sided \( p \)-value, PROC FREQ counts all sample tables
for which the test statistic is greater than or equal to the observed test statistic. Then the $p$-value estimate equals the number of these tables divided by the total number of tables sampled.

\[ \hat{P}_{MC} = \frac{M}{N} \]
\[ M = \text{number of samples with } (\text{Test Statistic} \geq t) \]
\[ N = \text{total number of samples} \]
\[ t = \text{observed Test Statistic} \]

PROC FREQ computes left-sided and two-sided $p$-value estimates in a similar manner. For left-sided $p$-values, PROC FREQ evaluates whether the test statistic for each sampled table is less than or equal to the observed test statistic. For two-sided $p$-values, PROC FREQ examines the sample test statistics according to the expression for $P_2$ given in the section “Asymptotic Tests” on page 1475. The variable $M$ is a binomially distributed variable with $N$ trials and success probability $p$. It follows that the asymptotic standard error of the Monte Carlo estimate is

\[ se(\hat{P}_{MC}) = \sqrt{\hat{P}_{MC}(1 - \hat{P}_{MC})/(N - 1)} \]

PROC FREQ constructs asymptotic confidence limits for the $p$-values according to

\[ \hat{P}_{MC} \pm z_{\alpha/2} \cdot se(\hat{P}_{MC}) \]

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution, and the confidence level $\alpha$ is determined by the ALPHA= option in the EXACT statement.

When the Monte Carlo estimate $\hat{P}_{MC}$ equals 0, then PROC FREQ computes the confidence limits for the $p$-value as

\[ (0, \ 1 - \alpha^{(1/N)}) \]

When the Monte Carlo estimate $\hat{P}_{MC}$ equals 1, then PROC FREQ computes the confidence limits as

\[ (\alpha^{(1/N)}, \ 1) \]

**Computational Resources**

For each variable in a table request, PROC FREQ stores all of the levels in memory. If all variables are numeric and not formatted, this requires about 84 bytes for each variable level. When there are character variables or formatted numeric variables, the memory that is required depends on the formatted variable lengths, with longer formatted lengths requiring more memory. The number of levels for each variable is limited only by the largest integer that your operating environment can store.
For any single crosstabulation table requested, PROC FREQ builds the entire table in memory, regardless of whether the table has zero cell counts. Thus, if the numeric variables A, B, and C each have 10 levels, PROC FREQ requires 2520 bytes to store the variable levels for the table request A*B*C, as follows:

\[3 \text{ variables} \times 10 \text{ levels/variable} \times 84 \text{ bytes/level}\]

In addition, PROC FREQ requires 8000 bytes to store the table cell frequencies

\[1000 \text{ cells} \times 8 \text{ bytes/cell}\]

even though there may be only 10 observations.

When the variables have many levels or when there are many multiway tables, your computer may not have enough memory to construct the tables. If PROC FREQ runs out of memory while constructing tables, it stops collecting levels for the variable with the most levels and returns the memory that is used by that variable. The procedure then builds the tables that do not contain the disabled variables.

If there is not enough memory for your table request and if increasing the available memory is impractical, you can reduce the number of multiway tables or variable levels. If you are not using the CMH or AGREE option in the TABLES statement to compute statistics across strata, reduce the number of multiway tables by using PROC SORT to sort the data set by one or more of the variables or by using the DATA step to create an index for the variables. Then remove the sorted or indexed variables from the TABLES statement and include a BY statement that uses these variables. You can also reduce memory requirements by using a FORMAT statement in the PROC FREQ step to reduce the number of levels. Additionally, reducing the formatted variable lengths reduces the amount of memory that is needed to store the variable levels. For more information on using formats, see the “Grouping with Formats” section on page 1465.

### Output Data Sets

PROC FREQ produces two types of output data sets that you can use with other statistical and reporting procedures. These data sets are produced as follows:

- Specifying a TABLES statement with an OUT= option creates an output data set that contains frequency or crosstabulation table counts and percentages.
- Specifying an OUTPUT statement creates an output data set that contains statistics.

PROC FREQ does not display the output data sets. Use PROC PRINT, PROC REPORT, or any other SAS reporting tool to display an output data set.
Contents of the TABLES Statement Output Data Set

The OUT= option in the TABLES statement creates an output data set that contains one observation for each combination of the variable values (or table cell) in the last table request. By default, each observation contains the frequency and percentage for the table cell. When the input data set contains missing values, the output data set also contains an observation with the frequency of missing values. The output data set includes the following variables:

- BY variables
- table request variables, such as A, B, C, and D in the table request A*B*C*D
- COUNT, a variable containing the cell frequency
- PERCENT, a variable containing the cell percentage

If you specify the OUTEXPECT and OUTPCT options in the TABLES statement, the output data set also contains expected frequencies and row, column, and table percentages, respectively. The additional variables are

- EXPECTED, a variable containing the expected frequency
- PCT_TABL, a variable containing the percentage of two-way table frequency, for \(n\)-way tables where \(n > 2\)
- PCT_ROW, a variable containing the percentage of row frequency
- PCT_COL, a variable containing the percentage of column frequency

If you specify the OUTCUM option in the TABLES statement, the output data set also contains cumulative frequencies and cumulative percentages for one-way tables. The additional variables are

- CUM_FREQ, a variable containing the cumulative frequency
- CUM_PCT, a variable containing the cumulative percentage

The OUTCUM option has no effect for two-way or multiway tables.

When you submit the following statements

```latex
proc freq;
  tables A A*B / out=D;
run;
```

the output data set D contains frequencies and percentages for the last table request, A*B. If A has two levels (1 and 2), B has three levels (1,2, and 3), and no table cell count is zero or missing, the output data set D includes six observations, one for each combination of A and B. The first observation corresponds to \(A=1\) and \(B=1\); the second observation corresponds to \(A=1\) and \(B=2\); and so on. The data set includes the variables COUNT and PERCENT. The value of COUNT is the number of observations with the given combination of A and B values. The value of PERCENT is the percent of the total number of observations having that A and B combination.

When PROC FREQ combines different variable values into the same formatted level, the output data set contains the smallest internal value for the formatted level. For...
example, suppose a variable $X$ has the values 1.1, 1.4, 1.7, 2.1, and 2.3. When you submit the statement

```sas
format X 1.;
```

in a PROC FREQ step, the formatted levels listed in the frequency table for $X$ are 1 and 2. If you create an output data set with the frequency counts, the internal values of $X$ are 1.1 and 1.7. To report the internal values of $X$ when you display the output data set, use a format of 3.1 with $X$.

**Contents of the OUTPUT Statement Output Data Set**

The OUTPUT statement creates a SAS data set containing the statistics that PROC FREQ computes for the last table request. You specify which statistics to store in the output data set. There is an observation with the specified statistics for each stratum or two-way table. If PROC FREQ computes summary statistics for a stratified table, the output data set also contains a summary observation with those statistics.

The OUTPUT data set can include the following variables.

- **BY** variables
- variables that identify the stratum, such as $A$ and $B$ in the table request $A*B*C*D$
- variables that contain the specified statistics

The output data set also includes variables with the $p$-values and degrees of freedom, asymptotic standard error (ASE), or confidence limits when PROC FREQ computes these values for a specified statistic.

The variable names for the specified statistics in the output data set are the names of the options enclosed in underscores. PROC FREQ forms variable names for the corresponding $p$-values, degrees of freedom, or confidence limits by combining the name of the option with the appropriate prefix from the following list:

- **DF**  – degrees of freedom
- **E**  – asymptotic standard error (ASE)
- **L**  – lower confidence limit
- **U**  – upper confidence limit
- **E0** – ASE under the null hypothesis
- **Z**  – standardized value
- **P**  – $p$-value
- **P2** – two-sided $p$-value
- **PL** – left-sided $p$-value
- **PR** – right-sided $p$-value
- **XP** – exact $p$-value
- **XP2** – exact two-sided $p$-value
- **XPL** – exact left-sided $p$-value
- **XPR** – exact right-sided $p$-value
- **XPT** – exact point probability
- **XL** – exact lower confidence limit
- **XR** – exact upper confidence limit
For example, variable names created for the Pearson chi-square, its degrees of freedom, its $p$-values are \_\_PCHI\_\_, DF\_\_PCHI\_\_, and P\_\_PCHI\_\_, respectively.

If the length of the prefix plus the statistic option exceeds eight characters, PROC FREQ truncates the option so that the name of the new variable is eight characters long.

**Displayed Output**

**Number of Variable Levels Table**

If you specify the NLEVELS option in the PROC FREQ statement, PROC FREQ displays the “Number of Variable Levels” table. This table provides the number of levels for all variables named in the TABLES statements. PROC FREQ determines the variable levels from the formatted variable values. See “Grouping with Formats” for details. The “Number of Variable Levels” table contains the following information:

- Variable name
- Levels, which is the total number of levels of the variable
- Number of Nonmissing Levels, if there are missing levels for any of the variables
- Number of Missing Levels, if there are missing levels for any of the variables

**One-Way Frequency Tables**

PROC FREQ displays one-way frequency tables for all one-way table requests in the TABLES statements, unless you specify the NOPRINT option in the PROC statement or the NOPRINT option in the TABLES statement. For a one-way table showing the frequency distribution of a single variable, PROC FREQ displays the following information:

- the name of the variable and its values
- Frequency counts, giving the number of observations that have each value
- specified Test Frequency counts, if you specify the CHISQ and TESTF= options to request a chi-square goodness-of-fit test for specified frequencies
- Percent, giving the percentage of the total number of observations with that value. (The NOPERCENT option suppresses this information.)
- specified Test Percents, if you specify the CHISQ and TESTP= options to request a chi-square goodness-of-fit test for specified percents. (The NOPERCENT option suppresses this information.)
- Cumulative Frequency counts, giving the sum of the frequency counts of that value and all other values listed above it in the table. The last cumulative frequency is the total number of nonmissing observations. (The NOCUM option suppresses this information.)
- Cumulative Percent values, giving the percentage of the total number of observations with that value and all others previously listed in the table. (The NOCUM or the NOPERCENT option suppresses this information.)
The one-way table also displays the Frequency Missing, or the number of observations with missing values.

**Statistics for One-Way Frequency Tables**

For one-way tables, two statistical options are available in the `TABLES` statement. The `CHISQ` option provides a chi-square goodness-of-fit test, and the `BINOMIAL` option provides binomial proportion statistics. PROC FREQ displays the following information, unless you specify the `NOPRINT` option in the PROC statement:

- If you specify the `CHISQ` option for a one-way table, PROC FREQ provides a chi-square goodness-of-fit test, displaying the Chi-Square statistic, the degrees of freedom (DF), and the probability value (Pr > ChiSq). If you specify the `CHISQ` option in the `EXACT` statement, PROC FREQ also displays the exact probability value for this test. If you specify the `POINT` option with the `CHISQ` option in the `EXACT` statement, PROC FREQ displays the exact point probability for the test statistic.

- If you specify the `BINOMIAL` option for a one-way table, PROC FREQ displays the estimate of the binomial Proportion, which is the proportion of observations in the first class listed in the one-way table. PROC FREQ also displays the asymptotic standard error (ASE) and the asymptotic and exact confidence limits for this estimate. For the binomial proportion test, PROC FREQ displays the asymptotic standard error under the null hypothesis (ASE Under H0), the standardized test statistic (Z), and the one-sided and two-sided probability values. If you specify the `BINOMIAL` option in the `EXACT` statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test. If you specify the `POINT` option with the `BINOMIAL` option in the `EXACT` statement, PROC FREQ displays the exact point probability for the test.

**Multiway Tables**

PROC FREQ displays all multiway table requests in the `TABLES` statements, unless you specify the `NOPRINT` option in the PROC statement or the `NOPRINT` option in the `TABLES` statement.

For two-way to multiway crosstabulation tables, the values of the last variable in the table request form the table columns. The values of the next-to-last variable form the rows. Each level (or combination of levels) of the other variables forms one stratum.

There are three ways to display multiway tables in PROC FREQ. By default, PROC FREQ displays multiway tables as separate two-way crosstabulation tables for each stratum of the multiway table. Also by default, PROC FREQ displays these two-way crosstabulation tables in table cell format. Alternatively, if you specify the `CROSSLIST` option, PROC FREQ displays the two-way crosstabulation tables in ODS column format. If you specify the `LIST` option, PROC FREQ displays multiway tables in list format.
Crosstabulation Tables

By default, PROC FREQ displays two-way crosstabulation tables in table cell format. The row variable values are listed down the side of the table, the column variable values are listed across the top of the table, and each row and column variable level combination forms a table cell.

Each cell of a crosstabulation table may contain the following information:

- Frequency, giving the number of observations that have the indicated values of the two variables. (The NOFREQ option suppresses this information.)
- the Expected cell frequency under the hypothesis of independence, if you specify the EXPECTED option
- the Deviation of the cell frequency from the expected value, if you specify the DEVIA TION option
- Cell Chi-Square, which is the cell’s contribution to the total chi-square statistic, if you specify the CELLCHI2 option
- Tot Pct, or the cell’s percentage of the total frequency, for n-way tables when \( n > 2 \), if you specify the TOTPCT option
- Percent, the cell’s percentage of the total frequency. (The NOPERCENT option suppresses this information.)
- Row Pct, or the row percentage, the cell’s percentage of the total frequency count for that cell’s row. (The NOROW option suppresses this information.)
- Col Pct, or column percentage, the cell’s percentage of the total frequency count for that cell’s column. (The NOCOL option suppresses this information.)
- Cumulative Col%, or cumulative column percent, if you specify the CUMCOL option

The table also displays the Frequency Missing, or the number of observations with missing values.

CROSSLIST Tables

If you specify the CROSSLIST option, PROC FREQ displays two-way crosstabulation tables with ODS column format. Using column format, a CROSSLIST table provides the same information (frequencies, percentages, and other statistics) as the default crosstabulation table with cell format. But unlike the default crosstabulation table, a CROSSLIST table has a table definition that you can customize with PROC TEMPLATE. For more information, refer to the chapter titled “The TEMPLATE Procedure” in the SAS Output Delivery System User’s Guide.

In the CROSSLIST table format, the rows of the display correspond to the crosstabulation table cells, and the columns of the display correspond to descriptive statistics such as frequencies and percentages. Each table cell is identified by the values of its TABLES row and column variable levels, with all column variable levels listed within each row variable level. The CROSSLIST table also provides row totals, column totals, and overall table totals.
For a crosstabulation table in the CROSSLIST format, PROC FREQ displays the following information:

- the row variable name and values
- the column variable name and values
- Frequency, giving the number of observations that have the indicated values of the two variables. (The NOFREQ option suppresses this information.)
- the Expected cell frequency under the hypothesis of independence, if you specify the EXPECTED option
- the Deviation of the cell frequency from the expected value, if you specify the DEVIA TION option
- Cell Chi-Square, which is the cell’s contribution to the total chi-square statistic, if you specify the CELCHI2 option
- Total Percent, or the cell’s percentage of the total frequency, for n-way tables when $n > 2$, if you specify the TOTPCT option
- Percent, the cell’s percentage of the total frequency. (The NOPERCENT option suppresses this information.)
- Row Percent, the cell’s percentage of the total frequency count for that cell’s row. (The NOROW option suppresses this information.)
- Column Percent, the cell’s percentage of the total frequency count for that cell’s column. (The NOCOL option suppresses this information.)

The table also displays the Frequency Missing, or the number of observations with missing values.

**LIST Tables**

If you specify the LIST option in the TABLES statement, PROC FREQ displays multiway tables in a list format rather than as crosstabulation tables. The LIST option displays the entire multiway table in one table, instead of displaying a separate two-way table for each stratum. The LIST option is not available when you also request statistical options. Unlike the default crosstabulation output, the LIST output does not display row percentages, column percentages, and optional information such as expected frequencies and cell chi-squares.

For a multiway table in list format, PROC FREQ displays the following information:

- the variable names and values
- Frequency counts, giving the number of observations with the indicated combination of variable values
- Percent, the cell’s percentage of the total number of observations. (The NOPERCENT option suppresses this information.)
- Cumulative Frequency counts, giving the sum of the frequency counts of that cell and all other cells listed above it in the table. The last cumulative frequency is the total number of nonmissing observations. (The NOCUM option suppresses this information.)
• Cumulative Percent values, giving the percentage of the total number of observations for that cell and all others previously listed in the table. (The NOCUM or the NOPERCENT option suppresses this information.)

The table also displays the Frequency Missing, or the number of observations with missing values.

**Statistics for Multiway Tables**

PROC FREQ computes statistical tests and measures for crosstabulation tables, depending on which statements and options you specify. You can suppress the display of all these results by specifying the NOPRINT option in the PROC statement. With any of the following information, PROC FREQ also displays the Sample Size and the Frequency Missing.

• If you specify the SCOROUT option, PROC FREQ displays the Row Scores and Column Scores that it uses for statistical computations. The Row Scores table displays the row variable values and the Score corresponding to each value. The Column Scores table displays the column variable values and the corresponding Scores. PROC FREQ also identifies the score type used to compute the row and column scores. You can specify the score type with the SCORES= option in the TABLES statement.

• If you specify the CHISQ option, PROC FREQ displays the following statistics for each two-way table: Pearson Chi-Square, Likelihood-Ratio Chi-Square, Continuity-Adjusted Chi-Square (for \(2 \times 2\) tables), Mantel-Haenszel Chi-Square, the Phi Coefficient, the Contingency Coefficient, and Cramer’s V. For each test statistic, PROC FREQ also displays the degrees of freedom (DF) and the probability value (Prob).

• If you specify the CHISQ option for \(2 \times 2\) tables, PROC FREQ also displays Fisher’s exact test. The test output includes the cell (1,1) frequency (F), the exact left-sided and right-sided probability values, the table probability (P), and the exact two-sided probability value.

• If you specify the FISHER option in the TABLES statement (or, equivalently, the FISHER option in the EXACT statement), PROC FREQ displays Fisher’s exact test for tables larger than \(2 \times 2\). The test output includes the table probability (P) and the probability value. In addition, PROC FREQ displays the CHISQ output listed earlier, even if you do not also specify the CHISQ option.

• If you specify the PCHI, LRCHI, or MHCHI option in the EXACT statement, PROC FREQ also displays the corresponding exact test: Pearson Chi-Square, Likelihood-Ratio Chi-Square, or Mantel-Haenszel Chi-Square, respectively. The test output includes the test statistic, the degrees of freedom (DF), and the asymptotic and exact probability values. If you also specify the POINT option in the EXACT statement, PROC FREQ displays the point probability for each exact test requested. If you specify the CHISQ option in the EXACT statement, PROC FREQ displays exact probability values for all three of these chi-square tests.
If you specify the MEASURES option, PROC FREQ displays the following statistics and their asymptotic standard errors (ASE) for each two-way table: Gamma, Kendall’s Tau-b, Stuart’s Tau-c, Somers’ D(C|R), Somers’ D(R|C), Pearson Correlation, Spearman Correlation, Lambda Asymmetric (C|R), Lambda Asymmetric (R|C), Lambda Symmetric, Uncertainty Coefficient (C|R), Uncertainty Coefficient (R|C), and Uncertainty Coefficient Symmetric. If you specify the CL option, PROC FREQ also displays confidence limits for these measures.

If you specify the PLCORR option, PROC FREQ displays the tetrachoric correlation for 2 × 2 tables or the polychoric correlation for larger tables. In addition, PROC FREQ displays the MEASURES output listed earlier, even if you do not also specify the MEASURES option.

If you specify the option GAMMA, KENTB, STUTC, SMDCR, SMDRC, PCORR, or SCORR in the TEST statement, PROC FREQ displays asymptotic tests for Gamma, Kendall’s Tau-b, Stuart’s Tau-c, Somers’ D(C|R), Somers’ D(R|C), the Pearson Correlation, or the Spearman Correlation, respectively. If you specify the MEASURES option in the TEST statement, PROC FREQ displays all these asymptotic tests. The test output includes the statistic, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the one-sided and two-sided probability values.

If you specify the PCORR or SCORR option in the EXACT statement, PROC FREQ displays asymptotic and exact tests for the Pearson Correlation or the Spearman Correlation, respectively. The test output includes the correlation, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the asymptotic and exact one-sided and two-sided probability values. If you also specify the POINT option in the EXACT statement, PROC FREQ displays the point probability for each exact test requested.

If you specify the RISKDIFF option for 2 × 2 tables, PROC FREQ displays the Column 1 and Column 2 Risk Estimates. For each column, PROC FREQ displays Row 1 Risk, Row 2 Risk, Total Risk, and Risk Difference, together with their asymptotic standard errors (ASE), Asymptotic Confidence Limits, and Exact Confidence Limits. Exact confidence limits are not available for the risk difference.

If you specify the MEASURES option or the RELRISK option for 2 × 2 tables, PROC FREQ displays Estimates of the Relative Risk for Case-Control and Cohort studies, together with their Confidence Limits. These measures are also known as the Odds Ratio and the Column 1 and 2 Relative Risks. If you specify the OR option in the EXACT statement, PROC FREQ also displays Exact Confidence Limits for the Odds Ratio.

If you specify the TREND option, PROC FREQ displays the Cochran-Armitage Trend Test for tables that are 2 × C or R × 2. For this test, PROC FREQ gives the Statistic (Z) and the one-sided and two-sided probability values. If you specify the TREND option in the EXACT statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test.
If you specify the POINT option with the TREND option in the EXACT statement, PROC FREQ displays the exact point probability for the test statistic.

- If you specify the JT option, PROC FREQ displays the Jonckheere-Terpstra Test, showing the Statistic (JT), the standardized test statistic (Z), and the one-sided and two-sided probability values. If you specify the JT option in the EXACT statement, PROC FREQ also displays the exact one-sided and two-sided probability values for this test. If you specify the POINT option with the JT option in the EXACT statement, PROC FREQ displays the exact point probability for the test statistic.

- If you specify the AGREE option and the PRINTKWT option, PROC FREQ displays the Kappa Coefficient Weights for square tables greater than $2 \times 2$.

- If you specify the AGREE option, for two-way tables PROC FREQ displays McNemar's Test and the Simple Kappa Coefficient for $2 \times 2$ tables. For square tables larger than $2 \times 2$, PROC FREQ displays Bowker’s Test of Symmetry, the Simple Kappa Coefficient, and the Weighted Kappa Coefficient. For McNemar’s Test and Bowker’s Test of Symmetry, PROC FREQ displays the Statistic (S), the degrees of freedom (DF), and the probability value (Pr > S). If you specify the MCNEM option in the EXACT statement, PROC FREQ also displays the exact probability value for McNemar’s test. If you specify the POINT option with the MCNEM option in the EXACT statement, PROC FREQ displays the exact point probability for the test statistic. For the simple and weighted kappa coefficients, PROC FREQ displays the kappa values, asymptotic standard errors (ASE), and Confidence Limits.

- If you specify the KAPPA or WTKAP option in the TEST statement, PROC FREQ displays asymptotic tests for the simple kappa coefficient or the weighted kappa coefficient, respectively. If you specify the AGREE option in the TEST statement, PROC FREQ displays both these asymptotic tests. The test output includes the kappa coefficient, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the one-sided and two-sided probability values.

- If you specify the KAPPA or WTKAP option in the EXACT statement, PROC FREQ displays asymptotic and exact tests for the simple kappa coefficient or the weighted kappa coefficient, respectively. The test output includes the kappa coefficient, its asymptotic standard error (ASE), Confidence Limits, the ASE under the null hypothesis H0, the standardized test statistic (Z), and the asymptotic and exact one-sided and two-sided probability values. If you specify the POINT option in the EXACT statement, PROC FREQ displays the point probability for each exact test requested.

- If you specify the MC option in the EXACT statement, PROC FREQ displays Monte Carlo estimates for all exact $p$-values requested by statistic-options in the EXACT statement. The Monte Carlo output includes the $p$-value Estimate, its Confidence Limits, the Number of Samples used to compute the Monte Carlo estimate, and the Initial Seed for random number generation.

- If you specify the AGREE option, for multiple strata PROC FREQ displays Overall Simple and Weighted Kappa Coefficients, with their asymptotic standard errors (ASE) and Confidence Limits. PROC FREQ also displays Tests for
Equal Kappa Coefficients, giving the Chi-Squares, degrees of freedom (DF), and probability values (Pr > ChiSq) for the Simple Kappa and Weighted Kappa. For multiple strata of $2 \times 2$ tables, PROC FREQ displays Cochran’s $Q$, giving the Statistic ($Q$), the degrees of freedom (DF), and the probability value (Pr > $Q$).

- If you specify the CMH option, PROC FREQ displays Cochran-Mantel-Haenszel Statistics for the following three alternative hypotheses: Nonzero Correlation, Row Mean Scores Differ (ANOVA Statistic), and General Association. For each of these statistics, PROC FREQ gives the degrees of freedom (DF) and the probability value (Prob). For $2 \times 2$ tables, PROC FREQ also displays Estimates of the Common Relative Risk for Case-Control and Cohort studies, together with their confidence limits. These include both Mantel-Haenszel and Logit stratum-adjusted estimates of the common Odds Ratio, Column 1 Relative Risk, and Column 2 Relative Risk. Also for $2 \times 2$ tables, PROC FREQ displays the Breslow-Day Test for Homogeneity of the Odds Ratios. For this test, PROC FREQ gives the Chi-Square, the degrees of freedom (DF), and the probability value (Pr > ChiSq).

- If you specify the CMH option in the TABLES statement and also specify the COMOR option in the EXACT statement, PROC FREQ displays exact confidence limits for the Common Odds Ratio for multiple strata of $2 \times 2$ tables. PROC FREQ also displays the Exact Test of $H_0$: Common Odds Ratio = 1. The test output includes the Cell $(1,1)$ Sum (S), Mean of S Under $H_0$, One-sided Pr $\leq S$, and Point Pr = $S$. PROC FREQ also provides exact two-sided probability values for the test, computed according to the following three methods: $2 \times$ One-sided, Sum of probabilities $\leq$ Point probability, and Pr $\geq |S - \text{Mean}|$.

**ODS Table Names**

PROC FREQ assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 29.11 lists the ODS table names together with their descriptions and the options required to produce the tables. Note that the ALL option in the TABLES statement invokes the CHISQ, MEASURES, and CMH options.

Examples

Example 29.1. Creating an Output Data Set with Table Cell Frequencies

The eye and hair color of children from two different regions of Europe are recorded in the data set Color. Instead of recording one observation per child, the data are recorded as cell counts, where the variable Count contains the number of children exhibiting each of the 15 eye and hair color combinations. The data set does not include missing combinations.

```sas
data Color;
    input Region Eyes $ Hair $ Count @@;
    label Eyes = 'Eye Color'
      Hair = 'Hair Color'
      Region= 'Geographic Region';
datalines;
1 blue fair 23 1 blue red 7 1 blue medium 24
1 blue dark 11 1 green fair 19 1 green red 7
1 green medium 18 1 green dark 14 1 brown fair 34
1 brown red 5 1 brown medium 41 1 brown dark 40
1 brown black 3 2 blue fair 46 2 blue red 21
2 blue medium 44 2 blue dark 40 2 blue black 6
2 green fair 50 2 green red 31 2 green medium 37
2 green dark 23 2 brown fair 56 2 brown red 42
2 brown medium 53 2 brown dark 54 2 brown black 13;
```

The following statements read the Color data set and create an output data set containing the frequencies, percentages, and expected cell frequencies of the Eyes by Hair two-way table. The TABLES statement requests three tables: Eyes and Hair frequency tables and an Eyes by Hair crosstabulation table. The OUT= option creates the FreqCnt data set, which contains the crosstabulation table frequencies. The OUTEXPECT option outputs the expected cell frequencies to FreqCnt, and the SPARSE option includes the zero cell counts. The WEIGHT statement specifies that Count contains the observation weights. These statements create Output 29.1.1 through Output 29.1.3.
proc freq data=Color;
  weight Count;
  tables Eyes Hair Eyes*Hair / out=FreqCnt outexpect sparse;
  title1 'Eye and Hair Color of European Children';
run;
proc print data=FreqCnt noobs;
  title2 'Output Data Set from PROC FREQ';
run;

Output 29.1.1 displays the two frequency tables produced, one showing the distribution of eye color, and one showing the distribution of hair color. By default, PROC FREQ lists the variables values in alphabetical order. The 'Eyes*Hair' specification produces a crosstabulation table, shown in Output 29.1.2, with eye color defining the table rows and hair color defining the table columns. A zero cell count for green eyes and black hair indicates that this eye and hair color combination does not occur in the data.

The output data set (Output 29.1.3) contains frequency counts and percentages for the last table. The data set also includes an observation for the zero cell count (SPARSE) and a variable with the expected cell frequency for each table cell (OUTEXPECT).

Example 29.2. Computing Chi-Square Tests for One-Way Frequency Tables

This example examines whether the children’s hair color (from Example 29.1 on page 1527) has a specified multinomial distribution for the two regions. The hypothesized distribution for hair color is 30% fair, 12% red, 30% medium, 25% dark, and 3% black.

In order to test the hypothesis for each region, the data are first sorted by Region. Then the FREQ procedure uses a BY statement to produce a separate table for each BY group (Region). The option ORDER=DATA orders the frequency table values (hair color) by their order in the data set. The TABLES statement requests a frequency table for hair color, and the option NOCUM suppresses the display of the cumulative frequencies and percentages. The TESTP= option specifies the hypothesized percentages for the chi-square test; the number of percentages specified equals the number of table levels, and the percentages sum to 100. The following statements produce Output 29.2.1.

```sas
proc sort data=Color;
  by Region;
run;
proc freq data=Color order=data;
  weight Count;
  tables Hair / nocum testp=(30 12 30 25 3);
  by Region;
  title 'Hair Color of European Children';
run;
```

The frequency tables in Output 29.2.1 list the variable values (hair color) in the order in which they appear in the data set. The “Test Percent” column lists the hypothesized percentages for the chi-square test. Always check that you have ordered the TESTP= percentages to correctly match the order of the variable levels.

PROC FREQ computes a chi-square statistic for each region. The chi-square statistic is significant at the 0.05 level for Region 2 (p=0.0003) but not for Region 1. This indicates a significant departure from the hypothesized percentages in Region 2.

Example 29.3. Computing Binomial Proportions for One-Way Frequency Tables

The binomial proportion is computed as the proportion of observations for the first level of the variable that you are studying. The following statements compute the proportion of children with brown eyes (from the data set in Example 29.1 on page 1527) and test this value against the hypothesis that the proportion is 50%. Also, these statements test whether the proportion of children with fair hair is 28%.

```sas
proc freq data=Color order=freq;
  weight Count;
  tables Eyes / binomial alpha=.1;
  tables Hair / binomial(p=.28);
  title 'Hair and Eye Color of European Children';
run;
```

The first TABLES statement produces a frequency table for eye color. The BINOMIAL option computes the binomial proportion and confidence limits, and it tests the hypothesis that the proportion for the first eye color level (brown) is 0.5. The option ALPHA=.1 specifies that 90% confidence limits should be computed. The second TABLES statement creates a frequency table for hair color and computes the binomial proportion and confidence limits, but it tests that the proportion for the first hair color (fair) is 0.28. These statements produce Output 29.3.1 and Output 29.3.2.

The frequency table in Output 29.3.1 displays the variable values in order of descending frequency count. Since the first variable level is 'brown', PROC FREQ computes the binomial proportion of children with brown eyes. PROC FREQ also computes its asymptotic standard error (ASE), and asymptotic and exact 90% confidence limits. If you do not specify the ALPHA= option, then PROC FREQ computes the default 95% confidence limits.

Because the value of \( Z \) is less than zero, PROC FREQ computes a left-sided \( p \)-value (0.0019). This small \( p \)-value supports the alternative hypothesis that the true value of the proportion of children with brown eyes is less than 50%.

Output 29.3.2 displays the results from the second TABLES statement. PROC FREQ computes the default 95% confidence limits since the ALPHA= option is not specified. The value of \( Z \) is greater than zero, so PROC FREQ computes a right-sided \( p \)-value (0.1188). This large \( p \)-value provides insufficient evidence to reject the null hypothesis that the proportion of children with fair hair is 28%.

Example 29.4. Analyzing a 2x2 Contingency Table

This example computes chi-square tests and Fisher’s exact test to compare the probability of coronary heart disease for two types of diet. It also estimates the relative risks and computes exact confidence limits for the odds ratio.

The data set FatComp contains hypothetical data for a case-control study of high fat diet and the risk of coronary heart disease. The data are recorded as cell counts, where the variable Count contains the frequencies for each exposure and response combination. The data set is sorted in descending order by the variables Exposure and Response, so that the first cell of the 2 x 2 table contains the frequency of positive exposure and positive response. The FORMAT procedure creates formats to identify the type of exposure and response with character values.

```sas
proc format;
  value ExpFmt 1='High Cholesterol Diet'
                  0='Low Cholesterol Diet';
  value RspFmt 1='Yes'
                  0='No';
runc;

data FatComp;
  input Exposure Response Count;
  label Response='Heart Disease';
datalines;
  0 0 6
  0 1 2
  1 0 4
  1 1 11;
proc sort data=FatComp;
  by descending Exposure descending Response;
runc;
```

In the following statements, the TABLES statement creates a two-way table, and the option ORDER=DATA orders the contingency table values by their order in the data set. The CHISQ option produces several chi-square tests, while the RELRISK option produces relative risk measures. The EXACT statement creates the exact Pearson chi-square test and exact confidence limits for the odds ratio. These statements produce Output 29.4.1 through Output 29.4.3.

```sas
proc freq data=FatComp order=data;
  weight Count;
  tables Exposure*Response / chisq relrisk;
  exact pchi or;
  format Exposure ExpFmt. Response RspFmt.;
  title 'Case-Control Study of High Fat/Cholesterol Diet';
runc;
```
### Output 29.4.1. Contingency Table

**Case-Control Study of High Fat/Cholesterol Diet**

The FREQ Procedure

Table of Exposure by Response

<table>
<thead>
<tr>
<th>Exposure</th>
<th>Response (Heart Disease)</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Frequency</td>
<td>Percent</td>
<td>Row Pct</td>
</tr>
<tr>
<td>High Cholesterol Diet</td>
<td>11</td>
<td>47.83</td>
<td>73.33</td>

</tr>
</tbody>
</table>

Sample Size = 23

Output 29.4.2 displays the chi-square statistics. Since the expected counts in some of the table cells are small, PROC FREQ gives a warning that the asymptotic chi-square tests may not be appropriate. In this case, the exact tests are appropriate. The alternative hypothesis for this analysis states that coronary heart disease is more likely to be associated with a high fat diet, so a one-sided test is desired. Fisher’s exact right-sided test analyzes whether the probability of heart disease in the high fat group exceeds the probability of heart disease in the low fat group; since this p-value is small, the alternative hypothesis is supported.
Output 29.4.3.  Relative Risk

Case-Control Study of High Fat/Cholesterol Diet

Statistics for Table of Exposure by Response

Estimates of the Relative Risk (Row1/Row2)

<table>

<tr>
<td>95% Upper Conf Limit</td>
<td>105.5488</td>
</tr>
</tbody>
</table>

Sample Size = 23

The odds ratio, displayed in Output 29.4.3, provides an estimate of the relative risk when an event is rare. This estimate indicates that the odds of heart disease is 8.25 times higher in the high fat diet group; however, the wide confidence limits indicate that this estimate has low precision.

Example 29.5. Creating an Output Data Set Containing Chi-Square Statistics

This example uses the Color data from Example 29.1 (page 1527) to output the Pearson chi-square and the likelihood-ratio chi-square statistics to a SAS data set. The following statements create a two-way table of eye color versus hair color.

```sas
proc freq data=Color order=data;
  weight Count;
  tables Eyes*Hair / chisq expected cellchi2 norow nocol;
  output out=ChiSqData pchi lrchi n nmiss;
  title 'Chi-Square Tests for 3 by 5 Table of Eye and Hair Color';
run;
proc print data=ChiSqData noobs;
  title1 'Chi-Square Statistics for Eye and Hair Color';
  title2 'Output Data Set from the FREQ Procedure';
run;
```

The CHISQ option produces chi-square tests, the EXPECTED option displays expected cell frequencies in the table, and the CELLCHI2 option displays the cell contribution to the chi-square. The NOROW and NOCOL options suppress the display of row and column percents in the table.
Example 29.5. Creating an Output Data Set Containing Chi-Square Statistics

The OUTPUT statement creates the ChiSqData data set with eight variables: the N option stores the number of nonmissing observations, the NMISS option stores the number of missing observations, and the PCHI and LRCHI options store Pearson and likelihood-ratio chi-square statistics, respectively, together with their degrees of freedom and p-values.

The preceding statements produce Output 29.5.1 and Output 29.5.2.

Output 29.5.1. Contingency Table

<table>
<thead>
<tr>
<th>Eyes (Eye Color)</th>
<th>Hair (Hair Color)</th>
<th>Frequency</th>
<th>Expected</th>
<th>Cell Chi-Square</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>blue</td>
<td>fair</td>
<td>69</td>
<td>66.425</td>

<tr>
<td></td>
<td>Total</td>
<td>222</td>
<td>29.92</td>
<td>29.13</td>
<td></td>
</tr>
</tbody>
</table>

The contingency table in Output 29.5.1 displays eye and hair color in the order in which they appear in the Color data set. The Pearson chi-square statistic in Output 29.5.2 provides evidence of an association between eye and hair color (p=0.0073). The cell chi-square values show that most of the association is due to more green-eyed children with fair or red hair and fewer with dark or black hair. The opposite occurs with the brown-eyed children.
Output 29.5.2. Chi-Square Statistics

Chi-Square Tests for 3 by 5 Table of Eye and Hair Color

Statistics for Table of Eyes by Hair

<td>20.9248</td>
<td>8</td>
<td>25.9733</td>
<td>8</td>
<td>0.001061424</td>
</tr>
</tbody>
</table>

The OUT= data set is displayed in Output 29.5.3. It contains one observation with the sample size, the number of missing values, and the chi-square statistics and corresponding degrees of freedom and p-values as in Output 29.5.2.

Example 29.6. Computing Cochran-Mantel-Haenszel Statistics for a Stratified Table

The data set Migraine contains hypothetical data for a clinical trial of migraine treatment. Subjects of both genders receive either a new drug therapy or a placebo. Their response to treatment is coded as ‘Better’ or ‘Same’. The data are recorded as cell counts, and the number of subjects for each treatment and response combination is recorded in the variable Count.

data Migraine;
  input Gender $ Treatment $ Response $ Count @@;
datalines;
female Active Better 16 female Active Same 11
female Placebo Better 5 female Placebo Same 20
male Active Better 12 male Active Same 16
male Placebo Better 7 male Placebo Same 19;
The following statements create a three-way table stratified by Gender, where Treatment forms the rows and Response forms the columns. The CMH option produces the Cochran-Mantel-Haenszel statistics. For this stratified $2 \times 2$ table, estimates of the common relative risk and the Breslow-Day test for homogeneity of the odds ratios are also displayed. The NOPRINT option suppresses the display of the contingency tables. These statements produce Output 29.6.1 through Output 29.6.3.

```plaintext
proc freq data=Migraine;
  weight Count;
  tables Gender*Treatment*Response / cmh noprint;
  title 'Clinical Trial for Treatment of Migraine Headaches';
run;
```

**Output 29.6.1.** Cochran-Mantel-Haenszel Statistics

**Clinical Trial for Treatment of Migraine Headaches**

The FREQ Procedure

Summary Statistics for Treatment by Response
Controlling for Gender

Cochran-Mantel-Haenszel Statistics (Based on Table Scores)

<table>
<thead>
<tr>

<td>0.0040</td>
</tr>
<tr>
<td>3</td>
<td>General Association</td>
<td>1</td>
<td>8.3052</td>
<td>0.0040</td>
</tr>
</tbody>
</table>

Total Sample Size = 106

For a stratified $2 \times 2$ table, the three CMH statistics displayed in Output 29.6.1 test the same hypothesis. The significant $p$-value (0.004) indicates that the association between treatment and response remains strong after adjusting for gender.
Output 29.6.2. CMH Option: Relative Risks

Clinical Trial for Treatment of Migraine Headaches

Summary Statistics for Treatment by Response
Controlling for Gender

Estimates of the Common Relative Risk (Row1/Row2)

<table>
<thead>
<tr>

<td>0.4705</td>
</tr>
<tr>
<td>(Col2 Risk)</td>
<td>Logit</td>
<td>0.6613</td>
<td>0.4852</td>
</tr>
</tbody>
</table>

Total Sample Size = 106

The CMH option also produces a table of relative risks, as shown in Output 29.6.2. Because this is a prospective study, the relative risk estimate assesses the effectiveness of the new drug: the “Cohort (Col1 Risk)” values are the appropriate estimates for the first column, or the risk of improvement. The probability of migraine improvement with the new drug is just over two times the probability of improvement with the placebo.

Output 29.6.3. CMH Option: Breslow-Day Test

Clinical Trial for Treatment of Migraine Headaches

Summary Statistics for Treatment by Response
Controlling for Gender

Breslow-Day Test for Homogeneity of the Odds Ratios

<p>| | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Chi-Square</td>
<td>1.4929</td>
</tr>
<tr>
<td>DF</td>
<td>1</td>
</tr>
<tr>
<td>Pr &gt; ChiSq</td>
<td>0.2218</td>
</tr>
</tbody>
</table>

Total Sample Size = 106

The large p-value for the Breslow-Day test (0.2218) in Output 29.6.3 indicates no significant gender difference in the odds ratios.
Example 29.7. Computing the Cochran-Armitage Trend Test

The data set Pain contains hypothetical data for a clinical trial of a drug therapy to control pain. The clinical trial investigates whether adverse responses increase with larger drug doses. Subjects receive either a placebo or one of four drug doses. An adverse response is recorded as Adverse='Yes'; otherwise, it is recorded as Adverse='No'. The number of subjects for each drug dose and response combination is contained in the variable Count.

```plaintext
data pain;
  input Dose Adverse $ Count @@;
datalines;
0 No 26 0 Yes 6
1 No 26 1 Yes 7
2 No 23 2 Yes 9
3 No 18 3 Yes 14
4 No 9 4 Yes 23
;
```

The TABLES statement in the following program produces a two-way table. The MEASURES option produces measures of association, and the CL option produces confidence limits for these measures. The TREND option tests for a trend across the ordinal values of the Dose variable with the Cochran-Armitage test. The EXACT statement produces exact p-values for this test, and the MAXTIME= option terminates the exact computations if they do not complete within 60 seconds. The TEST statement computes an asymptotic test for Somer’s $D(C|R)$. These statements produce Output 29.7.1 through Output 29.7.3.

```plaintext
proc freq data=Pain;
  weight Count;
  tables Dose*Adverse / trend measures cl;
test smdcr;
  exact trend / maxtime=60;
  title1 'Clinical Trial for Treatment of Pain';
run;
```
Output 29.7.1. Contingency Table

Clinical Trial for Treatment of Pain

The FREQ Procedure

</tbody>
</table>

Sample Size = 161

Output 29.7.2 displays the measures of association produced by the MEASURES option. Somer’s $D(C|R)$ measures the association treating the column variable (Adverse) as the response and the row variable (Dose) as a predictor. Because the asymptotic 95% confidence limits do not contain zero, this indicates a strong positive association. Similarly, the Pearson and Spearman correlation coefficients show evidence of a strong positive association, as hypothesized.
Output 29.7.3. Trend Test

Clinical Trial for Treatment of Pain

Statistics for Table of Dose by Adverse

Cochran-Armitage Trend Test

<table>
<thead>
<tr>

<tr>
<td>One-sided Pr &lt;= Z</td>
<td>7.237E-07</td>
</tr>
<tr>
<td>Two-sided Pr &gt;=</td>
<td>Z</td>
</tr>
</tbody>
</table>

Sample Size = 161

The Cochran-Armitage test (Output 29.7.3) supports the trend hypothesis. The small left-sided p-values for the Cochran-Armitage test indicate that the probability of the Column 1 level (Adverse='No') decreases as Dose increases or, equivalently, that the probability of the Column 2 level (Adverse='Yes') increases as Dose increases. The two-sided p-value tests against either an increasing or decreasing alternative. This is an appropriate hypothesis when you want to determine whether the drug has progressive effects on the probability of adverse effects but the direction is unknown.

Example 29.8. Computing Friedman’s Chi-Square Statistic

Friedman’s test is a nonparametric test for treatment differences in a randomized complete block design. Each block of the design may be a subject or a homogeneous group of subjects. If blocks are groups of subjects, the number of subjects in each block must equal the number of treatments. Treatments are randomly assigned to subjects within each block. If there is one subject per block, then the subjects are repeatedly measured once under each treatment. The order of treatments is randomized for each subject.

In this setting, Friedman’s test is identical to the ANOVA (row means scores) CMH statistic when the analysis uses rank scores (SCORES=RANK). The three-way table uses subject (or subject group) as the stratifying variable, treatment as the row variable, and response as the column variable. PROC FREQ handles ties by assigning midranks to tied response values. If there are multiple subjects per treatment in each block, the ANOVA CMH statistic is a generalization of Friedman’s test.

The data set Hypnosis contains data from a study investigating whether hypnosis has the same effect on skin potential (measured in millivolts) for four emotions (Lehmann 1975, p. 264). Eight subjects are asked to display fear, joy, sadness, and calmness under hypnosis. The data are recorded as one observation per subject for each emotion.
data Hypnosis;
  length Emotion $ 10;
  input Subject Emotion $ SkinResponse @@;
datalines;
1 fear 23.1 1 joy 22.7 1 sadness 22.5 1 calmness 22.6
2 fear 57.6 2 joy 53.2 2 sadness 53.7 2 calmness 53.1
3 fear 10.5 3 joy 9.7 3 sadness 10.8 3 calmness 8.3
4 fear 23.6 4 joy 19.6 4 sadness 21.1 4 calmness 21.6
5 fear 11.9 5 joy 13.8 5 sadness 13.7 5 calmness 13.3
6 fear 54.6 6 joy 47.1 6 sadness 39.2 6 calmness 37.0
7 fear 21.0 7 joy 13.6 7 sadness 13.7 7 calmness 14.8
8 fear 20.3 8 joy 23.6 8 sadness 16.3 8 calmness 14.8
;

In the following statements, the TABLES statement creates a three-way table stratified by Subject and a two-way table; the variables Emotion and SkinResponse form the rows and columns of each table. The CMH2 option produces the first two Cochran-Mantel-Haenszel statistics, the option SCORES=RANK specifies that rank scores are used to compute these statistics, and the NOPRINT option suppresses the contingency tables. These statements produce Output 29.8.1 and Output 29.8.2.

```sas
proc freq data=Hypnosis;
  tables Subject*Emotion*SkinResponse / cmh2 scores=rank noprint;
run;
```

Output 29.8.1. CMH Statistics: Stratifying by Subject

<table>
<thead>
<tr>
<th>Statistic</th>
<th>Alternative Hypothesis</th>
<th>DF</th>
<th>Value</th>
<th>Prob</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Nonzero Correlation</td>
<td>1</td>
<td>0.2400</td>
<td>0.6242</td>
</tr>
<tr>
<td>2</td>
<td>Row Mean Scores Differ</td>
<td>3</td>
<td>6.4500</td>
<td>0.0917</td>
</tr>
</tbody>
</table>

Total Sample Size = 32

Because the CMH statistics in Output 29.8.1 are based on rank scores, the Row Mean Scores Differ statistic is identical to Friedman’s chi-square ($Q = 6.45$). The $p$-value of 0.0917 indicates that differences in skin potential response for different emotions are significant at the 10% level but not at the 5% level.
Output 29.8.2. CMH Statistics: No Stratification

The FREQ Procedure

Summary Statistics for Emotion by SkinResponse
Cochran-Mantel-Haenszel Statistics (Based on Rank Scores)

<table>
<thead>
<tr>
<th>Statistic</th>
<th>Alternative Hypothesis</th>
<th>DF</th>
<th>Value</th>
<th>Prob</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Nonzero Correlation</td>
<td>1</td>
<td>0.0001</td>
<td>0.9933</td>
</tr>
<tr>
<td>2</td>
<td>Row Mean Scores Differ</td>
<td>3</td>
<td>0.5678</td>
<td>0.9038</td>
</tr>
</tbody>
</table>

Total Sample Size = 32

When you do not stratify by subject, the Row Mean Scores Differ CMH statistic is identical to a Kruskal-Wallis test and is not significant (p=0.9038 in Output 29.8.2). Thus, adjusting for subject is critical to reducing the background variation due to subject differences.

Example 29.9. Testing Marginal Homogeneity with Cochran’s Q

When a binary response is measured several times or under different conditions, Cochran’s Q tests that the marginal probability of a positive response is unchanged across the times or conditions. When there are more than two response categories, you can use the CATMOD procedure to fit a repeated-measures model.

The data set Drugs contains data for a study of three drugs to treat a chronic disease (Agresti 1990). Forty-six subjects receive drugs A, B, and C. The response to each drug is either favorable (‘F’) or unfavorable (‘U’).

```
proc format;
  value $ResponseFmt 'F'='Favorable'
  'U'='Unfavorable';

data drugs;
  input Drug_A $ Drug_B $ Drug_C $ Count @@;
datalines;
  F F F 6  U F F 2
  F F U 16 U F U 4
  F U F 2  U U F 6
  F U U 4  U U U 6
;```

The following statements create one-way frequency tables of the responses to each drug. The AGREE option produces Cochran’s $Q$ and other measures of agreement for the three-way table. These statements produce Output 29.9.1 through Output 29.9.3.

```sas
proc freq data=Drugs;
   weight Count;
   tables Drug_A Drug_B Drug_C / nocum;
   tables Drug_A*Drug_B*Drug_C / agree noprint;
   format Drug_A Drug_B Drug_C $ResponseFmt. ;
   title 'Study of Three Drug Treatments for a Chronic Disease';
run;
```

Output 29.9.1. One-Way Frequency Tables

<table>
<thead>
<tr>
<th>Drug_A</th>
<th>Frequency</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Favorable</td>
<td>28</td>
<td>60.87</td>
</tr>
<tr>
<td>Unfavorable</td>
<td>18</td>
<td>39.13</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Drug_B</th>
<th>Frequency</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Favorable</td>
<td>28</td>
<td>60.87</td>
</tr>
<tr>
<td>Unfavorable</td>
<td>18</td>
<td>39.13</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Drug_C</th>
<th>Frequency</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Favorable</td>
<td>16</td>
<td>34.78</td>
</tr>
<tr>
<td>Unfavorable</td>
<td>30</td>
<td>65.22</td>
</tr>
</tbody>
</table>

The one-way frequency tables in Output 29.9.1 provide the marginal response for each drug. For drugs A and B, 61% of the subjects reported a favorable response while 35% of the subjects reported a favorable response to drug C.
Output 29.9.2. Measures of Agreement

Study of Three Drug Treatments for a Chronic Disease

Statistics for Table 1 of Drug_B by Drug_C
Controlling for Drug_A=Favorable

McNemar’s Test
----------------------------------------
Statistic (S) 10.8889
DF 1
Pr > S 0.0010

Simple Kappa Coefficient
----------------------------------------
Kappa -0.0328
ASE 0.1167
95% Lower Conf Limit -0.2615
95% Upper Conf Limit 0.1960

Sample Size = 28

Statistics for Table 2 of Drug_B by Drug_C
Controlling for Drug_A=Unfavorable

McNemar’s Test
----------------------------------------
Statistic (S) 0.4000
DF 1
Pr > S 0.5271

Simple Kappa Coefficient
----------------------------------------
Kappa -0.1538
ASE 0.2230
95% Lower Conf Limit -0.5909
95% Upper Conf Limit 0.2832

Sample Size = 18

Study of Three Drug Treatments for a Chronic Disease

Summary Statistics for Drug_B by Drug_C
Controlling for Drug_A

Overall Kappa Coefficient
----------------------------------------
Kappa -0.0588
ASE 0.1034
95% Lower Conf Limit -0.2615
95% Upper Conf Limit 0.1439

Test for Equal Kappa Coefficients
----------------------------------------
Chi-Square 0.2314
DF 1
Pr > ChiSq 0.6305

Total Sample Size = 46
McNemar’s test (Output 29.9.2) shows strong discordance between drugs B and C when the response to drug A is favorable. The small negative value of the simple kappa indicates no agreement between drug B response and drug C response.

**Output 29.9.3.** Cochran’s $Q$

<table>
<thead>
<tr>
<th>Study of Three Drug Treatments for a Chronic Disease</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Summary Statistics for Drug_B by Drug_C</strong></td>
</tr>
<tr>
<td><strong>Controlling for Drug_A</strong></td>
</tr>
<tr>
<td><strong>Cochran’s Q, for Drug_A</strong></td>
</tr>
<tr>
<td>by Drug_B by Drug_C</td>
</tr>
<tr>
<td>------------------------------------------------</td>
</tr>
<tr>
<td><strong>Statistic (Q)</strong></td>
</tr>
<tr>
<td><strong>DF</strong></td>
</tr>
<tr>
<td><strong>Pr &gt; Q</strong></td>
</tr>
<tr>
<td><strong>Total Sample Size</strong></td>
</tr>
</tbody>
</table>

Cochran’s $Q$ is statistically significant ($p=0.0144$ in Output 29.9.3), which leads to rejection of the hypothesis that the probability of favorable response is the same for the three drugs.

**References**

Overview

The GAM procedure fits generalized additive models as those models are defined by Hastie and Tibshirani (1990). This procedure provides an array of powerful tools for data analysis, based on nonparametric regression and smoothing techniques.

Nonparametric regression relaxes the usual assumption of linearity and enables you to uncover structure in the relationship between the independent variables and the dependent variable that might otherwise be missed. The SAS System provides many procedures for nonparametric regression, such as the LOESS procedure for local regression and the TPSPLINE procedure for thin-plate smoothing splines. The generalized additive models fit by the GAM procedure combine

- an additivity assumption (Stone 1985) that enables relatively many nonparametric relationships to be explored simultaneously with
- the distributional flexibility of generalized linear models (Nelder 1972)

Thus, you can use the GAM procedure when you have multiple independent variables whose effect you want to model nonparametrically, or when the dependent variable is not normally distributed. See the “Nonparametric Regression” section on page 1569 for more details on the form of generalized additive models.

The GAM procedure

- provides nonparametric estimates for additive models
- supports the use of multidimensional data
- supports multiple SCORE statements
- fits both generalized semiparametric additive models and generalized additive models
- enables you to choose a particular model by specifying the model degrees of freedom or smoothing parameter

Experimental graphics are now available with the GAM procedure. For more information, see the “ODS Graphics” section on page 1581.
Getting Started

The following example illustrates the use of the GAM procedure to explore in a nonparametric way how two factors affect a response. The data come from a study (Sockett et al. 1987) of the factors affecting patterns of insulin-dependent diabetes mellitus in children. The objective is to investigate the dependence of the level of serum C-peptide on various other factors in order to understand the patterns of residual insulin secretion. The response measurement is the logarithm of C-peptide concentration (pmol/ml) at diagnosis, and the predictor measurements are age and base deficit (a measure of acidity):

```sas
title 'Patterns of Diabetes';
data diabetes;
  input Age BaseDeficit CPeptide @@;
  logCP = log(CPeptide);
datalines;
5.2 -8.1 4.8 8.8 -16.1 4.1 10.5 -0.9 5.2
10.6 -7.8 5.5 10.4 -29.0 5.0 1.8 -19.2 3.4
12.7 -18.9 3.4 15.6 -10.6 4.9 5.8 -2.8 5.6
1.9 -25.0 3.7 2.2 -3.1 3.9 4.8 -7.8 4.5
7.9 -13.9 4.8 5.2 -4.5 4.9 0.9 -11.6 3.0
11.8 -2.1 4.6 7.9 -2.0 4.8 11.5 -9.0 5.5
10.6 -11.2 4.5 8.5 -0.2 5.3 11.1 -6.1 4.7
12.8 -1.0 6.6 11.3 -3.6 5.1 1.0 -8.2 3.9
14.5 -0.5 5.7 11.9 -2.0 5.1 8.1 -1.6 5.2
13.8 -11.9 3.7 15.5 -0.7 4.9 9.8 -1.2 4.8
11.0 -14.3 4.4 12.4 -0.8 5.2 11.1 -16.8 5.1
5.1 -5.1 4.6 4.8 -9.5 3.9 4.2 -17.0 5.1
6.9 -3.3 5.1 13.2 -0.7 6.0 9.9 -3.3 4.9
12.5 -13.6 4.1 13.2 -1.9 4.6 8.9 -10.0 4.9
10.8 -13.5 5.1
; run;
```

The following statements perform the desired analysis. The PROC GAM statement invokes the procedure and specifies the `diabetes` data set as input. The MODEL statement specifies `logCP` as the response variable and requests that univariate smoothing splines with the default of 4 degrees of freedom be used to model the effect of `Age` and `BaseDeficit`:

```sas
title 'Patterns of Diabetes';
proc gam data=diabetes;
  model logCP = spline(Age) spline(BaseDeficit);
run;
```

The results are shown in Figure 30.1 and Figure 30.2.

Figure 30.2. Analysis of Model

Figure 30.2 displays summary statistics for the model. It consists of three tables. The first is the “Parameter Estimates” table for the parametric part of the model. It indicates that the linear trends for both Age and BaseDeficit are highly significant. The second table is the summary of smoothing components of the nonparametric part of the model. By default, each smoothing component has approximately 4 degrees of freedom (DF). For univariate spline components, one DF is taken up by the (parametric) linear part of the model, so the remaining approximate DF is 3, and the main point of this table is to present the smoothing parameter values that yield this DF for each component. Finally, the third table shows the “Analysis of Deviance” table for the nonparametric component of the model.

In order to explore the overall shape of the relationship between each factor and the response, use the experimental graphics features of PROC GAM to plot the partial predictions.
ods html;
ods graphics on;
proc gam data=diabetes;
   model logCP = spline(Age) spline(BaseDeficit);
run;
ods graphics off;
ods html close;

These graphical displays are requested by specifying the experimental ODS
GRAPHICS statement. For general information about ODS graphics, see Chapter
15, “Statistical Graphics Using ODS.” For specific information about the graphics
available in the GAM procedure, see the section “ODS Graphics” on page 1581.

![Smoothing Components](image)

**Figure 30.3.** Partial Predictions for each Predictor (Experimental)

Both plots show a strong quadratic pattern, with a possible indication of higher-order
behavior. Further investigation is required to determine whether these patterns are
real or not.
The syntax of the GAM procedure is similar to that of other regression procedures in the SAS System. The PROC GAM and MODEL statements are required. The SCORE statement can appear multiple times; all other statements appear only once.

The syntax for PROC GAM is described in the following sections in alphabetical order after the description of the PROC GAM statement.

**PROC GAM Statement**

```
PROC GAM < option > ;
```

The PROC GAM statement invokes the procedure. You can specify the following option.

```
DATA=SAS-data-set
```

specifies the SAS data set to be read by PROC GAM. The default value is the most recently created data set.

**BY Statement**

```
BY variables ;
```

You can specify a BY statement with PROC GAM to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

* Sort the data using the SORT procedure with a similar BY statement.
* Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the GAM procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
* Create an index for the BY variables using the DATASETS procedure.
For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**CLASS Statement**

CLASS variables;

The CLASS statement names the classification variables to be used in the analysis. Typical class variables are TREATMENT, SEX, RACE, GROUP, and REPLICA TION. If the CLASS statement is used, it must appear before the MODEL statement.

Classification variables can be either character or numeric. Class levels are determined from the formatted values of the CLASS variables. Thus, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide*, and the discussions for the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*.

**FREQ Statement**

FREQ variable;

The FREQ statement names a variable that provides frequencies for each observation in the DATA= data set. Specifically, if \( n \) is the value of the FREQ variable for a given observation, then that observation is used \( n \) times.

The analysis produced using a FREQ statement reflects the expanded number of observations. You can produce the same analysis (without the FREQ statement) by first creating a new data set that contains the expanded number of observations. For example, if the value of the FREQ variable is 5 for the first observation, the first five observations in the new data set are identical. Each observation in the old data set is replicated \( n_i \) times in the new data set, where \( n_i \) is the value of the FREQ variable for that observation.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

The FREQ statement is not available when a loess smoother is included in the model.

**ID Statement**

ID variables;

The variables in the ID statement are copied from the input data set to the OUT= data set. If you omit the ID statement, only the variables used in the MODEL statement and requested statistics are included in the output data set.
MODEL Statement

**MODEL**  dependent= <PARAM(effects)> <smoothing effects> </options> ;

**MODEL**  event/trails= <PARAM(effects)> <smoothing effects> </options> ;

The MODEL statement specifies the dependent variable and the independent effects you want to use to model its values. Specify the independent parametric variables inside the parentheses of PARAM(). The parametric variables can be either CLASS variables or continuous variables. Class variables must be declared with a CLASS statement. Interactions between variables can also be included as parametric effects. The syntax for the specification of effects is the same as for the GLM procedure.

Any number of smoothing effects can be specified, as follows:

<table>
<thead>
<tr>
<th>Smoothing Effect</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>SPLINE(variable &lt;, df=number&gt;)</td>
<td>fit smoothing spline with the variable and with DF=number</td>
</tr>
<tr>
<td>LOESS(variable &lt;, df=number&gt;)</td>
<td>fit local regression with the variable and with DF=number</td>
</tr>
<tr>
<td>SPLINE2(variable, variable &lt;, df=number&gt;)</td>
<td>fit bivariate thin-plate smoothing spline with DF=number</td>
</tr>
</tbody>
</table>

If you do not specify the DF=number option with a smoothing effect, DF=4 is used by default, unless you specify the METHOD=GCV model option. Note that for univariate spline components, a degree of freedom is removed by default to account for the linear portion of the model, so the value displayed in the Fit Summary and Analysis of Deviance tables will be one less than the value you specify.

Both parametric effects and smoothing effects are optional, but at least one of them must be present.

If only parametric variables are present, PROC GAM fits a parametric linear model using the terms inside the parentheses of PARAM(). If only smoothing effects are present, PROC GAM fits a nonparametric additive model. If both types of effect are present, PROC GAM fits a semiparametric model using the parametric effects as the linear part of the model.

The following table shows how to specify various models for a dependent variable y and independent variables x, x1, and x2.
Table 30.1. Syntax for Common GAM Models

<table>
<thead>
<tr>
<th>Type of Model</th>
<th>Syntax</th>
<th>Mathematical Form</th>
</tr>
</thead>
<tbody>
<tr>
<td>Parametric</td>
<td>model y = param(x);</td>
<td>( E(y) = \beta_0 + \beta_1 x )</td>
</tr>
<tr>
<td>Nonparametric</td>
<td>model y = spline(x);</td>
<td>( E(y) = \beta_0 + s(x) )</td>
</tr>
<tr>
<td>Nonparametric</td>
<td>model y = loess(x);</td>
<td>( E(y) = \beta_0 + s(x) )</td>
</tr>
<tr>
<td>Semiparametric</td>
<td>model y = param(x1) spline(x2);</td>
<td>( E(y) = \beta_0 + \beta_1 x_1 + s(x_2) )</td>
</tr>
<tr>
<td>Additive</td>
<td>model y = spline(x1) spline(x2);</td>
<td>( E(y) = \beta_0 + s_1(x_1) + s_2(x_2) )</td>
</tr>
<tr>
<td>Thin-plate spline</td>
<td>model y = spline2(x1,x2);</td>
<td>( E(y) = \beta_0 + s(x_1, x_2) )</td>
</tr>
</tbody>
</table>

You can specify the following options in the MODEL statement.

**ALPHA=number**

specifies the significance level \( \alpha \) of the confidence limits on the final nonparametric component estimates when you request confidence limits to be included in the output data set. Specify number as a value between 0 and 1. The default value is 0.05. See the “OUTPUT Statement” section on page 1568 for more information on the OUTPUT statement.

**DIST=distribution-id**

specifies the distribution family used in the model. The distribution-id can be either GAUSSIAN, BINOMIAL, BINARY, GAMMA, IGAUSSIAN, or POISSON. The canonical link is used with those distributions. Although theoretically, alternative links are possible, with nonparametric models the final fit is relatively insensitive to the precise choice of link function. Therefore, only the canonical link for each distribution family is implemented in PROC GAM. The loess smoother is not available for DIST=BINOMIAL when the number of trials is greater than 1.

**EPSILON=number**

specifies the convergence criterion for the backfitting algorithm. The default value is 1E−8.

**EPSSCORE=number**

specifies the convergence criterion for the local score algorithm. The default value is 1E−8.

**ITPRINT**

produces an iteration summary table for the smoothing effects.

**MAXITER=number**

specifies the maximum number of iterations for the backfitting algorithm. The default value is 50.

**MAXITSCORE=number**

specifies the maximum number of iterations for the local score algorithm. The default value is 100.
**METHOD=GCV**

specifies that the value of the smoothing parameter should be selected by generalized cross validation. If you specify both METHOD=GCV and the DF= option for the smoothing effects, the user-specified DF= is used, and the METHOD=GCV option is ignored. See the “Selection of Smoothing Parameters” section on page 1575 for more details on the GCV method.

**NOTEST**

requests that the procedure not produce the “Analysis of Deviance” table. This option reduces the running time of the procedure.

**OUTPUT Statement**

```
OUTPUT OUT=SAS-data-set < keyword · · · keyword > ;
```

The OUTPUT statement creates a new SAS data set containing diagnostic measures calculated after fitting the model.

You can request a variety of diagnostic measures that are calculated for each observation in the data set. The new data set contains the variables specified in the MODEL statement in addition to the requested variables. If no `keyword` is present, the data set contains only the predicted values.

Details on the specifications in the OUTPUT statement are as follows.

- **OUT=SAS-data-set**
  specifies the name of the new data set to contain the diagnostic measures. This specification is required.

- **keyword**
  specifies the statistics to include in the output data set. The keywords and the statistics they represent are as follows:

  - `PREDICTED` predicted values for each smoothing component and overall predicted values at design points
  - `UCLM` upper confidence limits for each predicted smoothing component
  - `LCLM` lower confidence limits for each predicted smoothing component
  - `ADIAG` diagonal element of the hat matrix associated with the observation for each smoothing spline component
  - `RESIDUAL` residual standardized by its weights
  - `STD` standard deviation of the prediction for each smoothing component
  - `ALL` implies all preceding keywords

The names of the new variables that contain the statistics are formed by using a prefix of one or more characters that identify the statistic, followed by an underscore ( _ ), followed by the variable name.
The prefixes of the new variables are as follows:

<table>
<thead>
<tr>
<th>Keywords</th>
<th>Prefix</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRED</td>
<td>P_-</td>
</tr>
<tr>
<td>UCLM</td>
<td>UCLM_-</td>
</tr>
<tr>
<td>LCLM</td>
<td>LCLM_-</td>
</tr>
<tr>
<td>ADIAG</td>
<td>ADIAG_-</td>
</tr>
<tr>
<td>RESID</td>
<td>R_-</td>
</tr>
<tr>
<td>STD</td>
<td>STD_ for spline</td>
</tr>
<tr>
<td></td>
<td>STDP_ for loess</td>
</tr>
</tbody>
</table>

For example, suppose that you have a dependent variable \( y \) and an independent smoothing variable \( x \), and you specify the keywords PRED and ADIAG. In this case, the output SAS data set will contain the variables P_-y, P_-x, and ADIAG_-x.

**SCORE Statement**

```
SCORE DATA=SAS-data-set OUT=SAS-data-set;
```

The SCORE statement calculates predicted values for a new data set. The variables generated by the SCORE statement use the same naming conventions with prefixes as the OUTPUT statement. If you have multiple data sets to predict, you can specify multiple SCORE statements. You must use a SCORE statement for each data set.

The following options must be specified in the SCORE statement.

- **DATA=SAS-data-set**
  specifies an input SAS data set containing all the variables included in independent effects in the MODEL statement. The predicted response is computed for each observation in the SCORE DATA= data set.

- **OUT=SAS-data-set**
  specifies the name of the SAS data set to contain the predictions.

**Details**

**Nonparametric Regression**

Nonparametric regression relaxes the usual assumption of linearity and enables you to explore the data more flexibly, uncovering structure in the data that might otherwise be missed.

However, many forms of nonparametric regression do not perform well when the number of independent variables in the model is large. The sparseness of data in this setting causes the variances of the estimates to be unacceptably large unless the sample size is extremely large. The problem of rapidly increasing variance for increasing dimensionality is sometimes referred to as the “curse of dimensionality.” Interpretability is another problem with nonparametric regression based on kernel
and smoothing spline estimates. The information these estimates contain about the relationship between the dependent and independent variables is often difficult to comprehend.

To overcome these difficulties, Stone (1985) proposed additive models. These models estimate an additive approximation to the multivariate regression function. The benefits of an additive approximation are at least twofold. First, since each of the individual additive terms is estimated using a univariate smoother, the curse of dimensionality is avoided, at the cost of not being able to approximate universally. Second, estimates of the individual terms explain how the dependent variable changes with the corresponding independent variables.

To extend the additive model to a wide range of distribution families, Hastie and Tibshirani (1990) proposed generalized additive models. These models enable the mean of the dependent variable to depend on an additive predictor through a non-linear link function. The models permit the response probability distribution to be any member of the exponential family of distributions. Many widely used statistical models belong to this general class; they include additive models for Gaussian data, nonparametric logistic models for binary data, and nonparametric log-linear models for Poisson data.

### Additive Models and Generalized Additive Models

This section describes the methodology and the fitting procedure behind generalized additive models.

Let $Y$ be a response random variable and $X_1, X_2, \cdots, X_p$ be a set of predictor variables. A regression procedure can be viewed as a method for estimating the expected value of $Y$ given the values of $X_1, X_2, \cdots, X_p$. The standard linear regression model assumes a linear form for the conditional expectation

$$
E(Y|X_1, X_2, \cdots, X_p) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta_p X_p
$$

Given a sample, estimates of $\beta_0, \beta_1, \cdots, \beta_p$ are usually obtained by the least squares method.

The additive model generalizes the linear model by modeling the conditional expectation as

$$
E(Y|X_1, X_2, \cdots, X_p) = s_0 + s_1(X_1) + s_2(X_2) + \cdots + s_p(X_p)
$$

where $s_i(X), i = 1, 2, \ldots, p$ are smooth functions.

In order to be estimable, the smooth functions $s_i$ have to satisfy standardized conditions such as $E s_j(X_j) = 0$. These functions are not given a parametric form but instead are estimated in a nonparametric fashion.

While traditional linear models and additive models can be used in most statistical data analysis, there are types of problems for which they are not appropriate. For
example, the normal distribution may not be adequate for modeling discrete responses such as counts or bounded responses such as proportions.

Generalized additive models address these difficulties, extending additive models to many other distributions besides just the normal. Thus, generalized additive models can be applied to a much wider range of data analysis problems.

Similar to generalized linear models, generalized additive models consist of a random component, an additive component, and a link function relating the two components. The response $Y$, the random component, is assumed to have exponential family density

$$f_Y(y; \theta; \phi) = \exp \left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\}$$

where $\theta$ is called the natural parameter and $\phi$ is the scale parameter. The mean of the response variable $\mu$ is related to the set of covariates $X_1, X_2, \ldots, X_p$ by a link function $g$. The quantity

$$\eta = s_0 + \sum_{i=1}^{p} s_i(X_i)$$

defines the additive component, where $s_1(\cdot), \ldots, s_p(\cdot)$ are smooth functions, and the relationship between $\mu$ and $\eta$ is defined by $g(\mu) = \eta$. The most commonly used link function is the canonical link, for which $\eta = \theta$.

Generalized additive models and generalized linear models can be applied in similar situations, but they serve different analytic purposes. Generalized linear models emphasize estimation and inference for the parameters of the model, while generalized additive models focus on exploring data nonparametrically. Generalized additive models are more suitable for exploring the data and visualizing the relationship between the dependent variable and the independent variables.

**Backfitting and Local Scoring Algorithms**

Much of the development and notation in this section follows Hastie and Tibshirani (1986). Consider the estimation of the smoothing terms $s_0, s_1(\cdot), \ldots, s_p(\cdot)$ in the additive model

$$\eta(X) = s_0 + \sum_{i=1}^{p} s_j(X_j)$$

where $E[s_j(X_j)] = 0$ for every $j$. Since the algorithm for additive models is the basis for fitting generalized additive models, the algorithm for additive models is discussed first.

Many ways are available to approach the formulation and estimation of additive models. The backfitting algorithm is a general algorithm that can fit an additive model using any regression-type fitting mechanisms.
Define the \( j \)th set of partial residuals as
\[
R_j = Y - s_0 - \sum_{k \neq j} s_k(X_k)
\]
then \( E(R_j | X_j) = s_j(X_j) \). This observation provides a way for estimating each smoothing function \( s_j(\cdot) \) given estimates \( \{\hat{s}_i(\cdot), i \neq j\} \) for all the others. The resulting iterative procedure is known as the backfitting algorithm (Friedman and Stuetzle 1981). The following formulation is taken from Hastie and Tibshirani (1986).

**The Backfitting Algorithm**

The unweighted form of the backfitting algorithm is as follows:

1. **Initialization:** 
   \[ s_0 = E(Y), s_1 = s_2 = \cdots = s_p = 0, m = 0. \]

2. **Iterate:** 
   \[ m = m + 1 \]
   for \( j = 1 \) to \( p \) do:
   \[
   R_j = Y - s_0 - \sum_{k=1}^{j-1} s_k^{m}(X_k) - \sum_{k=j+1}^{p} s_k^{m-1}(X_k)
   \]
   \[ s_j^{m} = E(R_j | X_j). \]

3. **Until:** 
   \[ \text{RSS} = \text{Avg}(Y - s_0 - \sum_{j=1}^{p} s_j^{m}(X_j))^2 \text{ fails to decrease, or satisfies the convergence criterion.} \]

In the preceding notation, \( s_j^{m}(\cdot) \) denotes the estimate of \( s_j(\cdot) \) at the \( m \)th iteration.

It can be shown that with many smoothers (including linear regression, univariate and bivariate splines, and combinations of these), RSS never increases at any step. This implies that the algorithm always converges (Hastie and Tibshirani, 1986). Note, however, that for distributions other than Gaussian, numerical instabilities with weights may cause convergence problems. Even when the algorithm converges, the individual functions need not be unique, since dependence among the covariates can lead to more than one representation for the same fitted surface.

A weighted backfitting algorithm has the same form as for the unweighted case, except that the smoothers are weighted. In PROC GAM, weights are used with non-Gaussian data in the local scoring procedure described later in this section.

The GAM procedure uses the following condition as the convergence criterion for the backfitting algorithm:

\[
\frac{\sum_{j=1}^{n} \sum_{i=1}^{k} (s_i^{m-1}(x_j) - s_i^{m}(x_j))^2}{1 + \sum_{j=1}^{n} \sum_{i=1}^{k} (s_i^{m-1}(x_j))^2} \leq \epsilon
\]

where \( \epsilon = 10^{-8} \) by default; you can change this with the EPSILON= option on the MODEL statement.
The algorithm so far described fits just additive models. The algorithm for generalized additive models is a little more complicated. Generalized additive models extend generalized linear models in the same manner that additive models extend linear regression models, that is, by replacing form \( \alpha + \sum_j X_j \beta_j \) with the additive form \( \alpha + \sum_j f_j(X_j) \). Refer to “Generalized Linear Models Theory” in Chapter 31, “The GENMOD Procedure,” for more information.

PROC GAM fits generalized additive models using a modified form of adjusted dependent variable regression, as described for generalized linear models in McCullagh and Nelder (1989), with the additive predictor taking the role of the linear predictor. Hastie and Tibshirani (1986) call this the local scoring algorithm. Important components of this algorithm depend on the link function for each distribution, as shown in the following table.

<table>
<thead>
<tr>
<th>Distribution</th>
<th>Link</th>
<th>Adjusted Dependent(Z)</th>
<th>Weights(w)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>identity</td>
<td>( y )</td>
<td>1</td>
</tr>
<tr>
<td>Bin ((n, \mu))</td>
<td>logit</td>
<td>( \eta + (y - \mu)/n \mu (1 - \mu) )</td>
<td>( n \mu (1 - \mu) )</td>
</tr>
<tr>
<td>Gamma</td>
<td>(-1/\mu)</td>
<td>( \eta + (y - \mu)/\mu^2 )</td>
<td>( \mu^2 )</td>
</tr>
<tr>
<td>Poisson</td>
<td>log</td>
<td>( \eta + (y - \mu)/\mu )</td>
<td>( \mu )</td>
</tr>
<tr>
<td>Inverse Gaussian</td>
<td>(1/\mu^2)</td>
<td>( \eta - 2(y - \mu)/\mu^3 )</td>
<td>( \mu^3/4 )</td>
</tr>
</tbody>
</table>

Once the distribution and hence these quantities are defined, the local scoring algorithm proceeds as follows:

**The General Local Scoring Algorithm**

1. **Initialization:**
   \[ s_i = g(E(y)), s_0^1 = s_2^0 = \cdots = s_p^0 = 0, m = 0. \]

2. **Iterate:**
   \[ m = m + 1 \]
   Form the predictor \( \eta_i \), mean \( \mu_i \), weights \( w_i \), and adjusted dependent variable \( z_i \) based on the previous iteration
   \[
   \eta_i^{m-1} = s_0 + \sum_{j=1}^{p} s_j^{m-1}(x_{ij}) \\
   \mu_i^{m-1} = g^{-1}(\eta_i^{m-1}) \\
   w_i = \left( \partial \mu_i / \partial \eta_i \right)^2_{m-1} V_{i-1}^{-1} \\
   z_i = \eta_i^{m-1} + (y_i - \mu_i^{m-1}) \left( \partial \eta_i / \partial \mu_i \right)_{m-1}
   \]
   Fit an additive model to \( Z \) using the backfitting algorithm with weights \( W \) to obtain estimated functions \( s_j^m(\cdot) \).

3. **Until:**
   The convergence criterion is satisfied or the deviance fails to decrease. The deviance is an extension to generalized models of the RSS; refer to “Goodness of Fit” in Chapter 31, “The GENMOD Procedure,” for a definition.
The GAM procedure uses the following condition as the convergence criterion for local scoring:

\[
\sum_{j=1}^{n} \sum_{i=1}^{k} \frac{w(x_i)(s_{i}^{m-1}(x_j) - s_{i}^{m}(x_j))^2}{\sum_{j=1}^{n} \sum_{i=1}^{k} w(x_i) + \sum_{j=1}^{n} \sum_{i=1}^{k} w(x_i)(s_{i}^{m-1}(x_j))^2} \leq \epsilon^s
\]

where \( \epsilon^s = 10^{-8} \) by default; you can change this with the \texttt{EPSSCORE=} option on the \texttt{MODEL} statement.

The estimating procedure for generalized additive models consists of two loops. Inside each step of the local scoring algorithm (outer loop), a weighted backfitting algorithm (inner loop) is used until convergence or until the RSS fails to decrease. Then, based on the estimates from this weighted backfitting algorithm, a new set of weights is calculated and the next iteration of the scoring algorithm starts. The scoring algorithm stops when the convergence criterion is satisfied or the deviance of the estimates ceases to decrease.

**Smoothers**

A smoother is a tool for summarizing the trend of a response measurement \( Y \) as a function of one or more predictor measurements \( X_1, \ldots, X_p \). It produces an estimate of the trend that is less variable than \( Y \) itself. An important property of a smoother is its nonparametric nature. It does not assume a rigid form for the dependence of \( Y \) on \( X_1, \ldots, X_p \). This section gives a brief overview of the smoothers that can be used with the GAM procedure.

**Cubic Smoothing Spline**

A smoothing spline is the solution to the following optimization problem: among all functions \( \eta(x) \) with two continuous derivatives, find one that minimizes the penalized least square

\[
\sum_{i=1}^{n} (y_i - \eta(x_i))^2 + \lambda \int_{a}^{b} (\eta^{''}(t))^2 dt
\]

where \( \lambda \) is a fixed constant, and \( a \leq x_1 \leq \cdots \leq x_n \leq b \). The first term measures closeness to the data while the second term penalizes curvature in the function. It can be shown that there exists an explicit, unique minimizer, and that minimizer is a natural cubic spline with knots at the unique values of \( x_i \).

The value \( \lambda/(1 + \lambda) \) is the smoothing parameter. When \( \lambda \) is large, the smoothing parameter is close to 1, producing a smoother curve; small values of \( \lambda \), corresponding to smoothing parameters near 0, are apt to produce rougher curves, more nearly interpolating the data.
Local Regression

Local regression was proposed by Cleveland, Devlin, and Grosse (1988). The idea of local regression is that at a predictor $x$, the regression function $\eta(x)$ can be locally approximated by the value of a function in some specified parametric class. Such a local approximation is obtained by fitting a regression surface to the data points within a chosen neighborhood of the point $x$. A weighted least squares algorithm is used to fit linear functions of the predictors at the centers of neighborhoods. The radius of each neighborhood is chosen so that the neighborhood contains a specified percentage of the data points. The smoothing parameter for the local regression procedure, which controls the smoothness of the estimated curve, is the fraction of the data in each local neighborhood. Data points in a given local neighborhood are weighted by a smooth decreasing function of their distance from the center of the neighborhood. Refer to Chapter 41, “The LOESS Procedure,” for more details.

Thin-Plate Smoothing Spline

The thin-plate smoothing spline is a multivariate version of the cubic smoothing spline. The theoretical foundations for the thin-plate smoothing spline are described in Duchon (1976, 1977) and Meinguet (1979). Further results and applications are given in Wahba and Wendelberger (1980). Refer to Chapter 74, “The TPSPLINE Procedure,” for more details.

Selection of Smoothing Parameters

CV and GCV

The smoothers discussed here have a single smoothing parameter. In choosing the smoothing parameter, cross validation can be used. Cross validation works by leaving points $(x_i, y_i)$ out one at a time, estimating the squared residual for smooth function at $x_i$ based on the remaining $n - 1$ data points, and choosing the smoother to minimize the sum of those squared residuals. This mimics the use of training and test samples for prediction. The cross validation function is defined as

$$CV(\lambda) = \frac{1}{n} \sum_{i=1}^{n} (y_i - \hat{\eta}_\lambda^{-i}(x_i))^2$$

where $\hat{\eta}_\lambda^{-i}(x_i)$ indicates the fit at $x_i$, computed by leaving out the $i$th data point. The quantity $nCV(\lambda)$ is sometimes called the prediction sum of squares or PRESS (Allen 1974).

All of the smoothers fit by the GAM procedure can be formulated as a linear combination of the sample responses

$$\hat{\eta}(x) = A(\lambda)Y$$
for some matrix $A(\lambda)$, which depends on $\lambda$. (The matrix $A(\lambda)$ depends on $x$ and the sample data, as well, but this dependence is suppressed in the preceding equation.) Let $a_{ii}$ be the diagonal elements of $A(\lambda)$. Then the $CV$ function can be expressed as

$$CV(\lambda) = \frac{1}{n} \sum_{i=1}^{n} \left\{ \frac{(y_i - \hat{\eta}_\lambda(x_i))}{1 - a_{ii}} \right\}^2$$

In most cases, it is very time consuming to compute the quantity $a_{ii}$. To solve this computational problem, Wahba (1990) has proposed the generalized cross validation function ($GCV$) that can be used to solve a wide variety of problems involving selection of a parameter to minimize the prediction risk.

The $GCV$ function is defined as

$$GCV(\lambda) = \frac{n \sum_{i=1}^{n} (y_i - \hat{\eta}_\lambda(x_i))^2}{(n - \text{tr}(A(\lambda)))^2}$$

The $GCV$ formula simply replaces the $a_{ii}$ with $\text{tr}(A(\lambda))/n$. Therefore, it can be viewed as a weighted version of $CV$. In most of the cases of interest, $GCV$ is closely related to $CV$ but much easier to compute. Specify the METHOD=GCV option on the MODEL statement in order to use the $GCV$ function to choose the smoothing parameters.

**Degrees of Freedom**

The estimated GAM model can be expressed as

$$\hat{\eta}(X) = \hat{s}_0 + \sum_{i=1}^{p} A_i(y, \lambda)Y$$

Because the weights are calculated based on previous iteration during the local scoring iteration, the matrices $A_i$ may depend on $Y$ for non-Gaussian data. However, for the final iteration, the $A_i$ matrix for the spline smoothers has the same role as the projection matrix in linear regression and therefore, nonparametric degrees of freedom (DF) for the $i$th spline smoother can be defined as

$$DF(\text{smoother}) = \text{tr}(A_i(y, \lambda))$$

For LOESS smoothers $A_i$ is not symmetric and so is not a projection matrix. In this case PROC GAM uses

$$DF(\text{smoother}) = \text{tr}(A_i(y, \lambda)'(A_i(y, \lambda))$$

The GAM procedure gives you the option of specifying the degrees of freedom for each individual smoothing component. If you choose a particular value for the degrees of freedom, then during every local scoring iteration the procedure will search
Confidence Intervals for Smoothers

for a corresponding smoothing parameter lambda that yields the specified value or comes as close as possible. The final estimate for the smoother during this local scoring iteration will be based on this lambda. Note that for univariate spline components, an additional degree of freedom is removed by default to account for the linear portion of the model, so the value displayed in the Fit Summary and Analysis of Deviance tables will be one less than the value you specify.

Confidence Intervals for Smoothers

In the GAM procedure, curvewise confidence intervals for smoothing splines and pointwise confidence intervals for loess are provided in the output dataset.

Curvewise Confidence Interval for Smoothing Spline

Viewing the spline model as a Bayesian model, Wahba (1983) proposed Bayesian confidence intervals for smoothing spline estimates as follows:

$$\hat{s}_\lambda(x_i) \pm z_{\alpha/2} \sqrt{\hat{\sigma}^2 a_{ii}(\lambda)}$$

where $a_{ii}(\lambda)$ is the $i$th diagonal element of the $A(\lambda)$ matrix and $z_{\alpha/2}$ is the $\alpha/2$ point of the normal distribution. The confidence intervals are interpreted as intervals “across the function” as opposed to point-wise intervals.

Suppose that you fit a spline estimate to experimental data that consists of a true function $f$ and a random error term, $\epsilon_i$. In repeated experiments, it is likely that about $100(1 - \alpha)$% of the confidence intervals cover the corresponding true values, although some values are covered every time and other values are not covered by the confidence intervals most of the time. This effect is more pronounced when the true response curve or surface has small regions of particularly rapid change.

Pointwise Confidence Interval for Loess Smoothers

As defined in Cleveland, Devlin, and Grosse (1988), a standardized residual for a loess smoother follows a $t$ distribution with $\rho$ degrees of freedom, where $\rho$ is called the “lookup degrees of freedom,” defined as

$$\rho = \delta_1^2 / \delta_2$$

where $\delta_1 = Trace((I - A(\lambda))^T(I - A(\lambda)))$ and $\delta_2 = Trace((I - A(\lambda))^T(I - A(\lambda)))^2$. Therefore an approximate pointwise confidence interval at $x_i$ is

$$\hat{s}_\lambda(x_i) \pm t_{\alpha/2,\rho} \hat{\sigma}(x_i)$$

where $\hat{\sigma}(x_i)$ is the estimate of the standard deviation.
Distribution Family and Canonical Link

In general, there is not just one reasonable link function for a given response variable distribution. For parametric models, the choice of link function can lead to substantively different estimates and tests. However, the inherent flexibility of nonparametric models makes them less likely to be sensitive to the precise choice of link function. Thus, for simplicity and computational efficiency, the GAM procedure uses only the canonical link for each distribution, as discussed below.

**The Gaussian Model**

With this model, the link function is the identity function, and the generalized additive model is the additive model.

**The Binomial Model**

A binomial response model assumes that the proportion of successes $Y$ is such that $Y$ has a $\text{Bin}(n, p(x))$ distribution. The $\text{Bin}(n, p(x))$ refers to the binomial distribution with parameters $n$ and $p(x)$. Often the data are binary, in which case $n = 1$. The canonical link is

$$g(p) = \log \frac{p}{n - p} = \eta$$

**The Poisson Model**

The link function for the Poisson model is the log function. Assuming that the mean of the Poisson distribution is $\mu(x)$, the dependence of $\mu(x)$ and independent variable $x_1, \cdots, x_k$ is

$$g(\mu) = \log(\mu) = \eta$$

**The Gamma Model**

Let the mean of the Gamma distribution be $\mu(x)$. The canonical link function for the Gamma distribution is $-1/\mu(x)$. Therefore, the relationship between $\mu(x)$ and the independent variable $x_1, \cdots, x_k$ is

$$g(\mu) = -\frac{1}{\mu} = \eta$$

**The Inverse Gaussian Model**

Let the mean of the Inverse Gaussian distribution be $\mu(x)$. The canonical link function for inverse Gaussian distribution is $1/\mu^2$. Therefore, the relationship between $\mu(x)$ and the independent variable $x_1, \cdots, x_k$ is

$$g(\mu) = \frac{1}{\mu^2} = \eta$$
Dispersion Parameter

Continuous distributions in the exponential family (Gaussian, Gamma, and Inverse Gaussian) have a dispersion parameter that can be estimated by the scaled deviance. For these continuous response distributions, PROC GAM incorporates this dispersion parameter estimate into standard errors of the parameter estimates, prediction standard errors of spline components, and chi-square statistics. The discrete distributions used in GAM (Binomial and Poisson) do not have a dispersion parameter. For more details on the distributions, dispersion parameter, and deviance, refer to “Generalized Linear Models Theory” in Chapter 31, “The GENMOD Procedure.”

Forms of Additive Models

Suppose that $y$ is a continuous variable and $x_1$ and $x_2$ are two explanatory variables of interest. To fit an additive model, you can use a MODEL statement similar to that used in many regression procedures in the SAS System:

```sas
model y = spline(x1) spline(x2);
```

This model statement requires the procedure to fit the following model:

$$\eta(x_1, x_2) = \text{Intercept} + s_1(x_1) + s_2(x_2)$$

where the $s_i()$ terms denote nonparametric spline functions of the respective explanatory variables.

The GAM procedure can fit semiparametric models. The following MODEL statement assumes a linear relation with $x_1$ and an unknown functional relation with $x_2$:

```sas
model y = param(x1) spline(x2);
```

If you want to fit a model containing a functional two-way interaction between $x_1$ and $x_2$, you can use the following MODEL statement:

```sas
model y = spline2(x1,x2);
```

In this case, the GAM procedure fits a model equivalent to that of PROC TPSPLINE.

Estimates from PROC GAM

PROC GAM provides the ability to fit both nonparametric and semiparametric models. In order to better understand the underlying trend of any given factor, PROC GAM separates the linear trend from any general nonparametric trend during the fitting as well as in the final report. This makes it easy for you to determine whether the significance of a smoothing variable is associated with a simple linear trend or a more complicated pattern.
For example, suppose you want to fit a semiparametric model as

\[ y = \alpha_0 + \alpha_1 z + s_1(x_1) + s_2(x_2) \]

The GAM estimate for this model is

\[ y = \alpha_0 + \alpha_1 z + \beta_1 x_1 + \beta_2 x_2 + f_1(x_1) + f_2(x_2) \]

where \( f_1 \) and \( f_2 \) are linear-adjusted nonparametric estimates of the \( s_1 \) and \( s_2 \) effects. The \( p \)-values for \( \alpha_0, \alpha_1, \beta_1, \) and \( \beta_2 \) are reported in the parameter estimates table. \( \beta_1 \) and \( \beta_2 \) are the estimates labeled Linear\((x_1)\) and Linear\((x_2)\) in the table. The \( p \)-values for \( f_1 \) and \( f_2 \) are reported in the analysis of deviance table.

Only \( \hat{f}_1, \hat{f}_2, \) and \( \hat{y} \) are output to the output data set, with corresponding variable names \( P-x_1, P-x_2, \) and \( P-y, \) respectively. For Gaussian data, the complete marginal prediction for variable \( x_1 \) is

\[ \beta_1 x_1 + P-x_1 \]

For non-Gaussian data, an appropriate transformation is required to get back to the original data scale.

**ODS Table Names**

PROC GAM assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, refer to Chapter 14, “Using the Output Delivery System.”

<table>

By referring to the names of such tables, you can use the ODS OUTPUT statement to place one or more of these tables in output data sets.
This section describes the use of ODS for creating statistical graphs with the GAM procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release. To request these graphs you must specify the ODS GRAPHICS statement in addition to the options indicated below. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

When the ODS GRAPHICS are in effect, the GAM procedure will produce plots of the partial predictions for each nonparametric predictor in the model. Use the PLOTS option on the PROC GAM statement to control aspects of these plots.

**PLOTS** \(<(general-plot-options)>=keywords<(plot-options)>\)
specifies characteristics of the graphics produced when you use the experimental ODS GRAPHICS statement. You can specify the following *general-plot-options* in parentheses after the PLOTS option:

- **CLM** specifies that smoothing component plots should include a 95% confidence band. Note that producing this band can be computationally intensive for large data sets.
- **COMMONAXES** specifies that smoothing component plots within a single graphics panel should all have the same vertical axis limits. This enables you to visually judge relative effect size.
- **UNPACK|UNPACKPANELS** specifies that multiple smoothing component plots that are collected into graphics panels should be additionally displayed separately. Use this option if you want to access individual smoothing component plots within the panel.

You can specify the following keywords as arguments to the PLOTS= option.

- **COMPONENTS** \(<(number-list)|ALL>)\) specifies that only particular smoothing component plots should be produced. Plots for successive smoothing components are named COMPONENT1, COMPONENT2, and so on. For example, specify PLOTS=COMPONENT(1 3) to produce only the first and the third smoothing component plots.

**ODS Graph Names**

PROC GAM assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 30.3.

To request these graphs you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”
Table 30.3. ODS Graphics Produced by PROC GAM

<table>

</table>

By default, partial prediction plots for each component are displayed in panels of multiple plots named SmoothingComponentPanel1, SmoothingComponentPanel2, and so on. Use the PLOTS(UNPANEL) option on the PROC GAM statement to display these plots individually as well. Use the PLOTS(CLM) option to superimpose confidence limits for the partial predictions.

Examples

Example 30.1. Generalized Additive Model with Binary Data

The following example illustrates the capabilities of the GAM procedure and compares it to the GENMOD procedure.

The data used in this example are based on a study by Bell et al. (1994). Bell and his associates studied the result of multiple-level thoracic and lumbar laminectomy, a corrective spinal surgery commonly performed on children. The data in the study consist of retrospective measurements on 83 patients. The specific outcome of interest is the presence (1) or absence (0) of kyphosis, defined as a forward flexion of the spine of at least 40 degrees from vertical. The available predictor variables are Age in months at time of the operation, the starting of vertebrae levels involved in the operation (StartVert), and the number of levels involved (NumVert). The goal of this analysis is to identify risk factors for kyphosis. PROC GENMOD can be used to investigate the relationship among kyphosis and the predictors. The following DATA step creates the data kyphosis:

```

Example 30.1. Generalized Additive Model with Binary Data

The GENMOD analysis of the independent variable effects is shown in Output 30.1.1. Based on these results, the only significant factor is \texttt{StartVert} with a log odds ratio of $-0.1972$. The variable \texttt{NumVert} has a $p$-value of 0.0904 with a log odds ratio of 0.3031.

The GENMOD procedure assumes a strict linear relationship between the response and the predictors. The following SAS statements use PROC GAM to investigate a less restrictive model, with moderately flexible spline terms for each of the predictors:
title 'Comparing PROC GAM with PROC GENMOD';
proc gam data=kyphosis;
   model Kyphosis = spline(Age ,df=3)
                   spline(StartVert,df=3)
                   spline(NumVert ,df=3) / dist=binomial;
run;

The MODEL statement requests an additive model using a univariate smoothing
spline for each term. The option dist=binomial with binary responses specifies a
logistic model. Each term is fit using a univariate smoothing spline with three de-
grees of freedom. Of these three degrees of freedom, one is taken up by the linear
portion of the fit and two are left for the nonlinear spline portion. Although this might
seem to be an unduly modest amount of flexibility, it is better to be conservative with
a data set this small.

Output 30.1.2 and Output 30.1.3 list the output from PROC GAM.

The critical part of the GAM results is the “Analysis of Deviance” table, shown in Output 30.1.3. For each smoothing effect in the model, this table gives a $\chi^2$-test comparing the deviance between the full model and the model without this variable. In this case the analysis of deviance results indicates that the effect of Age is highly significant, the effect of StartVert is nearly significant, and the effect of NumVert is insignificant at the 5% level. Plots of predictions against predictor can be used to investigate why PROC GAM and PROC GENMOD produce different results. The following statements use the experimental ODS GRAPHICS statement to produce plots of the individual smoothing components. The CLM suboption for the PLOTS option adds a curvewise Bayesian confidence band to each smoothing component, while the COMMONAXES suboption forces all three smoothing component plots to share the same vertical axis limits, allowing a visual judgment of nonparametric effect size.
For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GAM procedure, see the section “ODS Graphics” on page 1581. The smoothing component plots are displayed in Output 30.1.4.

Output 30.1.4. Partial Prediction for Each Predictor (Experimental)

The plots show that the partial predictions corresponding to both Age and StartVert have a quadratic pattern, while NumVert has a more complicated but weaker pattern. However, in the plot for NumVert, notice that about half the vertical range of the function is determined by the point at the upper extreme. It would be a good idea,
therefore, to rerun the analysis without this point, to explore how much it affects the conclusions. You can do this by simply including a WHERE clause when specifying the data set for the GAM procedure, as in the following code:

```plaintext
ods html;
sods graphics on;

proc gam data=kyphosis(where=(NumVert^=14)) plots(clm commonaxes);
    model Kyphosis = spline(Age ,df=3)
                    spline(StartVert,df=3)
                    spline(NumVert ,df=3) / dist=binomial;
run;

ods graphics off;
sods html close;
```

**Output 30.1.5.** Analysis After Removing NumVert=14

<table>
<thead>
<tr>

<td>3.2090</td>
<td>0.2010</td>
</tr>
</tbody>
</table>

The analysis of deviance table from this reanalysis is shown in Output 30.1.5, and Output 30.1.6 shows the recomputed partial predictor plots.
Removing data point NumVert=14 has little effect on either the analysis of deviance results or the estimated curves for StartVert and NumVert. But the removal has a noticeable effect on the variable NumVert, whose curve now also seems quadratic, though it is much less pronounced than for the other two variables.

An important difference between the first analysis of this data with GENMOD and the subsequent analysis with GAM is that GAM indicates that age is a significant predictor of kyphosis. The difference is due to the fact that the GENMOD model only includes a linear effect in Age whereas the GAM model allows a more complex relationship, which the plots indicate is nearly quadratic. Having used the GAM procedure to discover an appropriate form of the dependence of Kyphosis on each of the three independent variables, you can use the GENMOD procedure to fit and assess the corresponding parametric model. The following code fits a GENMOD model with quadratic terms for all three variables, including tests for the joint linear and quadratic effects of each variable. The resulting contrast tests are shown in Output 30.1.7.
Example 30.2. Poisson Regression Analysis of Component Reliability

In this example, the number of maintenance repairs on a complex system are modeled as realizations of Poisson random variables. The system under investigation has a large number of components, which occasionally break down and are replaced or repaired. During a four-year period, the system was observed to be in a state of steady operation, meaning that the rate of operation remained approximately constant. A monthly maintenance record is available for that period, which tracks the number of components removed for maintenance each month. The data are listed in the following statements that create a SAS data set.

```sas
proc genmod data=kyphosis(where=(NumVert^=14));
  model kyphosis = Age *Age StartVert StartVert*StartVert NumVert NumVert *NumVert /link=logit dist=binomial;
  contrast 'Age' Age 1, Age*Age 1;
  contrast 'StartVert' StartVert 1, StartVert*StartVert 1;
  contrast 'NumVert' NumVert 1, NumVert*NumVert 1;
run;
```

Output 30.1.7. Joint Linear and Quadratic Tests

**Comparing PROC GAM with PROC GENMOD**

The GENMOD Procedure

PROC GENMOD is modeling the probability that Kyphosis='0'. One way to change this to model the probability that Kyphosis='1' is to specify the DESCENDING option in the PROC statement.

<table>
<thead>
<tr>
<th>Contrast</th>
<th>DF</th>
<th>Chi-Square</th>
<th>Pr &gt; ChiSq</th>

<td>LR</td>
</tr>
<tr>
<td>NumVert</td>
<td>2</td>
<td>3.56</td>
<td>0.1684</td>
<td>LR</td>
</tr>
</tbody>
</table>

The results for the quadratic GENMOD model are now quite consistent with the GAM results.

From this example, you can see that PROC GAM is very useful in visualizing the data and detecting the nonlinearity among the variables.
For planning purposes, it is of interest to understand the long- and short-term trends in the maintenance needs of the system. Over the long term, it is suspected that the quality of new components and repair work improves over time, so the number of component removals would tend to decrease from year to year. It is not known whether the robustness of the system is affected by seasonal variations in the operating environment, but this possibility is also of interest.

Because the maintenance record is in the form of counts, the number of removals are modeled as realizations of Poisson random variables. Denote by $\lambda_{ij}$ the unobserved component removal rate for year $i$ and month $j$. Since the data were recorded at regular intervals (from a system operating at a constant rate), each $\lambda_{ij}$ is assumed to be a function of year and month only.

A preliminary two-way analysis is performed using PROC GENMOD to make broad inferences on repair trends. A log-link is specified for the model

$$\log \lambda_{ij} = \mu + \alpha^Y_i + \alpha^M_j$$

where $\mu$ is a grand mean, $\alpha^Y_i$ is the effect of the $i$th year, and $\alpha^M_j$ is the effect of the $j$th month. A CLASS statement declares the variables year and month as categorical. Type III sum of squares are requested to test whether there is an overall effect of year and/or month only.

Output 30.2.1. PROC GENMOD Listing for Type III Analysis

Analysis of Component Reliability
Two-way model

The GENMOD Procedure

LR Statistics For Type III Analysis

<table>
<thead>
<tr>
<th>Source</th>
<th>DF</th>
<th>Chi-Square</th>
<th>Pr &gt; ChiSq</th>
</tr>
</thead>
<tbody>
<tr>
<td>year</td>
<td>3</td>
<td>2.63</td>
<td>0.4527</td>
</tr>
<tr>
<td>month</td>
<td>11</td>
<td>21.12</td>
<td>0.0321</td>
</tr>
</tbody>
</table>

Output 30.2.1 displays the listed Type III statistics for the fitted model. With the test for year effects yielding a \( p \)-value of 0.4527, there is no evidence of a long-term trend in maintenance rates. Apparently, the quality of new or repaired components did not change between 1987 and 1990. However, the test for monthly trends does yield a small \( p \)-value of 0.0321, indicating that seasonal trends are just barely significant at the \( \alpha = 0.05 \) level.

The Type III tests indicate that the year term may be dropped from the model. The focus of the analysis is now on identifying the form of the underlying seasonal trend, which is a task that PROC GAM is especially suited for. PROC GAM will be used to fit both a reduced categorical model, with year eliminated, and a nonparametric spline model. Although PROC GENMOD also has the capability to fit categorical models, as demonstrated above, PROC GAM will be used to fit both models for a better comparison.

The following PROC GAM statements specify the reduced categorical model. For this part of the analysis, a CLASS statement is again used to specify that month is a categorical variable. In the follow-up, the seasonal effect will be treated as a nonparametric function of month.

```r
title2 'One-way model';
proc gam data=equip;
   class month;
   model removals=param(month)
         / dist=Poisson;
   output out=est predicted;
run;
```

The following statements generate a plot of the estimated seasonal trend. Note that the predicted values in the output data set correspond to the logarithms of the \( \lambda_{ij} \), and so the exponential function is applied to put them on the scale of the original data. The plot is displayed in Output 30.2.2.
The predicted repair rates shown in Output 30.2.2 form a jagged seasonal pattern. Ignoring the month-to-month fluctuations, which are difficult to explain and may be artifacts of random noise, the general removal rate trend starts by increasing at the beginning of the year; the trend flattens out in February and then decreases through
August; it flattens out again in September and begins an increasing trend that continues throughout the rest of the year.

One advantage of nonparametric regression is its ability to highlight general trends in the data, such as those described above, and attribute local fluctuations to unexplained random noise. The nonparametric regression model used by PROC GAM specifies that the underlying removal rates $\lambda_j$ are of the form

$$\log \lambda_j = \beta_0 + \beta_1 \text{Month}_j + s(\text{Month}_j)$$

where $\beta_1$ is a linear coefficient and $s()$ is a nonparametric regression function. $\beta_1$ and $s()$ define the linear and nonparametric parts, respectively, of the seasonal trend.

The following statements request that PROC GAM fit a cubic spline model to the monthly repair data. The output listing is displayed in Output 30.2.3.

```plaintext
title 'Analysis of Component Reliability';
title2 'Spline model';
proc gam data=equip;
   model removals=spline(month)
      / dist=Poisson method=gcv;
run;
```

The METHOD=GCV option is used to determine an appropriate level of smoothing. The keywords LCLM and UCLM in the OUTPUT statement request that lower and upper 95% confidence bounds on each $s(\text{Month}_j)$ be included in the output data set.

</tr>
</tbody>
</table>

Notice in the listing of Output 30.2.4 that the DF value chosen for the nonlinear portion of the spline by minimizing GCV is about 1.88, which is smaller than the default value of 3. This indicates that the spline model of the seasonal trend is relatively simple. As indicated by the “Analysis of Deviance” table, it is a significant feature of the data: the table lists a $p$-value of 0.0103 for the hypothesis of no seasonal trend. Note also that the “Parameter Estimates” table lists a $p$-value of 0.2362 for the hypothesis of no linear factor in the seasonal trend.

The following statements use the experimental ODS GRAPHICS statement to plot the smoothing component for the effect of Month on predicted repair rates.

```
ods html;
ods graphics on;
proc gam data=equip;
   model removals=spline(month) / dist=Poisson method=gcv;
run;
ods graphics off;
ods html close;
```
For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GAM procedure, see the section “ODS Graphics” on page 1581. The smoothing component plot is displayed in Output 30.2.5.

**Output 30.2.5.** Predicted Seasonal Trend from a Cubic Spline Model (Experimental)

In Output 30.2.5, it is apparent that the pattern of repair rates follows the general pattern observed in Output 30.2.2. However, the plot of Output 30.2.5, is much cleaner as the month-to-month fluctuations are smoothed out to reveal the broader seasonal trend.

You can use the PLOTS(CLM) option to added a 95% confidence band to the plot of $s(Month_j)$, as in the following statements.

```plaintext
ods html; ods graphics on;
proc gam data=equip plots(clm);
  model removals=spline(month)
    / dist=Poisson method=gcv;
run;
ods graphics off; ods html close;
```
The plot is displayed in Output 30.2.6.

**Output 30.2.6.** Estimated Nonparametric Factor of Seasonal Trend, Along with 95% Confidence Bounds (Experimental)

The small \( p \)-value in Output 30.2.1 of 0.0321 for the hypothesis of no seasonal trend indicates that the data exhibit significant seasonal structure. However, Output 30.2.6 is a graphical illustration of a degree of indistinctness in that structure. For instance, the horizontal reference line at zero is entirely within the 95% confidence band; that is, the estimated nonlinear part of the trend is relatively flat. Thus, despite evidence of seasonality based on the parametric model, it is difficult to narrow down its significant effects to a specific part of the year.

**Example 30.3. Comparing PROC GAM with PROC LOESS**

In an analysis of simulated data from a hypothetical chemistry experiment, additive nonparametric regression performed by PROC GAM is compared to the unrestricted multidimensional procedure of PROC LOESS.

In each repetition of the experiment, a catalyst is added to a chemical solution, thereby inducing synthesis of a new material. The data are measurements of the temperature of the solution, the amount of catalyst added, and the yield of the chemical reaction. The following code reads and plots the raw data.
Example 30.3. Comparing PROC GAM with PROC LOESS

Chapter 30. The GAM Procedure (Experimental)

Output 30.3.1. Surface Plot of Yield by Temperature and Amount of Catalyst

A surface fitted to the plot of Output 30.3.1 by PROC LOESS will be of a very general (and flexible) type, since the procedure requires only weak assumptions about the structure of the dependencies among the data. PROC GAM, on the other hand, makes stronger structural assumptions by restricting the fitted surface to an additive form. These differences will be demonstrated in this example.

The following code requests that both PROC LOESS and PROC GAM fit surfaces to the data.

```sas
ods output OutputStatistics=PredLOESS;
proc loess data=ExperimentA;
   model Yield = Temperature Catalyst 
                  / scale=sd degree=2 select=gcv;
run;
ods output close;

proc gam data=ExperimentA;
   model Yield = loess(Temperature) loess(Catalyst) 
                  / method=gcv;
   output out=PredGAM;
run;
```

In both cases the smoothing parameter was chosen as the value that minimizes GCV. This is performed automatically by PROC LOESS and PROC GAM.

The following code generates plots of the predicted yields, which are displayed in Output 30.3.2.
title2 'PROC LOESS fitted surface';
proc g3d data=PredLOESS;
   format pred f6.3;
   plot Temperature*Catalyst=pred
      / name='LOESSA' zmin=2 zmax=11;
run;

title2 'PROC GAM additive fitted surface';
proc g3d data=PredGAM;
   format P_Yield f6.3;
   plot Temperature*Catalyst=P_Yield
      / name='GAMA' zmin=2 zmax=11;
run;

goptions display;
proc greplay nofs tc=sashelp.templt template=v2;
   igout=gseg;
   treplay 1:loessa 2:gama;
run; quit;

Output 30.3.2. Fitted Regression Surfaces

Though both PROC LOESS and PROC GAM use the statistical technique loess, it is apparent from Output 30.3.2 that the manner in which it is applied is very different. By smoothing out the data in local neighborhoods, PROC LOESS essentially fits a surface to the data in pieces, one neighborhood at a time. The local regions are treated independently, so separate areas of the fitted surface are only weakly re-
lated. PROC GAM imposes additive structure, requiring that cross sections of the fitted surface always have the same shape and thereby relating regions that have a common value of the same individual regressor variable. Under that restriction, the loess technique need not be applied to the entire multidimensional scatter plot, but only to one-dimensional cross sections of the data.

The advantage of using additive model fitting is that its statistical power is directed toward univariate smoothing, and so it is able to discern the finer details of any underlying structure in the data. Regression data may be very sparse when viewed in the context of multidimensional space, even when every individual set of regressor values densely covers its range. This is the familiar curse of dimensionality. Sparse data greatly restricts the effectiveness of nonparametric procedures, but additive model fitting, when appropriate, is one way to overcome this limitation.

To examine these properties, plots of cross sections of unrestricted (PROC LOESS) and additive (PROC GAM) fitted surfaces for the variable Catalyst are generated by the following code. The code for creating the cross section plots and overlaying them is somewhat complicated, so a macro %XPlot is employed to make it easy to create this plot for the results of each procedure.

```plaintext
axis1 minor=none order=(2 to 11 by 2)
  label=(angle=90 rotate=0 "Predicted Yield");
axis2 minor=none order=(0.005 to 0.080 by 0.025)
  label="Catalyst";
symbol1 color=blue interpol=join value=none
  line=1 width=1;

%macro XPlot(proc=,name=);
  proc sort data=Pred&proc;
    by Catalyst Temperature;
  run;

data PredX&proc;
  keep Pred80 Pred90 Pred100 Pred110 Pred120 Pred130 Pred140 Catalyst;
  array xPred{8:14} Pred80 Pred90 Pred100 Pred110 Pred120 Pred130 Pred140;
  retain Pred80 Pred90 Pred100 Pred110 Pred120 Pred130 Pred140;
  set Pred&proc;
  %if &proc=LOESS %then %do;
    xPred(Temperature/10) = pred;
  %end;
  %else %if &proc=GAM %then %do;
    xPred(Temperature/10) = P_Yield;
  %end;
  if abs(Temperature-140)<1 then output;
run;

proc gplot data=PredX&proc;
  plot Pred140*Catalyst=1 Pred130*Catalyst=1
```

Example 30.3. Comparing PROC GAM with PROC LOESS

Pred120*Catalyst=1 Pred110*Catalyst=1 Pred100*Catalyst=1 Pred90*Catalyst=1 Pred80*Catalyst=1 / overlay cframe=ligr name=&name vaxis=axis1 haxis=axis2;
run; quit;
%mend;
title;
title2 'PROC LOESS fitted surface, cross sections'; %XPLOT(proc=LOESS,name='XLOESSA');

   igout=gseg;
   treplay 1:xloessa 2:xgama;
run; quit;

The plots are displayed in Output 30.3.3.

Output 30.3.3. Cross sections of Fitted Regression Surfaces
Notice that the graphs in the top panel (PROC LOESS) of Output 30.3.3 have varying shapes, while every graph in the bottom panel (PROC GAM) is the same curve shifted vertically. This illustrates precisely the kind of structural differences that distinguish additive models. A second important comparison to make in Output 30.3.2 and Output 30.3.3 is the level of detail in the fitted regression surfaces. Cross sections of the PROC LOESS surface are rather flat, but those of the additive surface have a clear shape. In particular, the ridge near Catalyst=0.055 is only vaguely evident in the PROC LOESS surface, but it is plainly revealed by the additive procedure.

For an example of a situation where unrestricted multidimensional fitting is preferred over additive regression, consider the following simulated data from a similar experiment. The following code creates another SAS data set and plot.

Example 30.3. Comparing PROC GAM with PROC LOESS

```
140 0.065 5.799 140 0.070 7.992 140 0.075 7.835
140 0.080 8.985
```

; run;

**title2 'Raw data';**
**proc g3d data=ExperimentB;**
   **plot Temperature*Catalyst=Yield**
   / zmin=2 zmax=11;
**run;**

A plot of the raw data is displayed in **Output 30.3.4**.

**Output 30.3.4.** Raw Data from Experiment B

![Raw data](image)

Though the surface displayed in **Output 30.3.4** is quite jagged, a distinct feature of the plot is a large ridge that runs diagonally across its surface. One would expect that the ridge would appear in the fitted regression surface of an appropriate nonparametric procedure. Nevertheless, between PROC LOESS and PROC GAM, only PROC LOESS is able to capture this significant feature.

The SAS code for fitting the new data is essentially the same as that for the data set from the first experiment. Similar to **Output 30.3.2**, multivariate and additive fitted surfaces for these data are displayed in **Output 30.3.5**.
Output 30.3.5. Fitted Regression Surfaces

It is clear from Output 30.3.5 that the results of PROC LOESS and PROC GAM are completely different. While the plot in the top panel resembles the raw data plot in Output 30.3.4, the plot in the bottom panel is essentially featureless.

To understand what is happening, compare the scatter plots of Yield by Catalyst for the two data sets in this example. These are generated by the following code and displayed in Output 30.3.6.

```plaintext
axis1 minor=none order=(2 to 11 by 2)
   label=(angle=90 rotate=0 "Predicted Yield");
axis2 minor=none order=(0.005 to 0.080 by 0.025) label=("Catalyst");
symbol2 c=yellow v=dot i=none;
title2 'Experiment A';
proc gplot data=ExperimentA;
   plot Yield*Catalyst=2
      / cframe=ligr name='ExptA'
      vaxis=axis1 haxis=axis2;
run; quit;

title2 'Experiment B';
proc gplot data=ExperimentB;
   plot Yield*Catalyst=2
      / cframe=ligr name='ExptB'
      vaxis=axis1 haxis=axis2;
run; quit;
```
Example 30.3. Comparing PROC GAM with PROC LOESS

```
proc greplay nofs tc=sashelp.templt template=v2;
  igout=gseg;
  treplay 1:expta 2:exptb;
run; quit;
```

Output 30.3.6. Scatterplots of Yield by Catalyst

The top panel of Output 30.3.6 hints at the same kind of structure exhibited in the fitted cross sections of Output 30.3.3. In PROC GAM, the additive model component corresponding to Catalyst is fit to a similar scatter plot, with the partial residuals computed in the backfitting algorithm, so it is able to capture the trend seen here. In contrast, when the second data set is viewed from the perspective of Output 30.3.6, the diagonal ridge apparent in Output 30.3.4 is washed out, and no clear structure shows up in the scatter plot. As a result, the additive model fit produced by PROC GAM is relatively featureless.

Chapter 31
The GENMOD Procedure

Overview

The GENMOD procedure fits generalized linear models, as defined by Nelder and Wedderburn (1972). The class of generalized linear models is an extension of traditional linear models that allows the mean of a population to depend on a linear predictor through a nonlinear link function and allows the response probability distribution to be any member of an exponential family of distributions. Many widely used statistical models are generalized linear models. These include classical linear models with normal errors, logistic and probit models for binary data, and log-linear models for multinomial data. Many other useful statistical models can be formulated as generalized linear models by the selection of an appropriate link function and response probability distribution. Refer to McCullagh and Nelder (1989) for a discussion of statistical modeling using generalized linear models. The books by Aitkin, Anderson, Francis, and Hinde (1989) and Dobson (1990) are also excellent references with many examples of applications of generalized linear models. Firth (1991) provides an overview of generalized linear models.

The analysis of correlated data arising from repeated measurements when the measurements are assumed to be multivariate normal has been studied extensively. However, the normality assumption may not always be reasonable; for example, different methodology must be used in the data analysis when the responses are discrete and correlated. Generalized Estimating Equations (GEEs) provide a practical method with reasonable statistical efficiency to analyze such data.

Liang and Zeger (1986) introduced GEEs as a method of dealing with correlated data when, except for the correlation among responses, the data can be modeled as a generalized linear model. For example, correlated binary and count data in many cases can be modeled in this way.

The GENMOD procedure can fit models to correlated responses by the GEE method. You can use PROC GENMOD to fit models with most of the correlation structures from Liang and Zeger (1986) using GEEs. Refer to Liang and Zeger (1986), Diggle, Liang, and Zeger (1994), and Lipsitz, Fitzmaurice, Orav, and Laird (1994) for more details on GEEs.

Experimental graphics are now available with the GENMOD procedure for model assessment. For more information, see the “ODS Graphics” section on page 1695.
What Is a Generalized Linear Model?

A traditional linear model is of the form

\[ y_i = x_i^T \beta + \varepsilon_i \]

where \( y_i \) is the response variable for the \( i \)th observation. The quantity \( x_i \) is a column vector of covariates, or explanatory variables, for observation \( i \) that is known from the experimental setting and is considered to be fixed, or nonrandom. The vector of unknown coefficients \( \beta \) is estimated by a least squares fit to the data \( y \). The \( \varepsilon_i \) are assumed to be independent, normal random variables with zero mean and constant variance. The expected value of \( y_i \), denoted by \( \mu_i \), is

\[ \mu_i = x_i^T \beta \]

While traditional linear models are used extensively in statistical data analysis, there are types of problems for which they are not appropriate.

- It may not be reasonable to assume that data are normally distributed. For example, the normal distribution (which is continuous) may not be adequate for modeling counts or measured proportions that are considered to be discrete.
- If the mean of the data is naturally restricted to a range of values, the traditional linear model may not be appropriate, since the linear predictor \( x_i^T \beta \) can take on any value. For example, the mean of a measured proportion is between 0 and 1, but the linear predictor of the mean in a traditional linear model is not restricted to this range.
- It may not be realistic to assume that the variance of the data is constant for all observations. For example, it is not unusual to observe data where the variance increases with the mean of the data.

A generalized linear model extends the traditional linear model and is, therefore, applicable to a wider range of data analysis problems. A generalized linear model consists of the following components:

- The linear component is defined just as it is for traditional linear models:
  \[ \eta_i = x_i^T \beta \]

- A monotonic differentiable link function \( g \) describes how the expected value of \( y_i \) is related to the linear predictor \( \eta_i \):
  \[ g(\mu_i) = x_i^T \beta \]

- The response variables \( y_i \) are independent for \( i = 1, 2, \ldots \) and have a probability distribution from an exponential family. This implies that the variance of the response depends on the mean \( \mu \) through a variance function \( V \):
  \[ \text{var}(y_i) = \frac{\phi V(\mu_i)}{w_i} \]
where $\phi$ is a constant and $w_i$ is a known weight for each observation. The dispersion parameter $\phi$ is either known (for example, for the binomial or Poisson distribution, $\phi = 1$) or it must be estimated.

See the section “Response Probability Distributions” on page 1650 for the form of a probability distribution from the exponential family of distributions.

As in the case of traditional linear models, fitted generalized linear models can be summarized through statistics such as parameter estimates, their standard errors, and goodness-of-fit statistics. You can also make statistical inference about the parameters using confidence intervals and hypothesis tests. However, specific inference procedures are usually based on asymptotic considerations, since exact distribution theory is not available or is not practical for all generalized linear models.

### Examples of Generalized Linear Models

You construct a generalized linear model by deciding on response and explanatory variables for your data and choosing an appropriate link function and response probability distribution. Some examples of generalized linear models follow. Explanatory variables can be any combination of continuous variables, classification variables, and interactions.

**Traditional Linear Model**
- response variable: a continuous variable
- distribution: normal
- link function: identity $g(\mu) = \mu$

**Logistic Regression**
- response variable: a proportion
- distribution: binomial
- link function: logit $g(\mu) = \log \left( \frac{\mu}{1 - \mu} \right)$

**Poisson Regression in Log Linear Model**
- response variable: a count
- distribution: Poisson
- link function: log $g(\mu) = \log(\mu)$

**Gamma Model with Log Link**
- response variable: a positive, continuous variable
- distribution: gamma
- link function: log $g(\mu) = \log(\mu)$
The GENMOD Procedure

The GENMOD procedure fits a generalized linear model to the data by maximum likelihood estimation of the parameter vector \( \beta \). There is, in general, no closed form solution for the maximum likelihood estimates of the parameters. The GENMOD procedure estimates the parameters of the model numerically through an iterative fitting process. The dispersion parameter \( \phi \) is also estimated by maximum likelihood or, optionally, by the residual deviance or by Pearson’s chi-square divided by the degrees of freedom. Covariances, standard errors, and are computed for the estimated parameters based on the asymptotic normality of maximum likelihood estimators.

A number of popular link functions and probability distributions are available in the GENMOD procedure. The built-in link functions are

- identity: \( g(\mu) = \mu \)
- logit: \( g(\mu) = \log(\mu/(1 - \mu)) \)
- probit: \( g(\mu) = \Phi^{-1}(\mu) \), where \( \Phi \) is the standard normal cumulative distribution function
- power: \( g(\mu) = \begin{cases} \mu^\lambda & \text{if } \lambda \neq 0 \\ \log(\mu) & \text{if } \lambda = 0 \end{cases} \)
- log: \( g(\mu) = \log(\mu) \)
- complementary log-log: \( g(\mu) = \log(-\log(1 - \mu)) \)

The available distributions and associated variance functions are

- normal: \( V(\mu) = 1 \)
- binomial (proportion): \( V(\mu) = \mu(1 - \mu) \)
- Poisson: \( V(\mu) = \mu \)
- gamma: \( V(\mu) = \mu^2 \)
- inverse Gaussian: \( V(\mu) = \mu^3 \)
- negative binomial: \( V(\mu) = \mu + k\mu^2 \)
- multinomial

The negative binomial is a distribution with an additional parameter \( k \) in the variance function. PROC GENMOD estimates \( k \) by maximum likelihood, or you can optionally set it to a constant value. Refer to McCullagh and Nelder (1989, Chapter 11), Hilbe (1994), or Lawless (1987) for discussions of the negative binomial distribution.

The multinomial distribution is sometimes used to model a response that can take values from a number of categories. The binomial is a special case of the multinomial with two categories. See the section “Multinomial Models” on page 1671 and refer to McCullagh and Nelder (1989, Chapter 5) for a description of the multinomial distribution.

In addition, you can easily define your own link functions or distributions through DATA step programming statements used within the procedure.
An important aspect of generalized linear modeling is the selection of explanatory variables in the model. Changes in goodness-of-fit statistics are often used to evaluate the contribution of subsets of explanatory variables to a particular model. The deviance, defined to be twice the difference between the maximum attainable log likelihood and the log likelihood of the model under consideration, is often used as a measure of goodness of fit. The maximum attainable log likelihood is achieved with a model that has a parameter for every observation. See the section “Goodness of Fit” on page 1656 for formulas for the deviance.

One strategy for variable selection is to fit a sequence of models, beginning with a simple model with only an intercept term, and then include one additional explanatory variable in each successive model. You can measure the importance of the additional explanatory variable by the difference in deviances or fitted log likelihoods between successive models. Asymptotic tests computed by the GENMOD procedure enable you to assess the statistical significance of the additional term.

The GENMOD procedure enables you to fit a sequence of models, up through a maximum number of terms specified in a MODEL statement. A table summarizes twice the difference in log likelihoods between each successive pair of models. This is called a Type 1 analysis in the GENMOD procedure, because it is analogous to Type I (sequential) sums of squares in the GLM procedure. As with the PROC GLM Type I sums of squares, the results from this process depend on the order in which the model terms are fit.

The GENMOD procedure also generates a Type 3 analysis analogous to Type III sums of squares in the GLM procedure. A Type 3 analysis does not depend on the order in which the terms for the model are specified. A GENMOD procedure Type 3 analysis consists of specifying a model and computing likelihood ratio statistics for Type III contrasts for each term in the model. The contrasts are defined in the same way as they are in the GLM procedure. The GENMOD procedure optionally computes Wald statistics for Type III contrasts. This is computationally less expensive than likelihood ratio statistics, but it is thought to be less accurate because the specified significance level of hypothesis tests based on the Wald statistic may not be as close to the actual significance level as it is for likelihood ratio tests.

A Type 3 analysis generalizes the use of Type III estimable functions in linear models. Briefly, a Type III estimable function (contrast) for an effect is a linear function of the model parameters that involves the parameters of the effect and any interactions with that effect. A test of the hypothesis that the Type III contrast for a main effect is equal to 0 is intended to test the significance of the main effect in the presence of interactions. See Chapter 32, “The GLM Procedure,” and Chapter 11, “The Four Types of Estimable Functions,” for more information about Type III estimable functions. Also refer to Littell, Freund, and Spector (1991).

Additional features of the GENMOD procedure are

- likelihood ratio statistics for user-defined contrasts, that is, linear functions of the parameters, and $p$-values based on their asymptotic chi-square distributions
- estimated values, standard errors, and confidence limits for user-defined contrasts and least-squares means
ability to create a SAS data set corresponding to most tables displayed by the procedure (see Table 31.3 on page 1694)

- confidence intervals for model parameters based on either the profile likelihood function or asymptotic normality

- syntax similar to that of PROC GLM for the specification of the response and model effects, including interaction terms and automatic coding of classification variables

- ability to fit GEE models for clustered response data

### Getting Started

#### Poisson Regression

You can use the GENMOD procedure to fit a variety of statistical models. A typical use of PROC GENMOD is to perform Poisson regression.

You can use the Poisson distribution to model the distribution of cell counts in a multiway contingency table. Aitkin, Anderson, Francis, and Hinde (1989) have used this method to model insurance claims data. Suppose the following hypothetical insurance claims data are classified by two factors: age group (with two levels) and car type (with three levels).

```
data insure;
  input n c car$ age;
  ln = log(n);
  datalines;
  500 42 small 1
  1200 37 medium 1
  100 1 large 1
  400 101 small 2
  500 73 medium 2
  300 14 large 2
; run;
```

In the preceding data set, the variable \( n \) represents the number of insurance policyholders and the variable \( c \) represents the number of insurance claims. The variable \( \text{car} \) is the type of car involved (classified into three groups) and the variable \( \text{age} \) is the age group of a policyholder (classified into two groups).

You can use PROC GENMOD to perform a Poisson regression analysis of these data with a log link function. This type of model is sometimes called a log-linear model.

Assume that the number of claims \( c \) has a Poisson probability distribution and that its mean, \( \mu_i \), is related to the factors \( \text{car} \) and \( \text{age} \) for observation \( i \) by
\[
\log(\mu_i) = \log(n_i) + x_i'\beta \\
= \log(n_i) + \beta_0 +
cari(1)\beta_1 + car_i(2)\beta_2 + car_i(3)\beta_3 +
age_i(1)\beta_4 + age_i(2)\beta_5
\]

The indicator variables \(car_i(j)\) and \(age_i(j)\) are associated with the \(j\)th level of the variables \(car\) and \(age\) for observation \(i\)

\[
car_i(j) = \begin{cases} 
1 & \text{if } car = j \\
0 & \text{if } car \neq j 
\end{cases}
\]

The \(\beta\)s are unknown parameters to be estimated by the procedure. The logarithm of the variable \(n\) is used as an offset, that is, a regression variable with a constant coefficient of 1 for each observation. A log linear relationship between the mean and the factors \(car\) and \(age\) is specified by the log link function. The log link function ensures that the mean number of insurance claims for each car and age group predicted from the fitted model is positive.

The following statements invoke the GENMOD procedure to perform this analysis:

```plaintext
proc genmod data=insure;
  class car age;
  model c = car age / dist = poisson
              link = log
              offset = ln;
run;
```

The variables \(car\) and \(age\) are specified as CLASS variables so that PROC GENMOD automatically generates the indicator variables associated with \(car\) and \(age\).

The MODEL statement specifies \(c\) as the response variable and \(car\) and \(age\) as explanatory variables. An intercept term is included by default. Thus, the model matrix \(X\) (the matrix which has as its \(i\)th row the transpose of the covariate vector for the \(i\)th observation) consists of a column of 1s representing the intercept term and columns of 0s and 1s derived from indicator variables representing the levels of the \(car\) and \(age\) variables.

That is, the model matrix is

\[
X = \begin{bmatrix}
1 & 1 & 0 & 0 & 1 & 0 \\
1 & 0 & 1 & 0 & 1 & 0 \\
1 & 0 & 0 & 1 & 1 & 0 \\
1 & 1 & 0 & 0 & 0 & 1 \\
1 & 0 & 1 & 0 & 0 & 1 \\
1 & 0 & 0 & 1 & 0 & 1 
\end{bmatrix}
\]
where the first column corresponds to the intercept, the next three columns correspond to the variable car, and the last two columns correspond to the variable age.

The response distribution is specified as Poisson, and the link function is chosen to be log. That is, the Poisson mean parameter \( \mu \) is related to the linear predictor by

\[
\log(\mu) = x_i' \beta
\]

The logarithm of \( n \) is specified as an offset variable, as is common in this type of analysis. In this case, the offset variable serves to normalize the fitted cell means to a per policyholder basis, since the total number of claims, not individual policyholder claims, are observed.

PROC GENMOD produces the following default output from the preceding statements.

**Figure 31.1. Model Information**

The “Model Information” table displayed in Figure 31.1 provides information about the specified model and the input data set.

**Figure 31.2. Class Level Information**

Figure 31.2 displays the “Class Level Information” table, which identifies the levels of the classification variables that are used in the model. Note that car is a character variable, and the values are sorted in alphabetical order. This is the default sort order, but you can select different sort orders with the ORDER= option in the PROC GENMOD statement (see the ORDER= option on page 1625 for details).
Figure 31.3. Goodness Of Fit

The “Criteria For Assessing Goodness Of Fit” table displayed in Figure 31.3 contains statistics that summarize the fit of the specified model. These statistics are helpful in judging the adequacy of a model and in comparing it with other models under consideration. If you compare the deviance of 2.8207 with its asymptotic chi-square with 2 degrees of freedom distribution, you find that the $p$-value is 0.24. This indicates that the specified model fits the data reasonably well.

Figure 31.4. Analysis Of Parameter Estimates

Figure 31.4 displays the “Analysis Of Parameter Estimates” table, which summarizes the results of the iterative parameter estimation process. For each parameter in the model, PROC GENMOD displays columns with the parameter name, the degrees of freedom associated with the parameter, the estimated parameter value, the standard error of the parameter estimate, the confidence intervals, and the Wald chi-square statistic and associated $p$-value for testing the significance of the parameter to the model. If a column of the model matrix corresponding to a parameter is found to be
linearly dependent, or aliased, with columns corresponding to parameters preceding it in the model, PROC GENMOD assigns it zero degrees of freedom and displays a value of zero for both the parameter estimate and its standard error.

This table includes a row for a scale parameter, even though there is no free scale parameter in the Poisson distribution. See the “Response Probability Distributions” section on page 1650 for the form of the Poisson probability distribution. PROC GENMOD allows the specification of a scale parameter to fit overdispersed Poisson and binomial distributions. In such cases, the SCALE row indicates the value of the overdispersion scale parameter used in adjusting output statistics. See the section “Overdispersion” on page 1659 for more on overdispersion and the meaning of the SCALE parameter output by the GENMOD procedure. PROC GENMOD displays a note indicating that the scale parameter is fixed, that is, not estimated by the iterative fitting process.

It is usually of interest to assess the importance of the main effects in the model. Type 1 and Type 3 analyses generate statistical tests for the significance of these effects. You can request these analyses with the TYPE1 and TYPE3 options in the MODEL statement.

```
proc genmod data=insure;
  class car age;
  model c = car age / dist = poisson
     link = log
     offset = ln
     type1
     type3;
run;
```

The results of these analyses are summarized in the tables that follow.

</tbody>
</table>

**Figure 31.5. Type 1 Analysis**

In the table for Type 1 analysis displayed in Figure 31.5, each entry in the deviance column represents the deviance for the model containing the effect for that row and all effects preceding it in the table. For example, the deviance corresponding to car in the table is the deviance of the model containing an intercept and car. As more terms are included in the model, the deviance decreases.

Entries in the chi-square column are likelihood ratio statistics for testing the significance of the effect added to the model containing all the preceding effects. The
chi-square value of 67.69 for car represents twice the difference in log likelihoods between fitting a model with only an intercept term and a model with an intercept and car. Since the scale parameter is set to 1 in this analysis, this is equal to the difference in deviances. Since two additional parameters are involved, this statistic can be compared with a chi-square distribution with two degrees of freedom. The resulting p-value (labeled Pr>Chi) of less than 0.0001 indicates that this variable is highly significant. Similarly, the chi-square value of 104.64 for age represents the difference in log likelihoods between the model with the intercept and car and the model with the intercept, car, and age. This effect is also highly significant, as indicated by the small p-value.

</tbody>
</table>

**Figure 31.6.** Type 3 Analysis

The Type 3 analysis results in the same conclusions as the Type 1 analysis. The Type 3 chi-square value for the car variable, for example, is twice the difference between the log likelihood for the model with the variables Intercept, car, and age included and the log likelihood for the model with the car variable excluded. The hypothesis tested in this case is the significance of the variable car given that the variable age is in the model. In other words, it tests the additional contribution of car in the model.

The values of the Type 3 likelihood ratio statistics for the car and age variables indicate that both of these factors are highly significant in determining the claims performance of the insurance policyholders.

**Generalized Estimating Equations**

This section illustrates the use of the REPEATED statement to fit a GEE model, using repeated measures data from the “Six Cities” study of the health effects of air pollution (Ware et al. 1984). The data analyzed are the 16 selected cases in Lipsitz, Fitzmaurice, et al. (1994). The binary response is the wheezing status of 16 children at ages 9, 10, 11, and 12 years. The mean response is modeled as a logistic regression model using the explanatory variables city of residence, age, and maternal smoking status at the particular age. The binary responses for individual children are assumed to be equally correlated, implying an exchangeable correlation structure.

The data set and SAS statements that fit the model by the GEE method are as follows:
data six;
  input case city$ @@;
  do i=1 to 4;
    input age smoke wheeze @@;
    output;
  end;
datalines;
1 portage 9 0 1 10 0 1 11 0 1 12 0 0
2 kingston 9 1 1 10 2 1 11 2 0 12 2 0
3 kingston 9 0 1 10 0 0 11 1 0 12 1 0
4 portage 9 0 0 10 0 1 11 0 1 12 1 0
5 kingston 9 0 0 10 1 0 11 1 0 12 1 0
6 portage 9 0 0 10 1 0 11 1 0 12 1 0
7 kingston 9 1 0 10 1 0 11 0 0 12 0 0
8 portage 9 1 0 10 1 0 11 1 0 12 2 0
9 portage 9 2 1 10 2 0 11 1 0 12 1 0
10 kingston 9 0 0 10 0 0 11 0 0 12 1 0
11 kingston 9 1 1 10 0 0 11 0 1 12 0 1
12 portage 9 1 0 10 0 0 11 0 0 12 0 0
13 kingston 9 1 0 10 0 1 11 1 1 12 1 1
14 portage 9 1 0 10 2 0 11 1 0 12 2 1
15 kingston 9 1 0 10 1 0 11 1 0 12 2 1
16 portage 9 1 1 10 1 1 11 2 0 12 1 0
; run;

proc genmod data=six ;
class case city ;
  model wheeze = city age smoke / dist=bin;
  repeated subject=case / type=exch covb corrw;
run;

The CLASS statement and the MODEL statement specify the model for the mean of the wheeze variable response as a logistic regression with city, age, and smoke as independent variables, just as for an ordinary logistic regression.

The REPEATED statement invokes the GEE method, specifies the correlation structure, and controls the displayed output from the GEE model. The option SUBJECT=CASE specifies that individual subjects are identified in the input data set by the variable case. The SUBJECT= variable case must be listed in the CLASS statement. Measurements on individual subjects at ages 9, 10, 11, and 12 are in the proper order in the data set, so the WITHINSUBJECT= option is not required. The TYPE=EXCH option specifies an exchangeable working correlation structure, the COVB option specifies that the parameter estimate covariance matrix be displayed, and the CORRW option specifies that the final working correlation be displayed.

Initial parameter estimates for iterative fitting of the GEE model are computed as in an ordinary generalized linear model, as described previously. Results of the initial model fit displayed as part of the generated output are not shown here. Statistics for the initial model fit such as parameter estimates, standard errors, deviances, and
Pearson chi-squares do not apply to the GEE model, and are only valid for the initial model fit. The following tables display information that applies to the GEE model fit.

**Figure 31.7** displays general information about the GEE model fit.

Figure 31.10.  GEE Parameter Estimates Table

Syntax

You can specify the following statements in the GENMOD procedure. Items within the <> are optional.

PROC GENMOD < options >;
   ASSESS | ASSESSMENT keyword < / options >;
   BY variables;
   CLASS variables;
   CONTRAST 'label' effect values < . . . effect values > < /options >;
   DEVIANCE variable = expression;
   ESTIMATE 'label' effect values < . . . effect values > < /options >;
   FREQ | FREQUENCY variable;
   FWDLINK variable = expression;
   INVLINK variable = expression;
   LSMEANS effects < / options >;
   MODEL response = < effects > < /options >;
   OUTPUT < OUT=SAS-data-set>
      < keyword=name...keyword=name >;
   programming statements
   REPEATED SUBJECT= subject-effect < / options >;
   WEIGHT | SCWGT variable;
   VARIANCE variable = expression;

The PROC GENMOD statement invokes the procedure. All statements other than the MODEL statement are optional. The CLASS statement, if present, must precede the MODEL statement, and the CONTRAST statement must come after the MODEL statement.
PROC GENMOD Statement

PROC GENMOD < options > ;

The PROC GENMOD statement invokes the procedure. You can specify the following options.

**DATA=SAS-data-set**

specifies the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

**DESCENDING | DESCEND | DESC**

specifies that the levels of the response variable for the ordinal multinomial model and the binomial model with single variable response syntax be sorted in the reverse of the default order. For example, if RORDER=FORMATTED (the default), the DESCENDING option causes the levels to be sorted from highest to lowest instead of from lowest to highest. If RORDER=FREQ, the DESCENDING option causes the levels to be sorted from lowest frequency count to highest instead of from highest to lowest.

**NAMELEN=n**

specifies the length of effect names in tables and output data sets to be n characters long, where n is a value between 20 and 200 characters. The default length is 20 characters.

**ORDER=keyword**

specifies the sorting order for the levels of the classification variables (specified in the CLASS statement). This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use the CONTRAST or ESTIMATE statement. Note that the ORDER= option applies to the levels for all classification variables. The exception is the default ORDER=FORMATTED for numeric variables for which you have supplied no explicit format. In this case, the levels are ordered by their internal value. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the affected classification variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or ORDER=INTERNAL to get the more natural ordering. The following table displays the valid keywords and describes how PROC GENMOD interprets them.
ORDER= keyword | Levels Sorted by
---|---
DATA | order of appearance in the input data set
FORMATTED | external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ | descending frequency count; levels with the most observations come first in the order
INTERNAL | unformatted value

By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. For more information on sorting order, refer to the chapter titled “The SORT Procedure” in the SAS Procedures Guide.

RORDER=keyword specifies the sorting order for the levels of the response variable. This ordering determines which intercept parameter in the model corresponds to each level in the data. If RORDER=FORMATTED for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the response variable. The change was implemented because the former default behavior for RORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or RORDER=INTERNAL to get the more natural ordering. The following table displays the valid keywords and describes how PROC GENMOD interprets them.

RORDER= keyword | Levels Sorted by
---|---
DATA | order of appearance in the input data set
FORMATTED | external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ | descending frequency count; levels with the most observations come first in the order
INTERNAL | unformatted value
By default, RORDER=FORMATTED. For RORDER=FORMATTED and RORDER=INTERNAL, the sort order is machine dependent. The DESCENDING option in the PROC GENMOD statement causes the response variable to be sorted in the reverse of the order displayed in the previous table. For more information on sorting order, refer to the chapter on the SORT procedure in the *SAS Procedures Guide*.

The NOPRINT option, which suppresses displayed output in other SAS procedures, is not available in the PROC GENMOD statement. However, you can use the Output Delivery System (ODS) to suppress all displayed output, store all output on disk for further analysis, or create SAS data sets from selected output. You can suppress all displayed output with the statement ODS SELECT NONE:, and you can turn displayed output back on with the statement ODS SELECT ALL:. See Table 31.3 on page 1694 for the names of output tables available from PROC GENMOD. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

---

**ASSESS Statement (Experimental)**

```
ASSESS|ASSESSMENT VAR=(effect) | LINK < / options > ;
```

The ASSESS statement computes and plots, using ODS graphics, model-checking statistics based on aggregates of residuals. See the “Assessment of Models Based on Aggregates of Residuals” section on page 1680 for details about the model assessment methods available in GENMOD.

The types of aggregates available are cumulative residuals, moving sums of residuals, and lowess smoothed residuals. If you do not specify which aggregate to use, the assessments are based on cumulative sums. PROC GENMOD uses experimental ODS graphics for graphical displays. For specific information about the experimental graphics available in GENMOD, see the “ODS Graphics” section on page 1695.

You must specify either LINK or VAR= in order to create an analysis.

**LINK**

request the assessment of the link function by performing the analysis with respect to the linear predictor.

**VAR=(effect)**

specifies the functional form of a covariate be checked by performing the analysis with respect to the variable identified by the effect. The effect must be specified in the MODEL statement, and must contain only continuous variables (variables not listed in a CLASS statement).

You can specify the following options after the slash (/).

**CRPANEL**

requests a plot with four panels, each containing aggregates of the observed residuals and two simulated curves, be created.
LOWESS<\(\text{\(number\)}\)>
requests model assessment based on lowess smoothed residuals with optional \(\text{\(number\)}\)
the fraction of data used. \(\text{\(number\)}\) must be between zero and one. If \(\text{\(number\)}\) is not
specified, the default value one-third is used.

\(\text{\(NPATHS|NPATH|PATHS\backslash PATH=number\)}\)
specifies the number of simulated paths to plot on the default aggregate residuals plot.

\(\text{\(RESAMPLE|RESAMPLES<\(\text{\(=number\)}\)\)}\)
specifies a \(p\)-value be computed based on 1,000 simulated paths, or \(\text{\(number\)}\) paths, if
\(\text{\(number\)}\) is specified.

\(\text{\(SEED=}\text{\(number\)}\)
specifies a seed for the normal random number generator used in creating simulated
realizations of aggregates of residuals for plots and estimating \(p\)-values. Specifying
a seed allows you to produce identical graphs and \(p\)-values from run to run of the
procedure. If a seed is not specified, or if \(\text{\(number\)}\) is negative or zero, a random
number seed is derived from the time of day.

\(\text{\(WINDOW<\(\text{\(number\)}\)\)}\)
requests assessment based on a moving sum window of width \(\text{\(number\)}\). If \(\text{\(number\)}\) is not
specified, a value of one-half of the range of the \(x\)-coordinate is used.

**BY Statement**

```
BY variables;
```
You can specify a BY statement with PROC GENMOD to obtain separate analyses on
observations in groups defined by the BY variables. When a BY statement appears,
the procedure expects the input data set to be sorted in order of the BY variables.

Since sorting the data changes the order in which PROC GENMOD reads the data,
this can affect the sorting order for the levels of classification variables if you have
specified ORDER=DATA in the PROC GENMOD statement. This, in turn, affects
specifications in the CONTRAST statement.

If your input data set is not sorted in ascending order, use one of the following alter-
natives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY
  statement for the GENMOD procedure. The NOTSORTED option does not
  mean that the data are unsorted but rather that the data are arranged in groups
  (according to values of the BY variables) and that these groups are not neces-
  sarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language
Reference: Concepts*. For more information on the DATASETS procedure, refer to
the discussion in the *SAS Procedures Guide*. 
The CLASS statement names the classification variables to be used in the analysis. The CLASS statement must precede the MODEL statement. You can specify various v-options for each variable by enclosing them in parentheses after the variable name. You can also specify global v-options for the CLASS statement by placing them after a slash (/). Global v-options are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the global v-options specified on any one CLASS statement apply to all CLASS statements. However, individual CLASS variable v-options override the global v-options.

DESCENDING
DESC
reverses the sorting order of the classification variable.

MISSING
allows missing value (‘.’ for a numeric variable and blanks for a character variables) as a valid value for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the sorting order for the levels of classification variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use the CONTRAST or ESTIMATE statement. If ORDER=FORMATTED for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the affected classification variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or ORDER=INTERNAL to get the more natural ordering. The following table shows how PROC GENMOD interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

By default, ORDER=FORMATTED. For FORMATTED and INTERNAL, the sort order is machine dependent. For more information on sorting order, see the chapter

**PARAM=keyword**
specifies the parameterization method for the classification variable or variables. Design matrix columns are created from CLASS variables according to the following coding schemes. The default is PARAM=GLM. If PARAM=ORTHPOLY or PARAM=POLY, and the CLASS levels are numeric, then the ORDER= option in the CLASS statement is ignored, and the internal, unformatted values are used. See the “CLASS Variable Parameterization” section on page 1661 for further details.

- **EFFECT** specifies effect coding
- **GLM** specifies less-than-full-rank, reference-cell coding; this option can only be used as a global option
- **ORDINAL** specifies the cumulative parameterization for an ordinal CLASS variable.
- **POLYNOMIAL** specifies polynomial coding
- **POLY** specifies polynomial coding
- **REFERENCE** specifies reference cell coding
- **REF** specifies reference cell coding
- **ORTHEFFECT** orthogonalizes PARAM=EFFECT
- **ORTHORDINAL** orthogonalizes PARAM=ORDINAL
- **ORTHOTHERM** orthogonalizes PARAM=POLYNOMIAL
- **ORTHPOLY** orthogonalizes PARAM=REFERENCE
- **ORTHREF** orthogonalizes PARAM=REFERENCE

The EFFECT, POLYNOMIAL, REFERENCE, ORDINAL, and their orthogonal parameterizations are full rank. The REF= option in the CLASS statement determines the reference level for the EFFECT, REFERENCE, and their orthogonal parameterizations.

**REF= ’level’ | keyword**
specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. For an individual (but not a global) variable REF= option, you can specify the level of the variable to use as the reference level. For a global or individual variable REF= option, you can use one of the following keywords. The default is REF=LAST.

- **FIRST** designates the first ordered level as reference
- **LAST** designates the last ordered level as reference
CONTRAST Statement

TRUNCATE < =n >
specifies the length \( n \) of CLASS variable values to use in determining CLASS variable levels. If you specify TRUNCATE without the length \( n \), the first 16 characters of the formatted values are used. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to Version 9. The default is to use the full formatted length of the CLASS variable. The TRUNCATE option is only available as a global option.

CONTRAST Statement

CONTRAST 'label' effect values < , ... effect values > < /options > ;

The CONTRAST statement provides a means for obtaining a test for a specified hypothesis concerning the model parameters. This is accomplished by specifying a matrix \( L \) for testing the hypothesis \( L' \beta = 0 \). You must be familiar with the details of the model parameterization that PROC GENMOD uses. For more information, see the “Parameterization Used in PROC GENMOD” section on page 1661 and the “CLASS Variable Parameterization” section on page 1661. Computed statistics are based on the asymptotic chi-square distribution of the likelihood ratio statistic, or the generalized score statistic for GEE models, with degrees of freedom determined by the number of linearly independent rows in the \( L \) matrix. You can request Wald chi-square statistics with the Wald option in the CONTRAST statement.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the MODEL statement. Statistics for multiple CONTRAST statements are displayed in a single table.

The following parameters are specified in the CONTRAST statement:

- **label** identifies the contrast on the output. A label is required for every contrast specified. Labels can be up to 20 characters and must be enclosed in single quotes.
- **effect** identifies an effect that appears in the MODEL statement. The value INTERCEPT or intercept can be used as an effect when an intercept is included in the model. You do not need to include all effects that are included in the MODEL statement.
- **values** are constants that are elements of the \( L \) vector associated with the effect.

The rows of \( L' \) are specified in order and are separated by commas.

If you use the default less-than-full-rank GLM CLASS variable parameterization, each row of the \( L \) matrix is checked for estimability. If PROC GENMOD finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. Refer to Searle (1971) for a discussion of estimable functions. If the elements of \( L \) are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you
specify a CONTRAST statement involving A alone, the L matrix contains nonzero terms for both A and A*B, since A*B contains A.

When you use any of the full-rank PARAM= CLASS variable options, all parameters are directly estimable, and rows of L are not checked for estimability.

If an effect is not specified in the CONTRAST statement, all of its coefficients in the L matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

PROC GENMOD handles missing level combinations of classification variables in the same manner as the GLM and MIXED procedures. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the L matrix in your CONTRAST statement.

If you specify the WALD option, the test of hypothesis is based on a Wald chi-square statistic. If you omit the WALD option, the test statistic computed depends on whether an ordinary generalized linear model or a GEE-type model is specified.

For an ordinary generalized linear model, the CONTRAST statement computes the likelihood ratio statistic. This is defined to be twice the difference between the log likelihood of the model unconstrained by the contrast and the log likelihood with the model fitted under the constraint that the linear function of the parameters defined by the contrast is equal to 0. A p-value is computed based on the asymptotic chi-square distribution of the chi-square statistic.

If you specify a GEE model with the REPEATED statement, the test is based on a score statistic. The GEE model is fit under the constraint that the linear function of the parameters defined by the contrast is equal to 0. The score chi-square statistic is computed based on the generalized score function. See the “Generalized Score Statistics” section on page 1680 for more information.

The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement, that is, the rank of L.

You can specify the following options after a slash (/).

E requests that the L matrix be displayed.

SINGULAR = number

tunes the estimability checking. If v is a vector, define ABS(v) to be the absolute value of the element of v with the largest absolute value. Let K' be any row in the contrast matrix L. Define C to be equal to ABS(K') if ABS(K') is greater than 0; otherwise, C equals 1. If ABS(K' - K'T) is greater than C*number, then K is declared nonestimable. T is the Hermite form matrix (X'X)^-1(X'X), and (X'X)^-1 represents a generalized inverse of the matrix X'X. The value for number must be between 0 and 1; the default value is 1E-4.
WALD
requests that a Wald chi-square statistic be computed for the contrast rather than the
default likelihood ratio or score statistic. The Wald statistic for testing $L'\beta = 0$ is
defined by

$$S = (L'\hat{\beta})(L'\Sigma L)^{-1}(L'\hat{\beta})$$

where $\hat{\beta}$ is the maximum likelihood estimate and $\Sigma$ is its estimated covariance matrix.
The asymptotic distribution of $S$ is $\chi^2_r$, where $r$ is the rank of $L$. Computed $p$-values
are based on this distribution.

If you specify a GEE model with the REPEATED statement, $\Sigma$ is the empirical co-
variance matrix estimate.

DEVIANCE Statement

DEVIANCE  variable = expression ;

You can specify a probability distribution other than those available in PROC
GENMOD by using the DEVIANCE and VARIANCE statements. You do not need
to specify the DEVIANCE or VARIANCE statements if you use the DIST= MODEL
statement option to specify a probability distribution. The variable identifies the devi-
cance contribution from a single observation to the procedure, and it must be a valid SAS variable name that does not appear in the input data set. The expression can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence of the deviance on the mean and the response. You use the automatic variables _MEAN_ and _RESP_ to represent the mean and response in the expression.

Alternatively, the deviance function can be defined using programming statements
(see the section “Programming Statements” on page 1645) and assigned to a variable,
which is then listed as the expression. This form is convenient for using complex statements such as if-then-else clauses.

The DEVIANCE statement is ignored unless the VARIANCE statement is also spec-
ified.

ESTIMATE Statement

ESTIMATE  'label' effect values ... < /options > ;

The ESTIMATE statement is similar to a CONTRAST statement, except only one-
row $L'$ matrices are permitted.

If you use the default less-than-full-rank GLM CLASS variable parameterization,
each row is checked for estimability. If PROC GENMOD finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. Refer to Searle (1971) for a discussion of estimable functions.

The actual estimate, $L'/\beta$, its approximate standard error, and its confidence limits are displayed. A Wald chi-square test that $L'/\beta = 0$ is also displayed.
The approximate standard error of the estimate is computed as the square root of $L'\hat{\Sigma}L$, where $\hat{\Sigma}$ is the estimated covariance matrix of the parameter estimates. If you specify a GEE model in the REPEATED statement, $\hat{\Sigma}$ is the empirical covariance matrix estimate.

If you specify the EXP option, then $\exp(L'\beta)$, its standard error, and its confidence limits are also displayed.

The construction of the $L$ vector for an ESTIMATE statement follows the same rules as listed under the CONTRAST statement.

You can specify the following options in the ESTIMATE statement after a slash (/).

**ALPHA=** number
requests that a confidence interval be constructed with confidence level $1 - \text{number}$. The value of number must be between 0 and 1; the default value is 0.05.

**E**
requests that the $L$ matrix coefficients be displayed.

**EXP**
requests that $\exp(L'\beta)$, its standard error, and its confidence limits be computed.

---

**FREQ Statement**

```
FREQ | FREQUENCY  variable ;
```

The variable in the FREQ statement identifies a variable in the input data set containing the frequency of occurrence of each observation. PROC GENMOD treats each observation as if it appears $n$ times, where $n$ is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If it is less than 1 or if it is missing, the observation is not used.

---

**FWDLINK Statement**

```
FWDLINK  variable = expression ;
```

You can define a link function other than a built-in link function by using the FWDLINK statement. If you use the MODEL statement option LINK= to specify a link function, you do not need to use the FWDLINK statement. The variable identifies the link function to the procedure. The expression can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence on the mean.

Alternatively, the link function can be defined by using programming statements (see the “Programming Statements” section on page 1645) and assigned to a variable, which is then listed as the expression. The second form is convenient for using complex statements such as if-then-else clauses. The GENMOD procedure automatically computes derivatives of the link function required for iterative fitting. You must specify the inverse of the link function in the INVLINK statement when you specify the FWDLINK statement to define the link function. You use the automatic variable _MEAN_ to represent the mean in the preceding expression.
INVLINK Statement

\begin{verbatim}
INVLINK variable = expression ;
\end{verbatim}

If you define a link function in the FWDLINK statement, then you must define the inverse link function using the INVLINK statement. If you use the MODEL statement option LINK= to specify a link function, you do not need to use the INVLINK statement. The \textit{variable} identifies the inverse link function to the procedure. The \textit{expression} can be any arithmetic expression supported by the DATA step language, and it is used to define the functional dependence on the linear predictor.

Alternatively, the inverse link function can be defined using programming statements (see the section “Programming Statements” on page 1645) and assigned to a variable, which is then listed as the \textit{expression}. The second form is convenient for using complex statements such as if-then-else clauses. The automatic variable \_XBETA\_ represents the linear predictor in the preceding \textit{expression}.

LSMEANS Statement

\begin{verbatim}
LSMEANS effects < / options > ;
\end{verbatim}

The LSMEANS statement computes least-squares means (LS-means) corresponding to the specified effects for the linear predictor part of the model. The \textbf{L} matrix constructed to compute them is precisely the same as the one formed in PROC GLM.

The LSMEANS statement is not available for multinomial distribution models for ordinal response data.

Each LS-mean is computed as $L' \hat{\beta}$, where $L$ is the coefficient matrix associated with the least-squares mean and $\hat{\beta}$ is the estimate of the parameter vector. The approximate standard errors for the LS-mean is computed as the square root of $L' \hat{\Sigma} L$, where $\hat{\Sigma}$ is the estimated covariance matrix of the parameter estimates. If you specify a GEE model in the REPEATED statement, $\hat{\Sigma}$ is the empirical covariance matrix estimate.

LS-means can be computed for any effect in the MODEL statement that involves CLASS variables. You can specify multiple effects in one LSMEANS statement or multiple LSMEANS statements, and all LSMEANS statements must appear after the MODEL statement.

As in the ESTIMATE statement, the \textbf{L} matrix is tested for estimability, and if this test fails, PROC GENMOD displays “Non-est” for the LS-means entries.

Assuming the LS-mean is estimable, PROC GENMOD constructs a Wald chi-square test to test the null hypothesis that the associated population quantity equals zero.

You can specify the following options in the LSMEANS statement after a slash (/).

\textbf{ALPHA=number}

requests that a confidence interval be constructed for each of the LS-means with confidence level $(1 - \text{number}) \times 100\%$. The value of \text{number} must be between 0 and 1; the default value is 0.05, corresponding to a 95\% confidence interval.
requests that confidence limits be constructed for each of the LS-means. The confidence level is 0.95 by default; this can be changed with the ALPHA option.

**CORR**

displays the estimated correlation matrix of the LS-means as part of the “Least Squares Means” table.

**COV**

displays the estimated covariance matrix of the LS-means as part of the “Least Squares Means” table.

**DIFF**

requests that differences of the LS-means be displayed. All possible differences of LS-means, standard errors, and a Wald chi-square test are computed. Confidence limits are computed if the CL option is also specified.

**E**

requests that the L matrix coefficients for all LSMEANS effects be displayed.

**MODEL Statement**

```
MODEL response = < effects > / options ;
MODEL events/trials = < effects > / options ;
```

The MODEL statement specifies the response, or dependent variable, and the effects, or explanatory variables. If you omit the explanatory variables, the procedure fits an intercept-only model. An intercept term is included in the model by default. The intercept can be removed with the NOINT option.

You can specify the response in the form of a single variable or in the form of a ratio of two variables denoted events/trials. The first form is applicable to all responses. The second form is applicable only to summarized binomial response data. When each observation in the input data set contains the number of events (for example, successes) and the number of trials from a set of binomial trials, use the events/trials syntax.

In the events/trials model syntax, you specify two variables that contain the event and trial counts. These two variables are separated by a slash (/). The values of both events and (trials—events) must be nonnegative, and the value of the trials variable must be greater than 0 for an observation to be valid. The variable events or trials may take noninteger values.

When each observation in the input data set contains a single trial from a binomial or multinomial experiment, use the first form of the preceding MODEL statements. The response variable can be numeric or character. The ordering of response levels is critical in these models. You can use the RORDER= option in the PROC GENMOD statement to specify the response level ordering.

Responses for the Poisson distribution must be positive, but they can be noninteger values.
The effects in the MODEL statement consist of an explanatory variable or combination of variables. Explanatory variables can be continuous or classification variables. Classification variables can be character or numeric. Explanatory variables representing nominal, or classification, data must be declared in a CLASS statement. Interactions between variables can also be included as effects. Columns of the design matrix are automatically generated for classification variables and interactions. The syntax for specification of effects is the same as for the GLM procedure. See the “Specification of Effects” section on page 1659 for more information. Also refer to Chapter 32, “The GLM Procedure.”

You can specify the following options in the MODEL statement after a slash (/).

**AGGREGATE= (variable-list)**

specifies the subpopulations on which the Pearson chi-square and the deviance are calculated. This option applies only to the multinomial distribution or the binomial distribution with binary (single trial syntax) response. It is ignored if specified for other cases. Observations with common values in the given list of variables are regarded as coming from the same subpopulation. This affects the computation of the deviance and Pearson chi-square statistics. Variables in the list can be any variables in the input data set.

**ALPHA | ALPH | A=number**

sets the confidence coefficient for parameter confidence intervals to 1−number. The value of number must be between 0 and 1. The default value of number is 0.05.

**CICONV=number**

sets the convergence criterion for profile likelihood confidence intervals. See the section “Confidence Intervals for Parameters” on page 1666 for the definition of convergence. The value of number must be between 0 and 1. By default, CICONV=1E−4.

**CL**

requests that confidence limits for predicted values be displayed. See the OBSTATS option.

**CODING=EFFECT | FULLRANK**

specifies effect coding be used for all class variables in the model. This is the same as specifying PARAM=EFFECT as a CLASS statement option.

**CONVERGE=number**

sets the convergence criterion. The value of number must be between 0 and 1. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. The change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E−4. This convergence criterion is used in parameter estimation for a single model fit, Type 1 statistics, and likelihood ratio statistics for Type 3 analyses and CONTRAST statements.
CONVH=number

sets the relative Hessian convergence criterion. The value of number must be between 0 and 1. After convergence is determined with the change in parameter criterion specified with the CONVERGE= option, the quantity $tc = \frac{g^T H^{-1} g}{|f|}$ is computed and compared to number, where $g$ is the gradient vector, $H$ is the Hessian matrix for the model parameters, and $f$ is the log-likelihood function. If $tc$ is greater than number, a warning that the relative Hessian convergence criterion has been exceeded is printed. This criterion detects the occasional case where the change in parameter convergence criterion is satisfied, but a maximum in the log-likelihood function has not been attained. By default, CONVH=1E$^{-4}$.

CORRB

requests that the parameter estimate correlation matrix be displayed.

COVB

requests that the parameter estimate covariance matrix be displayed.

DIST | D | ERROR | ERR = keyword

specifies the built-in probability distribution to use in the model. If you specify the DIST= option and you omit a user-defined link function, a default link function is chosen as displayed in the following table. If you specify no distribution and no link function, then the GENMOD procedure defaults to the normal distribution with the identity link function.

<table>
<thead>
<tr>
<th>DIST=</th>
<th>Distribution</th>
<th>Default Link Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>BINOMIAL</td>
<td>BIN</td>
<td>B</td>
</tr>
<tr>
<td>GAMMA</td>
<td>GAM</td>
<td>G</td>

<td>NB</td>
<td></td>
</tr>
<tr>
<td>NORMAL</td>
<td>NOR</td>
<td>N</td>
</tr>
<tr>
<td>POISSON</td>
<td>POI</td>
<td>P</td>
</tr>
</tbody>
</table>

EXPECTED

requests that the expected Fisher information matrix be used to compute parameter estimate covariances and the associated statistics. The default action is to use the observed Fisher information matrix. See the SCORING= option.

ID=variable

causes the values of variable in the input data set to be displayed in the OBSTATS table. If an explicit format for variable has been defined, the formatted values are displayed. If the OBSTATS option is not specified, this option has no effect.

INITIAL=numbers

sets initial values for parameter estimates in the model. The default initial parameter values are weighted least squares estimates based on using the response data as the initial mean estimate. This option can be useful in case of convergence difficulty. The intercept parameter is initialized with the INTERCEPT= option and is not included.
here. The values are assigned to the variables in the MODEL statement in the same order in which they appear in the MODEL statement. The order of levels for CLASS variables is determined by the ORDER= option. Note that some levels of class variables can be aliased; that is, they correspond to linearly dependent parameters that are not estimated by the procedure. Initial values must be assigned to all levels of class variables, regardless of whether they are aliased or not. The procedure ignores initial values corresponding to parameters not being estimated. If you specify a BY statement, all class variables must take on the same number of levels in each BY group. Otherwise, class variables in some of the BY groups are assigned incorrect initial values. Types of INITIAL= specifications are illustrated in the following table.

<table>
<thead>
<tr>
<th>Type of List</th>
<th>Specification</th>
</tr>
</thead>
<tbody>
<tr>
<td>list separated by blanks</td>
<td>INITIAL = 3 4 5</td>
</tr>
<tr>
<td>list separated by commas</td>
<td>INITIAL = 3, 4, 5</td>
</tr>
<tr>
<td>x to y</td>
<td>INITIAL = 3 to 5</td>
</tr>
<tr>
<td>x to y by z</td>
<td>INITIAL = 3 to 5 by 1</td>
</tr>
<tr>
<td>combination of list types</td>
<td>INITIAL = 1, 3 to 5, 9</td>
</tr>
</tbody>
</table>

**INTERCEPT=**`number`

initializes the intercept term to `number` for parameter estimation. If you specify both the INTERCEPT= and the NOINT options, the intercept term is not estimated, but an intercept term of `number` is included in the model.

**ITPRINT**

displays the iteration history for all iterative processes: parameter estimation, fitting constrained models for contrasts and Type 3 analyses, and profile likelihood confidence intervals. The last evaluation of the gradient and the negative of the Hessian (second derivative) matrix are also displayed for parameter estimation. This option may result in a large amount of displayed output, especially if some of the optional iterative processes are selected.

**LINK =** `keyword`

specifies the link function to use in the model. The keywords and their associated built-in link functions are as follows.

<table>
<thead>
<tr>
<th>LINK=</th>
<th>Link Function</th>
</tr>
</thead>
<tbody>
<tr>
<td>CUMCLL</td>
<td>CCLL</td>
</tr>
<tr>
<td>CUMLOGIT</td>
<td>CLOGIT</td>
</tr>
<tr>
<td>CUMPROBIT</td>
<td>CPROBIT</td>
</tr>
<tr>
<td>CLOGLOG</td>
<td>CLL</td>
</tr>
<tr>
<td>IDENTITY</td>
<td>ID</td>
</tr>
<tr>
<td>LOG</td>
<td>log</td>
</tr>
<tr>
<td>LOGIT</td>
<td>logit</td>
</tr>
<tr>
<td>PROBIT</td>
<td>probit</td>
</tr>
<tr>
<td>POWER(<code>number</code>)</td>
<td>POW(<code>number</code>)</td>
</tr>
</tbody>
</table>
If no LINK= option is supplied and there is a user-defined link function, the user-defined link function is used. If you specify neither the LINK= option nor a user-defined link function, then the default canonical link function is used if you specify the DIST= option. Otherwise, if you omit the DIST= option, the identity link function is used.

The cumulative link functions are appropriate only for the multinomial distribution.

**LRCI**
requests that two-sided confidence intervals for all model parameters be computed based on the profile likelihood function. This is sometimes called the partially maximized likelihood function. See the “Confidence Intervals for Parameters” section on page 1666 for more information on the profile likelihood function. This computation is iterative and can consume a relatively large amount of CPU time. The confidence coefficient can be selected with the ALPHA=NUMBER option. The resulting confidence coefficient is $1 - \text{number}$. The default confidence coefficient is 0.95.

**MAXITER=**<br>**MAXIT=**<br>sets the maximum allowable number of iterations for all iterative computation processes in PROC GENMOD. By default, MAXITER=50.

**NOINT**
requests that no intercept term be included in the model. An intercept is included unless this option is specified.

**NOSCALE**
holds the scale parameter fixed. Otherwise, for the normal, inverse Gaussian, and gamma distributions, the scale parameter is estimated by maximum likelihood. If you omit the SCALE= option, the scale parameter is fixed at the value 1.

**OFFSET=**<br>**OFFSET=**<br>specifies a variable in the input data set to be used as an offset variable. This variable cannot be a CLASS variable, and it cannot be the response variable or one of the explanatory variables.

**OBSSTATS**
specifies that an additional table of statistics be displayed. For each observation, the following items are displayed:

- the value of the response variable (variables if the data are binomial), frequency, and weight variables
- the values of the regression variables
- predicted mean, $\hat{\mu} = g^{-1}(\eta)$, where $\eta = x_i'\hat{\beta}$ is the linear predictor and $g$ is the link function. If there is an offset, it is included in $x_i'\hat{\beta}$.
- estimate of the linear predictor $x_i'\hat{\beta}$. If there is an offset, it is included in $x_i'\hat{\beta}$.
- standard error of the linear predictor $x_i'\hat{\beta}$
- the value of the Hessian weight at the final iteration
lower confidence limit of the predicted value of the mean. The confidence coefficient is specified with the ALPHA= option. See the section “Confidence Intervals on Predicted Values” on page 1669 for the computational method.

upper confidence limit of the predicted value of the mean

raw residual, defined as $Y - \mu$

Pearson, or chi residual, defined as the square root of the contribution for the observation to the Pearson chi-square, that is

$$\frac{Y - \mu}{\sqrt{V(\mu)/w}}$$

where $Y$ is the response, $\mu$ is the predicted mean, $w$ is the value of the prior weight variable specified in a WEIGHT statement, and $V(\mu)$ is the variance function evaluated at $\mu$.

the standardized Pearson residual

deviance residual, defined as the square root of the deviance contribution for the observation, with sign equal to the sign of the raw residual

the standardized deviance residual

the likelihood residual

The RESIDUALS, PREDICTED, XVARS, and CL options cause only subgroups of the observation statistics to be displayed. You can specify more than one of these options to include different subgroups of statistics.

The ID=variable option causes the values of variable in the input data set to be displayed in the table. If an explicit format for variable has been defined, the formatted values are displayed.

If a REPEATED statement is present, a table is displayed for the GEE model specified in the REPEATED statement. Only the regression variables, response values, predicted values, confidence limits for the predicted values, linear predictor, raw residuals, and Pearson residuals for each observation in the input data set are available.

PREDICTED

requests that predicted values, the linear predictor, its standard error, and the Hessian weight be displayed. See the OBSTATS option.

RESIDUALS

requests that residuals and standardized residuals be displayed. See the OBSTATS option.
The GENMOD Procedure

\texttt{SCALE=number}
\texttt{SCALE=PEARSON}
\texttt{SCALE=P}
\texttt{PSCALE}
\texttt{SCALE=DEVIANCE}
\texttt{SCALE=D}
\texttt{DSCALE}

sets the value used for the scale parameter where the NOSCALE option is used. For the binomial and Poisson distributions, which have no free scale parameter, this can be used to specify an \textit{overdispersed} model. In this case, the parameter covariance matrix and the likelihood function are adjusted by the scale parameter. See the “Dispersion Parameter” section (page 1658) and the “Overdispersion” section (page 1659) for more information. If the NOSCALE option is not specified, then \texttt{number} is used as an initial estimate of the scale parameter.

Specifying \texttt{SCALE=PEARSON} or \texttt{SCALE=P} is the same as specifying the PSCALE option. This fixes the scale parameter at the value 1 in the estimation procedure. After the parameter estimates are determined, the exponential family dispersion parameter is assumed to be given by Pearson’s chi-square statistic divided by the degrees of freedom, and all statistics such as standard errors and likelihood ratio statistics are adjusted appropriately.

Specifying \texttt{SCALE=DEVIANCE} or \texttt{SCALE=D} is the same as specifying the DSCALE option. This fixes the scale parameter at a value of 1 in the estimation procedure.

After the parameter estimates are determined, the exponential family dispersion parameter is assumed to be given by the deviance divided by the degrees of freedom. All statistics such as standard errors and likelihood ratio statistics are adjusted appropriately.

\texttt{SCORING=number}

requests that on iterations up to \texttt{number}, the Hessian matrix is computed using the Fisher’s scoring method. For further iterations, the full Hessian matrix is computed. The default value is 1. A value of 0 causes all iterations to use the full Hessian matrix, and a value greater than or equal to the value of the MAXITER option causes all iterations to use Fisher’s scoring. The value of the \texttt{SCORING=} option must be 0 or a positive integer.

\texttt{SINGULAR=number}

sets the tolerance for testing singularity of the information matrix and the crossproducts matrix. Roughly, the test requires that a pivot be at least this number times the original diagonal value. By default, \texttt{number} is $10^7$ times the machine epsilon. The default \texttt{number} is approximately $10^{-9}$ on most machines.

\texttt{TYPE1}

requests that a Type 1, or sequential, analysis be performed. This consists of sequentially fitting models, beginning with the null (intercept term only) model and continuing up to the model specified in the MODEL statement. The likelihood ratio statistic between each successive pair of models is computed and displayed in a table.
A Type 1 analysis is not available for GEE models, since there is no associated likelihood.

**TYPE3**
requests that statistics for Type 3 contrasts be computed for each effect specified in the MODEL statement. The default analysis is to compute likelihood ratio statistics for the contrasts or score statistics for GEEs. Wald statistics are computed if the WALD option is also specified.

**WALD**
requests Wald statistics for Type 3 contrasts. You must also specify the TYPE3 option in order to compute Type 3 Wald statistics.

**WALDCI**
requests that two-sided Wald confidence intervals for all model parameters be computed based on the asymptotic normality of the parameter estimators. This computation is not as time consuming as the LRCI method, since it does not involve an iterative procedure. However, it is not thought to be as accurate, especially for small sample sizes. The confidence coefficient can be selected with the ALPHA= option in the same way as for the LRCI option.

**XVARS**
requests that the regression variables be included in the OBSTATS table.

**OUTPUT Statement**

```
OUTPUT < OUT=SAS-data-set >
    < keyword=name . . . keyword=name > ;
```

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors (XBETA) and their standard error estimates, the weights for the Hessian matrix, predicted values of the mean, confidence limits for predicted values, and residuals.

You can also request these statistics with the OBSTATS, PREDICTED, RESIDUALS, CL, or XVARS options in the MODEL statement. You can then create a SAS data set containing them with ODS OUTPUT commands. You may prefer to specify the OUTPUT statement for requesting these statistics since

- the OUTPUT statement produces no tabular output
- the OUTPUT statement creates a SAS data set more efficiently than ODS. This can be an advantage for large data sets.
- you can specify the individual statistics to be included in the SAS data set

If you use the multinomial distribution with one of the cumulative link functions for ordinal data, the data set also contains variables named _ORDER_ and _LEVEL_ that indicate the levels of the ordinal response variable and the values of the variable in the input data set corresponding to the sorted levels. These variables indicate that the predicted value for a given observation is the probability that the response variable is as large as the value of the Value variable.
The estimated linear predictor, its standard error estimate, and the predicted values and their confidence intervals are computed for all observations in which the explanatory variables are all nonmissing, even if the response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the explanatory variables not present in the data without affecting the model fit.

The following list explains specifications in the OUTPUT statement.

**OUT= SAS-data-set**

specifies the output data set. If you omit the OUT=option, the output data set is created and given a default name using the DATA in convention.

**keyword=name**

specifies the statistics to be included in the output data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the name of the new variable or variables to contain the statistic. You can list only one variable after the equal sign. Although you can use the OUTPUT statement without any keyword=name specifications, the output data set then contains only the original variables and, possibly, the variables Level and Value (if you use the multinomial model with ordinal data). Note that the residuals are not available for the multinomial model with ordinal data. Formulas for the statistics are given in the section “Predicted Values of the Mean” on page 1669 and the “Residuals” section on page 1669. The keywords allowed and the statistics they represent are as follows:

- **HESSWGT** diagonal element of the weight matrix used in computing the Hessian matrix
- **LOWER | L** lower confidence limit for the predicted value of the mean, or the lower confidence limit for the probability that the response is less than or equal to the value of Level or Value. The confidence coefficient is determined by the ALPHA=number option in the MODEL statement as \((1 - number) \times 100\%\). The default confidence coefficient is 95%.
- **PREDICTED | PRED | PROB | P** predicted value of the mean or the predicted probability that the response variable is less than or equal to the value of Level or Value if the multinomial model for ordinal data is used (in other words, \(Pr(Y \leq Value)\), where \(Y\) is the response variable)
- **RESCHI** Pearson (Chi) residual for identifying observations that are poorly accounted for by the model
- **RESDEV** deviance residual for identifying poorly fitted observations
- **RESLIK** likelihood residual for identifying poorly fitted observations
- **STDXBETA** standard error estimate of XBETA (see the XBETA keyword)
- **STDRESCHI** standardized Pearson (Chi) residual for identifying observations that are poorly accounted for by the model
- **STDRESDEV** standardized deviance residual for identifying poorly fitted observations
UPPER | U upper confidence limit for the predicted value of the mean, or the
lower confidence limit for the probability that the response is less
than or equal to the value of Level or Value. The confidence coeffi-
cient is determined by the ALPHA=number option in the MODEL
statement as \((1 - \text{number}) \times 100\%\). The default confidence coeffi-
cient is 95%.

XBETA estimate of the linear predictor \(x_i'\beta\) for observation \(i\), or \(\alpha_j + x_i'\beta\),
where \(j\) is the corresponding ordered value of the response variable
for the multinomial model with ordinal data. If there is an offset, it
is included in \(x_i'\beta\).

Programming Statements

Although the most commonly used link and probability distributions are available
as built-in functions, the GENMOD procedure enables you to define your own link
functions and response probability distributions using the FWDLINK, INVLINK,
VARIANCE, and DEVIANCE statements. The variables assigned in these state-
ments can have values computed in programming statements. These programming
statements can occur anywhere between the PROC GENMOD statement and the
RUN statement. Variable names used in programming statements must be unique.
Variables from the input data set may be referenced in programming statements.
The mean, linear predictor, and response are represented by the automatic variables
_MEAN_, _XBETA_, and _RESP_, which can be referenced in your program-
ming statements. Programming statements are used to define the functional depen-
dencies of the link function, the inverse link function, the variance function, and the
deviance function on the mean, linear predictor, and response variable.

The following code illustrates the use of programming statements. Even though you
usually request the Poisson distribution by specifying DIST=POISSON as a MODEL
statement option, you can define the variance and deviance functions for the Poisson
distribution by using the VARIANCE and DEVIANCE statements. For example, the
following code performs the same analysis as the Poisson regression example in the
“Getting Started” section on page 1616. The code must be in logical order for
computation, just as in a DATA step.

```sas
proc genmod;
   class car age;
   a = _MEAN_;
   y = _RESP_;
   d = 2 * ( y * log( y / a ) - ( y - a ) );
   variance var = a;
   deviance dev = d;
   model c = car age / link = log offset = ln;
run;
```

The variables var and dev are dummy variables used internally by the procedure to
identify the variance and deviance functions. Any valid SAS variable names can be
used.
Similarly, the log link function and its inverse could be defined with the FWDLINK and INVLINK statements.

```plaintext
fwdlink link = log(_MEAN_);
invlink ilink = exp(_XBETA_);
```

This code is for illustration, and it works well for most Poisson regression problems. If, however, in the iterative fitting process, the mean parameter becomes too close to 0, or a 0 response value occurs, an error condition occurs when the procedure attempts to evaluate the log function. You can circumvent this kind of problem by using if-then-else clauses or other conditional statements to check for possible error conditions and appropriately define the functions for these cases.

Data set variables can be referenced in user definitions of the link function and response distributions using programming statements and the FWDLINK, INVLINK, DEVIANCE, and VARIANCE statements.

See the DEVIANCE, VARIANCE, FWDLINK, and INVLINK statements for more information.

**REPEATED Statement**

```plaintext
REPEATED SUBJECT= subject-effect < / options > ;
```

The REPEATED statement specifies the covariance structure of multivariate responses for GEE model fitting in the GENMOD procedure. In addition, the REPEATED statement controls the iterative fitting algorithm used in GEEs and specifies optional output. Other GENMOD procedure statements, such as the MODEL and CLASS statements, are used in the same way as they are for ordinary generalized linear models to specify the regression model for the mean of the responses.

**SUBJECT=subject-effect**

identifies subjects in the input data set. The subject-effect can be a single variable, an interaction effect, a nested effect, or a combination. Each distinct value, or level, of the effect identifies a different subject, or cluster. Responses from different subjects are assumed to be statistically independent, and responses within subjects are assumed to be correlated. A subject-effect must be specified, and variables used in defining the subject-effect must be listed in the CLASS statement. The input data set does not need to be sorted by subject. See the SORTED option.

The options control how the model is fit and what output is produced. You can specify the following options after a slash (/).

**ALPHAINIT=numbers**

specifies initial values for log odds ratio regression parameters if the LOGOR= option is specified for binary data. If this option is not specified, an initial value of 0.01 is used for all the parameters.
CONVERGE=number
specifies the convergence criterion for GEE parameter estimation. If the maximum absolute difference between regression parameter estimates is less than the value of number on two successive iterations, convergence is declared. If the absolute value of a regression parameter estimate is greater than 0.08, then the absolute difference normalized by the regression parameter value is used instead of the absolute difference. The default value of number is 0.0001.

CORRW
displays the estimated working correlation matrix.

CORRB
displays the estimated regression parameter correlation matrix. Both model-based and empirical correlations are displayed.

COVB
displays the estimated regression parameter covariance matrix. Both model-based and empirical covariances are displayed.

ECORRB
displays the estimated regression parameter empirical correlation matrix.

ECOVB
displays the estimated regression parameter empirical covariance matrix.

INTERCEPT=number
specifies either an initial or a fixed value of the intercept regression parameter in the GEE model. If you specify the NOINT option in the MODEL statement, then the intercept is fixed at the value of number.

INITIAL=numbers
specifies initial values of the regression parameters estimation, other than the intercept parameter, for GEE estimation. If this option is not specified, the estimated regression parameters assuming independence for all responses are used for the initial values.

LOGOR=log odds ratio structure keyword
specifies the regression structure of the log odds ratio used to model the association of the responses from subjects for binary data. The response syntax must be of the single variable type, the distribution must be binomial, and the data must be binary. The following table displays the log odds ratio structure keywords and the corresponding log odds ratio regression structures. See the “Alternating Logistic Regressions” section on page 1676 for definitions of the log odds ratio types and examples of specifying log odds ratio models. You should specify either the LOGOR= or the TYPE= option, but not both.

<table>

</tbody>
</table>

**MAXITER=number**

specifies the maximum number of iterations allowed in the iterative GEE estimation process. The default number is 50.

**MCORRB**

displays the estimated regression parameter model-based correlation matrix.

**MCOVB**

displays the estimated regression parameter model-based covariance matrix.

**MODELSE**

displays an analysis of parameter estimates table using model-based standard errors. By default, an “Analysis of Parameter Estimates” table based on empirical standard errors is displayed.

**RUPDATE=number**

specifies the number of iterations between updates of the working correlation matrix. For example, RUPDATE=5 specifies that the working correlation is updated once for every five regression parameter updates. The default value of number is 1; that is, the working correlation is updated every time the regression parameters are updated.

**SORTED**

specifies that the input data are grouped by subject and sorted within subject. If this option is not specified, then the procedure internally sorts by subject-effect and within subject-effect, if a within subject-effect is specified.

**SUBCLUSTER=variable**

**SUBCLUST=variable**

specifies a variable defining subclusters for the 1-nested or \(k\)-nested log odds ratio association modeling structures.

**TYPE | CORR=correlation-structure keyword**

specifies the structure of the working correlation matrix used to model the correlation of the responses from subjects. The following table displays the correlation structure keywords and the corresponding correlation structures. The default working correlation type is the independent (CORR=IND). See the “Details” section on page 1650 for
definitions of the correlation matrix types. You should specify LOGOR= or TYPE= but not both.

<table>
<thead>
<tr>
<th>Keyword</th>
<th>Correlation Matrix Type</th>
</tr>
</thead>
<tbody>
<tr>

<td>m-dependent with m=number</td>
</tr>
<tr>
<td>UNSTR</td>
<td>UN</td>
</tr>
<tr>
<td>USER</td>
<td>FIXED (matrix)</td>
</tr>
</tbody>
</table>

For example, you can specify a fixed $4 \times 4$ correlation matrix with the option

\[
\text{TYPE=USER}( 1.0 \ 0.9 \ 0.8 \ 0.6 \\
0.9 \ 1.0 \ 0.9 \ 0.8 \\
0.8 \ 0.9 \ 1.0 \ 0.9 \\
0.6 \ 0.8 \ 0.9 \ 1.0 )
\]

V6CORR
specifies that the ‘Version 6’ method of computing the normalized Pearson chi-square be used for working correlation estimation and for model-based covariance matrix scale factor.

WITHINSUBJECT | WITHIN=within subject-effect
defines an effect specifying the order of measurements within subjects. Each distinct level of the within subject-effect defines a different response from the same subject. If the data are in proper order within each subject, you do not need to specify this option.

If some measurements do not appear in the data for some subjects, this option properly orders the existing measurements and treats the omitted measurements as missing values. If the WITHINSUBJECT= option is not used in this situation, measurements may be improperly ordered and missing values assumed for the last measurements in a cluster.

Variables used in defining the within subject-effect must be listed in the CLASS statement.

YPAIR=variable-list
specifies the variables in the ZDATA= data set corresponding to pairs of responses for log odds ratio association modeling.

ZDATA=SAS-data-set
specifies a SAS data set containing either the full $z$-matrix for log odds ratio association modeling or the $z$-matrix for a single complete cluster to be replicated for all clusters.
ZROW=variable-list
specifies the variables in the ZDATA= data set corresponding to rows of the z-matrix for log odds ratio association modeling.

VARIANCE Statement

VARIANCE variable = expression ;

You can specify a probability distribution other than the built-in distributions by using the VARIANCE and DEVIANCE statements. The variable name variable identifies the variance function to the procedure. The expression is used to define the functional dependence on the mean, and it can be any arithmetic expression supported by the DATA step language. You use the automatic variable _MEAN_ to represent the mean in the expression.

Alternatively, you can define the variance function with programming statements, as detailed in the section “Programming Statements” on page 1645. This form is convenient for using complex statements such as if-then-else clauses. Derivatives of the variance function for use during optimization are computed automatically. The DEVIANCE statement must also appear when the VARIANCE statement is used to define the variance function.

WEIGHT Statement

WEIGHT | SCWGT variable ;

The WEIGHT statement identifies a variable in the input data set to be used as the exponential family dispersion parameter weight for each observation. The exponential family dispersion parameter is divided by the WEIGHT variable value for each observation. This is true regardless of whether the parameter is estimated by the procedure or specified in the MODEL statement with the SCALE= option. It is also true for distributions such as the Poisson and binomial that are not usually defined to have a dispersion parameter. For these distributions, a WEIGHT variable weights the overdispersion parameter, which has the default value of 1.

The WEIGHT variable does not have to be an integer; if it is less than or equal to 0 or if it is missing, the corresponding observation is not used.

Details

Generalized Linear Models Theory

This is a brief introduction to the theory of generalized linear models. See the “References” section on page 1728 for sources of more detailed information.

Response Probability Distributions

In generalized linear models, the response is assumed to possess a probability distribution of the exponential form. That is, the probability density of the response Y for
continuous response variables, or the probability function for discrete responses, can be expressed as

\[ f(y) = \exp\left\{ \frac{y\theta - b(\theta)}{a(\phi)} + c(y, \phi) \right\} \]

for some functions \( a, b, \) and \( c \) that determine the specific distribution. For fixed \( \phi \), this is a one parameter exponential family of distributions. The functions \( a \) and \( c \) are such that \( a(\phi) = \phi/w \) and \( c = c(y, \phi/w) \), where \( w \) is a known weight for each observation. A variable representing \( w \) in the input data set may be specified in the WEIGHT statement. If no WEIGHT statement is specified, \( w_i = 1 \) for all observations.

Standard theory for this type of distribution gives expressions for the mean and variance of \( Y \).

\[ E(Y) = b'(\theta) \]
\[ \text{Var}(Y) = \frac{b''(\theta)\phi}{w} \]

where the primes denote derivatives with respect to \( \theta \). If \( \mu \) represents the mean of \( Y \), then the variance expressed as a function of the mean is

\[ \text{Var}(Y) = \frac{V(\mu)\phi}{w} \]

where \( V \) is the variance function.

Probability distributions of the response \( Y \) in generalized linear models are usually parameterized in terms of the mean \( \mu \) and dispersion parameter \( \phi \) instead of the natural parameter \( \theta \). The probability distributions that are available in the GENMOD procedure are shown in the following list. The PROC GENMOD scale parameter and the variance of \( Y \) are also shown.

- **Normal:**

  \[ f(y) = \frac{1}{\sqrt{2\pi\sigma}} \exp\left[-\frac{1}{2} \left( \frac{y - \mu}{\sigma} \right)^2 \right] \quad \text{for} \quad -\infty < y < \infty \]

  \[ \phi = \sigma^2 \]

  \[ \text{scale} = \sigma \]

  \[ \text{Var}(Y) = \sigma^2 \]
• Inverse Gaussian:

\[ f(y) = \frac{1}{\sqrt{2\pi y^3\sigma}} \exp \left[ -\frac{1}{2y} \left( \frac{y - \mu}{\mu \sigma} \right)^2 \right] \quad \text{for } 0 < y < \infty \]

\[ \phi = \sigma^2 \]

\[ \text{scale} = \sigma \]

\[ \text{Var}(Y) = \sigma^2 \mu^3 \]

• Gamma:

\[ f(y) = \frac{1}{\Gamma(\nu)y^{\nu-1}} \left( \frac{y\nu}{\mu} \right) \exp \left( -\frac{y\nu}{\mu} \right) \quad \text{for } 0 < y < \infty \]

\[ \phi = \nu^{-1} \]

\[ \text{scale} = \nu \]

\[ \text{Var}(Y) = \frac{\mu^2}{\nu} \]

• Negative Binomial:

\[ f(y) = \frac{\Gamma(y + 1/k)}{\Gamma(y + 1)\Gamma(1/k)} \left( \frac{(k\mu)^y}{(1 + k\mu)^{y + 1/k}} \right) \quad \text{for } y = 0, 1, 2, \ldots \]

\[ \text{dispersion} = k \]

\[ \text{Var}(Y) = \mu + k\mu^2 \]

• Poisson:

\[ f(y) = \frac{\mu^y e^{-\mu}}{y!} \quad \text{for } y = 0, 1, 2, \ldots \]

\[ \phi = 1 \]

\[ \text{Var}(Y) = \mu \]

• Binomial:

\[ f(y) = \binom{n}{r} \mu^r (1 - \mu)^{n-r} \quad \text{for } y = \frac{r}{n}, \quad r = 0, 1, 2, \ldots, n \]
\[ \phi = 1 \]
\[ \text{Var}(Y) = \frac{\mu(1 - \mu)}{n} \]

- Multinomial:
\[ f(y_1, y_2, \ldots, y_k) = \frac{m!}{y_1!y_2!\ldots y_k!} p_1^{y_1} p_2^{y_2} \ldots p_k^{y_k} \]

The negative binomial distribution contains a parameter \( k \), called the negative binomial dispersion parameter. This is not the same as the generalized linear model dispersion \( \phi \), but it is an additional distribution parameter that must be estimated or set to a fixed value.

For the binomial distribution, the response is the binomial proportion \( Y = \text{events/trials} \). The variance function is \( V(\mu) = \mu(1 - \mu) \), and the binomial trials parameter \( n \) is regarded as a weight \( w \).

If a weight variable is present, \( \phi \) is replaced with \( \phi/w \), where \( w \) is the weight variable.

PROC GENMOD works with a scale parameter that is related to the exponential family dispersion parameter \( \phi \) instead of with \( \phi \) itself. The scale parameters are related to the dispersion parameter as shown previously with the probability distribution definitions. Thus, the scale parameter output in the “Analysis of Parameter Estimates” table is related to the exponential family dispersion parameter. If you specify a constant scale parameter with the SCALE= option in the MODEL statement, it is also related to the exponential family dispersion parameter in the same way.

**Link Function**

The mean \( \mu_i \) of the response in the \( i \)th observation is related to a linear predictor through a monotonic differentiable link function \( g \).

\[ g(\mu_i) = x_i' \beta \]

Here, \( x_i \) is a fixed known vector of explanatory variables, and \( \beta \) is a vector of unknown parameters.

**Log-Likelihood Functions**

Log-likelihood functions for the distributions that are available in the procedure are parameterized in terms of the means \( \mu_i \) and the dispersion parameter \( \phi \). The term \( y_i \) represents the response for the \( i \)th observation, and \( w_i \) represents the known dispersion weight. The log-likelihood functions are of the form

\[ L(\mathbf{y}, \boldsymbol{\mu}, \phi) = \sum_i \log(f(y_i, \mu_i, \phi)) \]
where the sum is over the observations. The forms of the individual contributions

\( l_i = \log (f(y_i, \mu_i, \phi)) \)

are shown in the following list; the parameterizations are expressed in terms of the mean and dispersion parameters.

- **Normal:**
  \( l_i = -\frac{1}{2} \left[ \frac{w_i(y_i - \mu_i)^2}{\phi} + \log \left( \frac{\phi}{w_i} \right) + \log(2\pi) \right] \)

- **Inverse Gaussian:**
  \( l_i = -\frac{1}{2} \left[ \frac{w_i(y_i - \mu_i)^2}{y_i \mu_i^2 \phi} + \log \left( \frac{\phi y_i^2}{w_i} \right) + \log(2\pi) \right] \)

- **Gamma:**
  \( l_i = \frac{w_i}{\phi} \log \left( \frac{w_i y_i}{\phi \mu_i} \right) - \frac{w_i y_i}{\phi \mu_i} - \log(y_i) - \log \left( \Gamma \left( \frac{w_i}{\phi} \right) \right) \)

- **Negative Binomial:**
  \( l_i = y \log \left( \frac{k\mu}{w_i} \right) - (y + w_i/k) \log \left( 1 + \frac{k\mu}{w_i} \right) + \log \left( \frac{\Gamma(y + w_i/k)}{\Gamma(y + 1)\Gamma(w_i/k)} \right) \)

- **Poisson:**
  \( l_i = \frac{w_i}{\phi} [y_i \log(\mu_i) - \mu_i] \)

- **Binomial:**
  \( l_i = \frac{w_i}{\phi} [r_i \log(p_i) + (n_i - r_i) \log(1 - p_i)] \)

- **Multinomial:**
  \( l_i = \frac{w_i}{\phi} \sum_j y_{ij} \log(\mu_{ij}) \)

For the binomial, multinomial, and Poisson distribution, terms involving binomial coefficients or factorials of the observed counts are dropped from the computation of the log-likelihood function since they do not affect parameter estimates or their estimated covariances. The value of \( \phi \) used in computing the reported log-likelihood is either the final estimated value, or the fixed value, if the dispersion parameter is fixed.
**Maximum Likelihood Fitting**

The GENMOD procedure uses a ridge-stabilized Newton-Raphson algorithm to maximize the log-likelihood function \( L(y, \mu, \phi) \) with respect to the regression parameters. By default, the procedure also produces maximum likelihood estimates of the scale parameter as defined in the “Response Probability Distributions” section (page 1650) for the normal, inverse Gaussian, negative binomial, and gamma distributions.

On the \( r \)th iteration, the algorithm updates the parameter vector \( \beta_r \) with

\[
\beta_{r+1} = \beta_r - \mathbf{H}^{-1}\mathbf{s}
\]

where \( \mathbf{H} \) is the Hessian (second derivative) matrix, and \( \mathbf{s} \) is the gradient (first derivative) vector of the log-likelihood function, both evaluated at the current value of the parameter vector. That is,

\[
\mathbf{s} = [s_j] = \left[ \frac{\partial L}{\partial \beta_j} \right]
\]

and

\[
\mathbf{H} = [h_{ij}] = \left[ \frac{\partial^2 L}{\partial \beta_i \partial \beta_j} \right]
\]

In some cases, the scale parameter is estimated by maximum likelihood. In these cases, elements corresponding to the scale parameter are computed and included in \( \mathbf{s} \) and \( \mathbf{H} \).

If \( \eta_i = \mathbf{x}_i' \beta \) is the linear predictor for observation \( i \) and \( g \) is the link function, then \( \eta_i = g(\mu_i) \), so that \( \mu_i = g^{-1}(\mathbf{x}_i' \beta) \) is an estimate of the mean of the \( i \)th observation, obtained from an estimate of the parameter vector \( \beta \).

The gradient vector and Hessian matrix for the regression parameters are given by

\[
s = \sum_i w_i(y_i - \mu_i)\mathbf{x}_i \quad V(\mu_i)g''(\mu_i) + V'(\mu_i)g'(\mu_i)
\]

\[
\mathbf{H} = -\mathbf{X}'\mathbf{W}_o\mathbf{X}
\]

where \( \mathbf{X} \) is the design matrix, \( \mathbf{x}_i \) is the transpose of the \( i \)th row of \( \mathbf{X} \), and \( V \) is the variance function. The matrix \( \mathbf{W}_o \) is diagonal with its \( i \)th diagonal element

\[
w_{oi} = w_{ei} + w_i(y_i - \mu_i)\frac{V(\mu_i)g''(\mu_i) + V'(\mu_i)g'(\mu_i)}{(V(\mu_i))^2(g'(\mu_i))^3}\phi
\]

where

\[
w_{ei} = \frac{w_i}{\phi V(\mu_i)(g'(\mu_i))^2}
\]
The primes denote derivatives of $g$ and $V$ with respect to $\mu$. The negative of $H$ is called the observed information matrix. The expected value of $W_o$ is a diagonal matrix $W_e$ with diagonal values $w_{ei}$. If you replace $W_o$ with $W_e$, then the negative of $H$ is called the expected information matrix. $W_e$ is the weight matrix for the Fisher’s scoring method of fitting. Either $W_o$ or $W_e$ can be used in the update equation. The GENMOD procedure uses Fisher’s scoring for iterations up to the number specified by the SCORING option in the MODEL statement, and it uses the observed information matrix on additional iterations.

**Covariance and Correlation Matrix**

The estimated covariance matrix of the parameter estimator is given by

$$\Sigma = -H^{-1}$$

where $H$ is the Hessian matrix evaluated using the parameter estimates on the last iteration. Note that the dispersion parameter, whether estimated or specified, is incorporated into $H$. Rows and columns corresponding to aliased parameters are not included in $\Sigma$.

The correlation matrix is the normalized covariance matrix. That is, if $\sigma_{ij}$ is an element of $\Sigma$, then the corresponding element of the correlation matrix is $\sigma_{ij}/\sigma_i \sigma_j$, where $\sigma_i = \sqrt{\sigma_{ii}}$.

**Goodness of Fit**

Two statistics that are helpful in assessing the goodness of fit of a given generalized linear model are the scaled deviance and Pearson’s chi-square statistic. For a fixed value of the dispersion parameter $\phi$, the scaled deviance is defined to be twice the difference between the maximum achievable log likelihood and the log likelihood at the maximum likelihood estimates of the regression parameters.

Note that these statistics are not valid for GEE models.

If $l(y, \mu)$ is the log-likelihood function expressed as a function of the predicted mean values $\mu$ and the vector $y$ of response values, then the scaled deviance is defined by

$$D^*(y, \mu) = 2(l(y, y) - l(y, \mu))$$

For specific distributions, this can be expressed as

$$D^*(y, \mu) = \frac{D(y, \mu)}{\phi}$$

where $D$ is the deviance. The following table displays the deviance for each of the probability distributions available in PROC GENMOD.
In the binomial case, \( y_i = r_i / m_i \), where \( r_i \) is a binomial count and \( m_i \) is the binomial number of trials parameter.

In the multinomial case, \( y_{ij} \) refers to the observed number of occurrences of the \( j \)th category for the \( i \)th subpopulation defined by the AGGREGATE= variable, \( m_i \) is the total number in the \( i \)th subpopulation, and \( p_{ij} \) is the category probability.

Pearson’s chi-square statistic is defined as

\[
X^2 = \sum_i w_i (y_i - \mu_i)^2 / V(\mu_i)
\]

and the scaled Pearson’s chi-square is \( X^2 / \phi \).

The scaled version of both of these statistics, under certain regularity conditions, has a limiting chi-square distribution, with degrees of freedom equal to the number of observations minus the number of parameters estimated. The scaled version can be used as an approximate guide to the goodness of fit of a given model. Use caution before applying these statistics to ensure that all the conditions for the asymptotic distributions hold. McCullagh and Nelder (1989) advise that differences in deviances for nested models can be better approximated by chi-square distributions than the deviances themselves.

In cases where the dispersion parameter is not known, an estimate can be used to obtain an approximation to the scaled deviance and Pearson’s chi-square statistic. One strategy is to fit a model that contains a sufficient number of parameters so that all systematic variation is removed, estimate \( \phi \) from this model, and then use this estimate in computing the scaled deviance of sub-models. The deviance or Pearson’s chi-square divided by its degrees of freedom is sometimes used as an estimate of the dispersion parameter \( \phi \). For example, since the limiting chi-square distribution of the scaled deviance \( D_\phi = D / \phi \) has \( n - p \) degrees of freedom, where \( n \) is the number of observations and \( p \) the number of parameters, equating \( D_\phi \) to its mean and solving for \( \phi \) yields \( \phi = D / (n - p) \). Similarly, an estimate of \( \phi \) based on Pearson’s chi-square \( X^2 \) is \( \hat{\phi} = X^2 / (n - p) \). Alternatively, a maximum likelihood estimate of \( \phi \) can be
computed by the procedure, if desired. See the discussion in the “Type 1 Analysis” section on page 1665 for more on the estimation of the dispersion parameter.

**Dispersion Parameter**

There are several options available in PROC GENMOD for handling the exponential distribution dispersion parameter. The NOSCALE and SCALE options in the MODEL statement affect the way in which the dispersion parameter is treated. If you specify the SCALE=DEVIANCE option, the dispersion parameter is estimated by the deviance divided by its degrees of freedom. If you specify the SCALE=PEARSON option, the dispersion parameter is estimated by Pearson’s chi-square statistic divided by its degrees of freedom.

Otherwise, values of the SCALE and NOSCALE options and the resultant actions are displayed in the following table.

<table>
<thead>
<tr>
<th>NOSCALE</th>
<th>SCALE=value</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>present</td>
<td>present</td>
<td>scale fixed at value</td>
</tr>
<tr>
<td>present</td>
<td>not present</td>
<td>scale fixed at 1</td>
</tr>
<tr>
<td>not present</td>
<td>not present</td>
<td>scale estimated by ML</td>
</tr>
<tr>
<td>not present</td>
<td>present</td>
<td>scale estimated by ML, starting point at value</td>
</tr>
</tbody>
</table>

The meaning of the scale parameter displayed in the “Analysis Of Parameter Estimates” table is different for the Gamma distribution than for the other distributions. The relation of the scale parameter as used by PROC GENMOD to the exponential family dispersion parameter $\phi$ is displayed in the following table. For the binomial and Poisson distributions, $\phi$ is the overdispersion parameter, as defined in the “Overdispersion” section, which follows.

<table>
<thead>
<tr>
<th>Distribution</th>
<th>Scale</th>
</tr>
</thead>
<tbody>
<tr>
<td>normal</td>
<td>$\sqrt{\phi}$</td>
</tr>
<tr>
<td>inverse Gaussian</td>
<td>$\sqrt{\phi}$</td>
</tr>
<tr>
<td>gamma</td>
<td>$1/\phi$</td>
</tr>
<tr>
<td>binomial</td>
<td>$\sqrt{\phi}$</td>
</tr>
<tr>
<td>Poisson</td>
<td>$\sqrt{\phi}$</td>
</tr>
</tbody>
</table>

In the case of the negative binomial distribution, PROC GENMOD reports the “dispersion” parameter estimated by maximum likelihood. This is the negative binomial parameter $k$ defined in the “Response Probability Distributions” section (page 1650).
Overdispersion

Overdispersion is a phenomenon that sometimes occurs in data that are modeled with the binomial or Poisson distributions. If the estimate of dispersion after fitting, as measured by the deviance or Pearson’s chi-square, divided by the degrees of freedom, is not near 1, then the data may be overdispersed if the dispersion estimate is greater than 1 or underdispersed if the dispersion estimate is less than 1. A simple way to model this situation is to allow the variance functions of these distributions to have a multiplicative overdispersion factor $\phi$.

- binomial: $V(\mu) = \phi \mu (1 - \mu)$
- Poisson: $V(\mu) = \phi \mu$

The models are fit in the usual way, and the parameter estimates are not affected by the value of $\phi$. The covariance matrix, however, is multiplied by $\phi$, and the scaled deviance and log likelihoods used in likelihood ratio tests are divided by $\phi$. The profile likelihood function used in computing confidence intervals is also divided by $\phi$. If you specify an WEIGHT statement, $\phi$ is divided by the value of the WEIGHT variable for each observation. This has the effect of multiplying the contributions of the log-likelihood function, the gradient, and the Hessian by the value of the WEIGHT variable for each observation.

The SCALE= option in the MODEL statement enables you to specify a value of $\sigma = \sqrt{\phi}$ for the binomial and Poisson distributions. If you specify the SCALE=DEVIANCE option in the MODEL statement, the procedure uses the deviance divided by degrees of freedom as an estimate of $\phi$, and all statistics are adjusted appropriately. You can use Pearson’s chi-square instead of the deviance by specifying the SCALE=PEARSON option.

The function obtained by dividing a log-likelihood function for the binomial or Poisson distribution by a dispersion parameter is not a legitimate log-likelihood function. It is an example of a quasi-likelihood function. Most of the asymptotic theory for log likelihoods also applies to quasi-likelihoods, which justifies computing standard errors and likelihood ratio statistics using quasi-likelihoods instead of proper log likelihoods. Refer to McCullagh and Nelder (1989, Chapter 9) and McCullagh (1983) for details on quasi-likelihood functions.

Although the estimate of the dispersion parameter is often used to indicate overdispersion or underdispersion, this estimate may also indicate other problems such as an incorrectly specified model or outliers in the data. You should carefully assess whether this type of model is appropriate for your data.

Specification of Effects

Each term in a model is called an effect. Effects are specified in the MODEL statement in the same way as in the GLM procedure. You specify effects with a special notation that uses variable names and operators. There are two types of variables, classification (or class) variables and continuous variables. There are two primary types of operators, crossing and nesting. A third type, the bar operator, is used to
simplify effect specification. Crossing is the type of operator most commonly used in generalized linear models.

Variables that identify classification levels are called class variables in the SAS System and are identified in a CLASS statement. These may also be called categorical, qualitative, discrete, or nominal variables. Class variables can be either character or numeric. The values of class variables are called levels. For example, the class variable Sex could have levels ‘male’ and ‘female’.

In a model, an explanatory variable that is not declared in a CLASS statement is assumed to be continuous. Continuous variables must be numeric. For example, the heights and weights of subjects in an experiment are continuous variables.

The types of effects most useful in generalized linear models are shown in the following list. Assume that A, B, and C are class variables and that X1 and X2 are continuous variables.

- Regressor effects are specified by writing continuous variables by themselves: X1, X2.
- Polynomial effects are specified by joining two or more continuous variables with asterisks: X1*X2.
- Main effects are specified by writing class variables by themselves: A, B, C.
- Crossed effects (interactions) are specified by joining two or more class variables with asterisks: A*B, B*C, A*B*C.
- Nested effects are specified by following a main effect or crossed effect with a class variable or list of class variables enclosed in parentheses: B(A), C(B A), A*B(C). In the preceding example, B(A) is “B nested within A.”
- Combinations of continuous and class variables can be specified in the same way using the crossing and nesting operators.

The bar operator consists of two effects joined with a vertical bar (|). It is shorthand notation for including the left-hand side, the right-hand side, and the cross between them as effects in the model. For example, A | B is equivalent to A B A*B. The effects in the bar operator can be class variables, continuous variables, or combinations of effects defined using operators. Multiple bars are permitted. For example, A | B | C means A B C A*B A*C B*C A*B*C.

You can specify the maximum number of variables in any effect that results from bar evaluation by specifying the maximum number, preceded by an @ sign. For example, A | B | C@2 results in effects that involve two or fewer variables: A B C A*B A*C B*C.

For further information on types of effects and their specification, see Chapter 32, “The GLM Procedure.”
Parameterization Used in PROC GENMOD

Design Matrix

The linear predictor part of a generalized linear model is

\[ \eta = X \beta \]

where \( \beta \) is an unknown parameter vector and \( X \) is a known design matrix. By default, all models automatically contain an intercept term; that is, the first column of \( X \) contains all 1s. Additional columns of \( X \) are generated for classification variables, regression variables, and any interaction terms included in the model. PROC GENMOD parameterizes main effects and interaction terms using the same ordering rules that PROC GLM uses. This is important to understand when you want to construct likelihood ratios for custom contrasts using the CONTRAST statement. See Chapter 32, “The GLM Procedure,” for more details on model parameterization.

Some columns of \( X \) can be linearly dependent on other columns due to specifying an overparameterized model. For example, when you specify a model consisting of an intercept term and a class variable, the column corresponding to any one of the levels of the class variable is linearly dependent on the other columns of \( X \). PROC GENMOD handles this in the same manner as PROC GLM. The columns of \( X'X \) are checked in the order in which the model is specified for dependence on preceding columns. If a dependency is found, the parameter corresponding to the dependent column is set to 0 along with its standard error to indicate that it is not estimated. The order in which the levels of a class variable are checked for dependencies can be set by the ORDER= option in the PROC GENMOD statement.

You can exclude the intercept term from the model by specifying the NOINT option in the MODEL statement.

Missing Level Combinations

All levels of interaction terms involving classification variables may not be represented in the data. In that case, PROC GENMOD does not include parameters in the model for the missing levels.

CLASS Variable Parameterization

Consider a model with one CLASS variable \( A \) with four levels, 1, 2, 5, and 7. Details of the possible choices for the PARAM= option follow.

EFFECT

Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of \(-1\). For instance, if the reference level is 7 (REF=7), the design matrix columns for \( A \) are as follows.
Parameter estimates of CLASS main effects using the effect coding scheme estimate the difference in the effect of each nonreference level compared to the average effect over all four levels.

**GLM**

As in PROC GLM, four columns are created to indicate group membership. The design matrix columns for $A$ are as follows.

<table>
<thead>
<tr>
<th>GLM Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A$</td>
<td>$A1$</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
</tr>
<tr>
<td>5</td>
<td>0</td>
</tr>
<tr>
<td>7</td>
<td>0</td>
</tr>
</tbody>
</table>

Parameter estimates of CLASS main effects using the GLM coding scheme estimate the difference in the effects of each level compared to the last level.

**ORDINAL**

**THERMOMETER** Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for $A$ is 1), all three dummy variables have a value of 0. The design matrix columns for $A$ are as follows.

<table>
<thead>
<tr>
<th>Ordinal Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A$</td>
<td>$A2$</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>1</td>
</tr>
<tr>
<td>7</td>
<td>1</td>
</tr>
</tbody>
</table>

The first level of the effect is a control or baseline level. Parameter estimates of CLASS main effects using the ORDINAL coding scheme estimate the effect on the response as the ordinal factor.
is set to each succeeding level. When the parameters for an ordinal main effect have the same sign, the response effect is monotonic across the levels.

**POLYNOMIAL**

**POLY** Three columns are created. The first represents the linear term ($x$), the second represents the quadratic term ($x^2$), and the third represents the cubic term ($x^3$), where $x$ is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, \ldots according to their sorting order. The design matrix columns for $A$ are as follows.

<table>
<thead>
<tr>
<th>Polynomial Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A$</td>
<td>APOLY1 APOLY2 APOLY3</td>
</tr>
<tr>
<td>1</td>
<td>1 1 1</td>
</tr>
<tr>
<td>2</td>
<td>2 4 8</td>
</tr>
<tr>
<td>5</td>
<td>5 25 125</td>
</tr>
<tr>
<td>7</td>
<td>7 49 343</td>
</tr>
</tbody>
</table>

**REFERENCE**

**REF** Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of 0. For instance, if the reference level is 7 (REF=7), the design matrix columns for $A$ are as follows.

<table>
<thead>
<tr>
<th>Reference Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A$</td>
<td>A1 A2 A5</td>
</tr>
<tr>
<td>1</td>
<td>1 0 0</td>
</tr>
<tr>
<td>2</td>
<td>0 1 0</td>
</tr>
<tr>
<td>5</td>
<td>0 0 1</td>
</tr>
<tr>
<td>7</td>
<td>0 0 0</td>
</tr>
</tbody>
</table>

Parameter estimates of CLASS main effects using the reference coding scheme estimate the difference in the effect of each nonreference level compared to the effect of the reference level.

**ORTH EFFECT** The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for $A$ are as follows.
### Orthogonal Effect Coding

<table>
<thead>
<tr>
<th>Design Matrix</th>
<th>A</th>
<th>AOEFF1</th>
<th>AOEFF2</th>
<th>AOEFF3</th>
</tr>

</tbody>
</table>
Type 1 Analysis

A Type 1 analysis consists of fitting a sequence of models, beginning with a simple model with only an intercept term, and continuing through a model of specified complexity, fitting one additional effect on each step. Likelihood ratio statistics, that is, twice the difference of the log likelihoods, are computed between successive models. This type of analysis is sometimes called an analysis of deviance since, if the dispersion parameter is held fixed for all models, it is equivalent to computing differences of scaled deviances. The asymptotic distribution of the likelihood ratio statistics, under the hypothesis that the additional parameters included in the model are equal to 0, is a chi-square with degrees of freedom equal to the difference in the number of parameters estimated in the successive models. Thus, these statistics can be used in a test of hypothesis of the significance of each additional term fit.

This type of analysis is not available for GEE models, since the deviance is not computed for this type of model.

If the dispersion parameter $\phi$ is known, it can be included in the models; if it is unknown, there are two strategies allowed by PROC GENMOD. The dispersion parameter can be estimated from a maximal model by the deviance or Pearson's chi-square divided by degrees of freedom, as discussed in the “Goodness of Fit” section on page 1656, and this value can be used in all models. An alternative is to consider the dispersion to be an additional unknown parameter for each model and estimate it by maximum likelihood on each step. By default, PROC GENMOD estimates scale by maximum likelihood at each step.

A table of likelihood ratio statistics is produced, along with associated $p$-values based on the asymptotic chi-square distributions.

If you specify either the SCALE=DEVIANCE or the SCALE=PEARSON option in the MODEL statement, the dispersion parameter is estimated using the deviance or Pearson's chi-square statistic, and $F$ statistics are computed in addition to the chi-square statistics for assessing the significance of each additional term in the Type 1 analysis. See the section “F Statistics” on page 1668 for a definition of $F$ statistics.

This Type 1 analysis has the general property that the results depend on the order in which the terms of the model are fitted. The terms are fitted in the order in which they are specified in the MODEL statement.

Type 3 Analysis

A Type 3 analysis is similar to the Type III sums of squares used in PROC GLM, except that likelihood ratios are used instead of sums of squares. First, a Type III estimable function is defined for an effect of interest in exactly the same way as in PROC GLM. Then, maximum likelihood estimation is performed under the constraint that the Type III function of the parameters is equal to 0, using constrained optimization. Let the resulting constrained parameter estimates be $\tilde{\beta}$ and the log likelihood be $l(\tilde{\beta})$. Then the likelihood ratio statistic

$$S = 2(l(\hat{\beta}) - l(\tilde{\beta}))$$
where \( \hat{\beta} \) is the unconstrained estimate, has an asymptotic chi-square distribution under the hypothesis that the Type III contrast is equal to 0, with degrees of freedom equal to the number of parameters associated with the effect.

When a Type 3 analysis is requested, PROC GENMOD produces a table that contains the likelihood ratio statistics, degrees of freedom, and \( p \)-values based on the limiting chi-square distributions for each effect in the model. If you specify either the DSCALE or PSCALE option in the MODEL statement, \( F \) statistics are also computed for each effect.

Options for handling the dispersion parameter are the same as for a Type 1 analysis. The dispersion parameter can be specified to be a known value, estimated from the deviance or Pearson’s chi-square divided by degrees of freedom, or estimated by maximum likelihood individually for the unconstrained and constrained models. By default, PROC GENMOD estimates scale by maximum likelihood for each model fit.

The results of this type of analysis do not depend on the order in which the terms are specified in the MODEL statement.

A Type 3 analysis can consume considerable computation time since a constrained model is fitted for each effect. Wald statistics for Type 3 contrasts are computed if you specify the WALD option. Wald statistics for contrasts use less computation time than likelihood ratio statistics but may be less accurate indicators of the significance of the effect of interest. The Wald statistic for testing \( L/\beta = 0 \), where \( L \) is the contrast matrix, is defined by

\[
S = (L'\hat{\beta})'(L'\hat{\Sigma}L)^{-1}(L/\hat{\beta})
\]

where \( \beta \) is the maximum likelihood estimate and \( \Sigma \) is its estimated covariance matrix. The asymptotic distribution of \( S \) is chi-square with \( r \) degrees of freedom, where \( r \) is the rank of \( L \).

Generalized score tests for Type III contrasts are computed for GEE models if you specify the TYPE3 option in the MODEL statement when a REPEATED statement is also used. See the section “Generalized Score Statistics” on page 1680 for more information on generalized score statistics. Wald tests are also available with the Wald option in the CONTRAST statement.

### Confidence Intervals for Parameters

#### Likelihood Ratio-Based Confidence Intervals

PROC GENMOD produces likelihood ratio-based confidence intervals, also known as profile likelihood confidence intervals, for parameter estimates for generalized linear models. These are not computed for GEE models, since there is no likelihood for this type of model. Suppose that the parameter vector is \( \beta = [\beta_0, \beta_1, \ldots, \beta_p]' \) and
that you want a confidence interval for $\beta_j$. The profile likelihood function for $\beta_j$ is defined as

$$l^*(\beta_j) = \max_{\beta} l(\beta)$$

where $\tilde{\beta}$ is the vector $\beta$ with the $j$th element fixed at $\beta_j$ and $l$ is the log likelihood function. If $l = l(\tilde{\beta})$ is the log likelihood evaluated at the maximum likelihood estimate $\tilde{\beta}$, then $2(l - l^*(\beta_j))$ has a limiting chi-square distribution with one degree of freedom if $\beta_j$ is the true parameter value. A $(1 - \alpha)100\%$ confidence interval for $\beta_j$ is

$$\{\beta_j : l^*(\beta_j) \geq l_0 = l - 0.5\chi^2_{1 - \alpha,1}\}$$

where $\chi^2_{1 - \alpha,1}$ is the $100(1 - \alpha)$ percentile of the chi-square distribution with one degree of freedom. The endpoints of the confidence interval can be found by solving numerically for values of $\beta_j$ that satisfy equality in the preceding relation. PROC GENMOD solves this by starting at the maximum likelihood estimate of $\beta$. The log likelihood function is approximated with a quadratic surface, for which an exact solution is possible. The process is iterated until convergence to an endpoint is attained. The process is repeated for the other endpoint. Convergence is controlled by the CICONV= option in the MODEL statement. Suppose $\epsilon$ is the number specified in the CICONV= option. The default value of $\epsilon$ is $10^{-4}$. Let the parameter of interest be $\beta_j$ and define $r = u_j$, the unit vector with a 1 in position $j$ and 0s elsewhere. Convergence is declared on the current iteration if the following two conditions are satisfied:

$$|l^*(\beta_j) - l_0| \leq \epsilon$$
$$\left(s + \lambda r\right)^T H^{-1} \left(s + \lambda r\right) \leq \epsilon$$

where $l^*(\beta_j)$, $s$, and $H$ are the log likelihood, the gradient, and the Hessian evaluated at the current parameter vector and $\lambda$ is a constant computed by the procedure. The first condition for convergence means that the log-likelihood function must be within $\epsilon$ of the correct value, and the second condition means that the gradient vector must be proportional to the restriction vector $r$.

When you request the LRCI option in the MODEL statement, PROC GENMOD computes profile likelihood confidence intervals for all parameters in the model, including the scale parameter, if there is one. The interval endpoints are displayed in a table as well as the values of the remaining parameters at the solution.

**Wald Confidence Intervals**

You can request that PROC GENMOD produce Wald confidence intervals for the parameters. The $(1-\alpha)100\%$ Wald confidence interval for a parameter $\beta$ is defined as

$$\hat{\beta} \pm z_{1 - \alpha/2} \hat{\sigma}$$
where \( z_p \) is the 100\( p \)th percentile of the standard normal distribution, \( \hat{\beta} \) is the parameter estimate, and \( \hat{\sigma} \) is the estimate of its standard error.

### F Statistics

Suppose that \( D_0 \) is the deviance resulting from fitting a generalized linear model and that \( D_1 \) is the deviance from fitting a submodel. Then, under appropriate regularity conditions, the asymptotic distribution of \( (D_1 - D_0)/\phi \) is chi-square with \( r \) degrees of freedom, where \( r \) is the difference in the number of parameters between the two models and \( \phi \) is the dispersion parameter. If \( \phi \) is unknown, and \( \hat{\phi} \) is an estimate of \( \phi \) based on the deviance or Pearson’s chi-square divided by degrees of freedom, then, under regularity conditions, \( (n - p)\hat{\phi}/\phi \) has an asymptotic chi-square distribution with \( n - p \) degrees of freedom. Here, \( n \) is the number of observations and \( p \) is the number of parameters in the model that is used to estimate \( \phi \). Thus, the asymptotic distribution of

\[
F = \frac{D_1 - D_0}{r\hat{\phi}}
\]

is the \( F \) distribution with \( r \) and \( n - p \) degrees of freedom, assuming that \( (D_1 - D_0)/\phi \) and \( (n - p)\hat{\phi}/\phi \) are approximately independent.

This \( F \) statistic is computed for the Type 1 analysis, Type 3 analysis, and hypothesis tests specified in CONTRAST statements when the dispersion parameter is estimated by either the deviance or Pearson’s chi-square divided by degrees of freedom, as specified by the DSSCALE or PSSCALE option in the MODEL statement. In the case of a Type 1 analysis, model 0 is the higher-order model obtained by including one additional effect in model 1. For a Type 3 analysis and hypothesis tests, model 0 is the full specified model and model 1 is the sub-model obtained from constraining the Type III contrast or the user-specified contrast to be 0.

### Lagrange Multiplier Statistics

When you select the NOINT or NOSCALE option, restrictions are placed on the intercept or scale parameters. Lagrange multiplier, or score, statistics are computed in these cases. These statistics assess the validity of the restrictions, and they are computed as

\[
\chi^2 = \frac{s^2}{V}
\]

where \( s \) is the component of the score vector evaluated at the restricted maximum corresponding to the restricted parameter and \( V = I_{11} - I_{12}I_{22}^{-1}I_{21} \). The matrix \( I \) is the information matrix, 1 refers to the restricted parameter, and 2 refers to the rest of the parameters.

Under regularity conditions, this statistic has an asymptotic chi-square distribution with one degree of freedom, and \( p \) values are computed based on this limiting distribution.
If you set $k = 0$ in a negative binomial model, $s$ is the score statistic of Cameron and Trivedi (1998) for testing for overdispersion in a Poisson model against alternatives of the form $V(\mu) = \mu + k\mu^2$.

Refer to Rao (1973, p. 417) for more details.

**Predicted Values of the Mean**

**Predicted Values**

A predicted value, or fitted value, of the mean $\mu_i$ corresponding to the vector of covariates $x_i$ is given by

$$\hat{\mu}_i = g^{-1}(x'_i\hat{\beta})$$

where $g$ is the link function, regardless of whether $x_i$ corresponds to an observation or not. That is, the response variable can be missing and the predicted value is still computed for valid $x_i$. In the case where $x_i$ does not correspond to a valid observation, $x_i$ is not checked for estimability. You should check the estimability of $x_i$ in this case in order to ensure the uniqueness of the predicted value of the mean. If there is an offset, it is included in the predicted value computation.

**Confidence Intervals on Predicted Values**

Approximate confidence intervals for predicted values of the mean can be computed as follows. The variance of the linear predictor $\eta_i = x'_i\hat{\beta}$ is estimated by

$$\sigma_x^2 = x'_i \Sigma x_i$$

where $\Sigma$ is the estimated covariance of $\hat{\beta}$.

Approximate $100(1 - \alpha)$% confidence intervals are computed as

$$g^{-1} \left( x'_i\hat{\beta} \pm z_{1-\alpha/2} \sigma_x \right)$$

where $z_p$ is the 100$p$ percentile of the standard normal distribution and $g$ is the link function. If either endpoint in the argument is outside the valid range of arguments for the inverse link function, the corresponding confidence interval endpoint is set to missing.

**Residuals**

The GENMOD procedure computes three kinds of residuals. The raw residual is defined as

$$r_i = y_i - \mu_i$$

where $y_i$ is the $i$th response and $\mu_i$ is the corresponding predicted mean.
The Pearson residual is the square root of the \( i \)th contribution to the Pearson’s chi-square.

\[
r_{Pi} = (y_i - \mu_i) \sqrt{\frac{w_i}{V(\mu_i)}}
\]

Finally, the deviance residual is defined as the square root of the contribution of the \( i \)th observation to the deviance, with the sign of the raw residual.

\[
r_{Di} = \sqrt{d_i \text{sign}(y_i - \mu_i)}
\]

The adjusted Pearson, deviance, and likelihood residuals are defined by Agresti (1990), Williams (1987), and Davison and Snell (1991). These residuals are useful for outlier detection and for assessing the influence of single observations on the fitted model.

For the generalized linear model, the variance of the \( i \)th individual observation is given by

\[
v_i = \frac{\phi V(\mu_i)}{w_i}
\]

where \( \phi \) is the dispersion parameter, \( w_i \) is a user-specified prior weight (if not specified, \( w_i = 1 \)), \( \mu_i \) is the mean, and \( V(\mu_i) \) is the variance function. Let

\[
w_{ei} = v_i^{-1}(g'(\mu_i))^{-2}
\]

for the \( i \)th observation, where \( g'(\mu_i) \) is the derivative of the link function, evaluated at \( \mu_i \). Let \( W_e \) be the diagonal matrix with \( w_{ei} \) denoting the \( i \)th diagonal element. The weight matrix \( W_e \) is used in computing the expected information matrix.

Define \( h_i \) as the \( i \)th diagonal element of the matrix

\[
W_{e}^{1/2}X(X'W_eX)^{-1}X'W_{e}^{1/2}
\]

The Pearson residuals, standardized to have unit asymptotic variance, are given by

\[
r_{Pi} = \frac{y_i - \mu_i}{\sqrt{v_i(1 - h_i)}}
\]

The deviance residuals, standardized to have unit asymptotic variance, are given by

\[
r_{Di} = \frac{\text{sign}(y_i - \mu_i)\sqrt{d_i}}{\sqrt{\phi(1 - h_i)}}
\]

where \( d_i \) is the square root of the contribution to the total deviance from observation \( i \), and \( \text{sign}(y_i - \mu_i) \) is 1 if \( y_i - \mu_i \) is positive and -1 if \( y_i - \mu_i \) is negative. The likelihood residuals are defined by

\[
r_{Gi} = \text{sign}(y_i - \mu_i)\sqrt{(1 - h_i)r_{Di}^2 + h_i r_{Pi}^2}
\]
Multinomial Models

This type of model applies to cases where an observation can fall into one of \( k \) categories. Binary data occurs in the special case where \( k = 2 \). If there are \( m_i \) observations in a subpopulation \( i \), then the probability distribution of the number falling into the \( k \) categories \( y_i = (y_{i1}, y_{i2}, \cdots, y_{ik}) \) can be modeled by the multinomial distribution, defined in the “Response Probability Distributions” section (page 1650), with \( \sum_j y_{ij} = m_i \). The multinomial model is an ordinal model if the categories have a natural order.

The GENMOD procedure orders the response categories for ordinal multinomial models from lowest to highest by default. This is different from the binomial distribution, where the response probability for the lowest of the two categories is modeled. You can change the way GENMOD orders the response levels with the RORDER= option in the PROC GENMOD statement. The order that GENMOD uses is shown in the “Response Profiles” output table described in the section “Response Profile” on page 1685.

The GENMOD procedure supports only the ordinal multinomial model. If \( (p_{i1}, p_{i2}, \cdots, p_{ik}) \) are the category probabilities, the cumulative category probabilities are modeled with the same link functions used for binomial data. Let \( P_{ir} = \sum_{j=1}^{r} p_{ij}, r = 1, 2, \cdots, k - 1 \) be the cumulative category probabilities (note that \( P_{ik} = 1 \)). The ordinal model is

\[
g(P_{ir}) = \mu_r + x_i'\beta \quad \text{for} \quad r = 1, 2, \cdots, k - 1
\]

where \( \mu_1, \mu_2, \cdots, \mu_{k-1} \) are intercept terms that depend only on the categories and \( x_i \) is a vector of covariates that does not include an intercept term. The logit, probit, and complementary log-log link functions \( g \) are available. These are obtained by specifying the MODEL statement options DIST=MULTINOMIAL and LINK=CUMLOGIT (cumulative logit), LINK=CUMPROBIT (cumulative probit), or LINK=CUMCLL (cumulative complementary log-log). Alternatively,

\[
P_{ir} = F(\mu_r + x_i'\beta) \quad \text{for} \quad r = 1, 2, \cdots, k - 1
\]

where \( F = g^{-1} \) is a cumulative distribution function for the logistic, normal, or extreme value distribution.

PROC GENMOD estimates the intercept parameters \( \mu_1, \mu_2, \cdots, \mu_{k-1} \) and regression parameters \( \beta \) by maximum likelihood.

The subpopulations \( i \) are defined by constant values of the AGGREGATE= variable. This has no effect on the parameter estimates, but it does affect the deviance and Pearson chi-square statistics; it also affects parameter estimate standard errors if you specify the SCALE=DEVIANCE or SCALE=PEARSON options.
Generalized Estimating Equations

Let \( y_{ij}, j = 1, \ldots, n_i, i = 1, \ldots, K \) represent the \( j \)th measurement on the \( i \)th subject. There are \( n_i \) measurements on subject \( i \) and \( \sum_{i=1}^{K} n_i \) total measurements.

Correlated data are modeled using the same link function and linear predictor setup (systematic component) as the independence case. The random component is described by the same variance functions as in the independence case, but the covariance structure of the correlated measurements must also be modeled. Let the vector of measurements on the \( i \)th subject be \( Y_i = [y_{i1}, \ldots, y_{in_i}]' \) with corresponding vector of means \( \mu_i = [\mu_{i1}, \ldots, \mu_{in_i}]' \) and let \( V_i \) be the covariance matrix of \( Y_i \). Let the vector of independent, or explanatory, variables for the \( j \)th measurement on the \( i \)th subject be

\[
x_{ij} = [x_{ij1}, \ldots, x_{ijp}]'
\]

The Generalized Estimating Equation of Liang and Zeger (1986) for estimating the \( p \times 1 \) vector of regression parameters \( \beta \) is an extension of the independence estimating equation to correlated data and is given by

\[
S(\beta) = \sum_{i=1}^{K} D_i' V_i^{-1} (Y_i - \mu_i(\beta)) = 0
\]

where

\[
D_i = \frac{\partial \mu_i}{\partial \beta}
\]

Since

\[
g(\mu_{ij}) = x_{ij}' / \beta
\]

where \( g \) is the link function, the \( p \times n_i \) matrix of partial derivatives of the mean with respect to the regression parameters for the \( i \)th subject is given by

\[
D_i' = \frac{\partial \mu_i'}{\partial \beta} = \begin{bmatrix}
x_{i11} & \cdots & x_{i1p} 
g'(\mu_{i1}) & \cdots & g'(\mu_{i1}) 
\vdots & \ddots & \vdots 
x_{in_i1} & \cdots & x_{in_ip} 
g'(\mu_{in_i}) & \cdots & g'(\mu_{in_i})
\end{bmatrix}
\]

Working Correlation Matrix

Let \( R_i(\alpha) \) be an \( n_i \times n_i \) “working” correlation matrix that is fully specified by the vector of parameters \( \alpha \). The covariance matrix of \( Y_i \) is modeled as

\[
V_i = \phi A_i^{\frac{1}{2}} W_i^{-\frac{1}{2}} R(\alpha) W_i^{-\frac{1}{2}} A_i^{\frac{1}{2}}
\]
where $A_i$ is an $n_i \times n_i$ diagonal matrix with $v(\mu_{ij})$ as the $j$th diagonal element and $W_i$ is an $n_i \times n_i$ diagonal matrix with $w_{ij}$ as the $j$th diagonal where $w_{ij}$ is a weight specified with the WEIGHT statement. If there is no WEIGHT statement, $w_{ij} = 1$ for all $i$ and $j$. If $R_i(\alpha)$ is the true correlation matrix of $Y_i$, then $V_i$ is the true covariance matrix of $Y_i$.

The working correlation matrix is usually unknown and must be estimated. It is estimated in the iterative fitting process using the current value of the parameter vector $\beta$ to compute appropriate functions of the Pearson residual

$$e_{ij} = \frac{y_{ij} - \mu_{ij}}{\sqrt{v(\mu_{ij})/w_{ij}}}$$

If you specify the working correlation as $R_0 = I$, which is the identity matrix, the GEE reduces to the independence estimating equation.

Following are the structures of the working correlation supported by the GENMOD procedure and the estimators used to estimate the working correlations.
<table>
<thead>
<tr>
<th>Working Correlation Structure</th>
<th>Estimator</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Fixed</strong>&lt;br&gt;( \text{Corr}(Y_{ij}, Y_{ik}) = r_{jk} )&lt;br&gt;where ( r_{jk} ) is the ( jk )th element of a constant, user-specified correlation matrix ( R_0 ).</td>
<td>The working correlation is not estimated in this case.</td>
</tr>
<tr>
<td><strong>Independent</strong>&lt;br&gt;( \text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 &amp; j = k \ 0 &amp; j \neq k \end{cases} )</td>
<td>The working correlation is not estimated in this case.</td>
</tr>
</tbody>
</table>
| **\( m \)-dependent**<br>\( \text{Corr}(Y_{ij}, Y_{i,j+t}) = \begin{cases} 1 & t = 0 \\ \alpha_t & t = 1, 2, \ldots, m \\ 0 & t > m \end{cases} \) | \( \hat{\alpha}_t = \frac{1}{(K_t - p)\phi} \sum_{i=1}^{K} \sum_{j \leq n_i - t} e_{ij}e_{i,j+t} \)
\( K_t = \sum_{i=1}^{K} (n_i - t) \) |
| **Exchangeable**<br>\( \text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha & j \neq k \end{cases} \) | \( \hat{\alpha} = \frac{1}{(N^* - p)\phi} \sum_{i=1}^{K} \sum_{j<k} e_{ij}e_{ik} \)
\( N^* = .5 \sum_{i=1}^{K} n_i(n_i - 1) \) |
| **Unstructured**<br>\( \text{Corr}(Y_{ij}, Y_{ik}) = \begin{cases} 1 & j = k \\ \alpha_{jk} & j \neq k \end{cases} \) | \( \hat{\alpha}_{jk} = \frac{1}{(K - p)\phi} \sum_{i=1}^{K} e_{ij}e_{ik} \)
\( K_1 = \sum_{i=1}^{K} (n_i - 1) \) |
| **Autoregressive AR(1)**<br>\( \text{Corr}(Y_{ij}, Y_{i,j+t}) = \alpha^t \)<br>for \( t = 0, 1, 2, \ldots, n_i - j \) | \( \hat{\alpha} = \frac{1}{(K_1 - p)\phi} \sum_{i=1}^{K} \sum_{j \leq n_i - 1} e_{ij}e_{i,j+1} \)
\( K_1 = \sum_{i=1}^{K} (n_i - 1) \) |

**Dispersion Parameter**

The dispersion parameter \( \phi \) is estimated by

\[
\hat{\phi} = \frac{1}{N - p} \sum_{i=1}^{K} \sum_{j=1}^{n_i} e_{ij}^2
\]

where \( N = \sum_{i=1}^{K} n_i \) is the total number of measurements and \( p \) is the number of regression parameters.
The square root of \( \hat{\phi} \) is reported by PROC GENMOD as the scale parameter in the “Analysis of GEE Parameter Estimates Model-Based Standard Error Estimates” output table.

**Fitting Algorithm**

The following is an algorithm for fitting the specified model using GEEs. Note that this is not in general a likelihood-based method of estimation, so that inferences based on likelihoods are not possible for GEE methods.

1. Compute an initial estimate of \( \beta \) with an ordinary generalized linear model assuming independence.

2. Compute the working correlations \( R \) based on the standardized residuals, the current \( \beta \), and the assumed structure of \( R \).

3. Compute an estimate of the covariance:

\[
V_i = \phi A_i^{\frac{1}{2}} W_i^{-\frac{1}{2}} \hat{R}(\alpha) W_i^{-\frac{1}{2}} A_i^{\frac{1}{2}}
\]

4. Update \( \beta \):

\[
\beta_{r+1} = \beta_r + \left[ \sum_{i=1}^{K} \frac{\partial \mu_i'}{\partial \beta} V_i^{-1} \frac{\partial \mu_i}{\partial \beta} \right]^{-1} \left[ \sum_{i=1}^{K} \frac{\partial \mu_i'}{\partial \beta} V_i^{-1} (Y_i - \mu_i) \right]
\]

5. Iterate steps 2-4 until convergence

**Missing Data**

Refer to Diggle, Liang, and Zeger (1994, Chapter 11) for a discussion of missing values in longitudinal data. Suppose that you intend to take measurements \( Y_{i1}, \ldots, Y_{in} \) for the \( i \)th unit. Missing values for which \( Y_{ij} \) are missing whenever \( Y_{ik} \) is missing for all \( j \geq k \) are called *dropouts*. Otherwise, missing values that occur intermixed with nonmissing values are *intermittent* missing values. The GENMOD procedure can estimate the working correlation from data containing both types of missing values using the *all available pairs* method, in which all nonmissing pairs of data are used in the moment estimators of the working correlation parameters defined previously.

For example, for the unstructured working correlation model,

\[
\hat{\alpha}_{jk} = \frac{1}{(K' - p)\phi} \sum e_{ij} e_{ik}
\]

where the sum is over the units that have nonmissing measurements at times \( j \) and \( k \), and \( K' \) is the number of units with nonmissing measurements at \( j \) and \( k \). Estimates of the parameters for other working correlation types are computed in a similar manner, using available nonmissing pairs in the appropriate moment estimators.

The contribution of the \( i \)th unit to the parameter update equation is computed by omitting the elements of \( (Y_i - \mu_i) \), the columns of \( D_i' = \frac{\partial \mu_i'}{\partial \beta} \), and the rows and columns of \( V_i \) corresponding to missing measurements.
**Parameter Estimate Covariances**

The model-based estimator of Cov(\(\hat{\beta}\)) is given by

\[
\Sigma_m(\hat{\beta}) = \mathbf{I}_0^{-1}
\]

where

\[
\mathbf{I}_0 = \sum_{i=1}^{K} \frac{\partial \mu_i'}{\partial \beta} \mathbf{V}_i^{-1} \frac{\partial \mu_i}{\partial \beta}
\]

This is the GEE equivalent of the inverse of the Fisher information matrix that is often used in generalized linear models as an estimator of the covariance estimate of the maximum likelihood estimator of \(\beta\). It is a consistent estimator of the covariance matrix of \(\hat{\beta}\) if the mean model and the working correlation matrix are correctly specified.

The estimator

\[
\Sigma_e = \mathbf{I}_0^{-1} \mathbf{I}_1 \mathbf{I}_0^{-1}
\]

is called the empirical, or robust, estimator of the covariance matrix of \(\hat{\beta}\) where

\[
\mathbf{I}_1 = \sum_{i=1}^{K} \frac{\partial \mu_i'}{\partial \beta} \mathbf{V}_i^{-1} \text{Cov}(\mathbf{Y}_i) \mathbf{V}_i^{-1} \frac{\partial \mu_i}{\partial \beta}
\]

It has the property of being a consistent estimator of the covariance matrix of \(\hat{\beta}\), even if the working correlation matrix is misspecified, that is, if \(\text{Cov}(\mathbf{Y}_i) \neq \mathbf{V}_i\). In computing \(\mathbf{M}, \beta\) and \(\phi\) are replaced by estimates, and \(\text{Cov}(\mathbf{Y}_i)\) is replaced by the estimate

\[
(\mathbf{Y}_i - \mu_i(\hat{\beta}))(\mathbf{Y}_i - \mu_i(\hat{\beta}))'
\]

**Multinomial GEEs**

Lipsitz, Kim, and Zhao (1994) and Miller, Davis, and Landis (1993) describe how to extend GEEs to multinomial data. Currently, only the independent working correlation is available for multinomial models in PROC GENMOD.

**Alternating Logistic Regressions**

If the responses are binary (that is, they take only two values), then there is an alternative method to account for the association among the measurements. The Alternating Logistic Regressions (ALR) algorithm of Carey, Zeger, and Diggle (1993) models the association between pairs of responses with log odds ratios, instead of with correlations, as ordinary GEEs do.
For binary data, the correlation between the \( j \)th and \( k \)th response is, by definition,

\[
Corr(Y_{ij}, Y_{ik}) = \frac{\Pr(Y_{ij} = 1, Y_{ik} = 1) - \mu_{ij}\mu_{ik}}{\sqrt{\mu_{ij}(1 - \mu_{ij})\mu_{ik}(1 - \mu_{ik})}}
\]

The joint probability in the numerator satisfies the following bounds, by elementary properties of probability, since \( \mu_{ij} = \Pr(Y_{ij} = 1) \):

\[
\max(0, \mu_{ij} + \mu_{ik} - 1) \leq \Pr(Y_{ij} = 1, Y_{ik} = 1) \leq \min(\mu_{ij}, \mu_{ik})
\]

The correlation, therefore, is constrained to be within limits that depend in a complicated way on the means of the data.

The odds ratio, defined as

\[
OR(Y_{ij}, Y_{ik}) = \frac{\Pr(Y_{ij} = 1, Y_{ik} = 1) \Pr(Y_{ij} = 0, Y_{ik} = 0)}{\Pr(Y_{ij} = 1, Y_{ik} = 0) \Pr(Y_{ij} = 0, Y_{ik} = 1)}
\]

is not constrained by the means and is preferred, in some cases, to correlations for binary data.

The ALR algorithm seeks to model the logarithm of the odds ratio, \( \gamma_{ijk} = \log(OR(Y_{ij}, Y_{ik})) \), as

\[
\gamma_{ijk} = z'_{ijk}\alpha
\]

where \( \alpha \) is a \( q \times 1 \) vector of regression parameters and \( z_{ijk} \) is a fixed, specified vector of coefficients.

The parameter \( \gamma_{ijk} \) can take any value in \( (-\infty, \infty) \) with \( \gamma_{ijk} = 0 \) corresponding to no association.

The log odds ratio, when modeled in this way with a regression model, can take different values in subgroups defined by \( z_{ijk} \). For example, \( z_{ijk} \) can define subgroups within clusters, or it can define ‘block effects’ between clusters.

You specify a GEE model for binary data using log odds ratios by specifying a model for the mean, as in ordinary GEEs, and a model for the log odds ratios. You can use any of the link functions appropriate for binary data in the model for the mean, such as logistic, probit, or complementary log-log. The ALR algorithm alternates between a GEE step to update the model for the mean and a logistic regression step to update the log odds ratio model. Upon convergence, the ALR algorithm provides estimates of the regression parameters for the mean, \( \beta \), the regression parameters for the log odds ratios, \( \alpha \), their standard errors, and their covariances.
Specifying Log Odds Ratio Models

Specifying a regression model for the log odds ratio requires you to specify rows of the $z$-matrix $z_{ijk}$ for each cluster $i$ and each unique within-cluster pair $(j, k)$. The GENMOD procedure provides several methods of specifying $z_{ijk}$. These are controlled by the LOGOR=keyword and associated options in the REPEATED statement. The supported keywords and the resulting log odds ratio models are described as follows.

**EXCH** exchangeable log odds ratios. In this model, the log odds ratio is a constant for all clusters $i$ and pairs $(j, k)$. The parameter $\alpha$ is the common log odds ratio.

$$z_{ijk} = 1 \quad \text{for all } i, j, k$$

**FULLCLUST** fully parameterized clusters. Each cluster is parameterized in the same way, and there is a parameter for each unique pair within clusters. If a complete cluster is of size $n$, then there are $\frac{n(n-1)}{2}$ parameters in the vector $\alpha$. For example, if a full cluster is of size 4, then there are $\frac{4(4-1)}{2} = 6$ parameters, and the $z$-matrix is of the form

$$Z = \begin{bmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 \\
\end{bmatrix}$$

The elements of $\alpha$ correspond to log odds ratios for cluster pairs in the following order:

<table>
<thead>
<tr>
<th>Pair</th>
<th>Parameter</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1,2)</td>
<td>Alpha1</td>
</tr>
<tr>
<td>(1,3)</td>
<td>Alpha2</td>
</tr>
<tr>
<td>(1,4)</td>
<td>Alpha3</td>
</tr>
<tr>
<td>(2,3)</td>
<td>Alpha4</td>
</tr>
<tr>
<td>(2,4)</td>
<td>Alpha5</td>
</tr>
<tr>
<td>(3,4)</td>
<td>Alpha6</td>
</tr>
</tbody>
</table>

**LOGORVAR(variable)** log odds ratios by cluster. The argument variable is a variable name that defines the ‘block effects’ between clusters. The log odds ratios are constant within clusters, but they take a different value for each different value of the variable. For example, if Center is a variable in the input data set taking a different value for $k$ treatment centers, then specifying LOGOR=LOGORVAR(Center) requests a model with different log odds ratios for each of the $k$ centers, constant within center.
NESTK

$k$-nested log odds ratios. You must also specify the SUBCLUST=variable option to define subclusters within clusters. Within each cluster, PROC GENMOD computes a log odds ratio parameter for pairs having the same value of variable for both members of the pair and one log odds ratio parameter for each unique combination of different values of variable.

NEST1

1-nested log odds ratios. You must also specify the SUBCLUST=variable option to define subclusters within clusters. There are two log odds ratio parameters for this model. Pairs having the same value of variable correspond to one parameter; pairs having different values of variable correspond to the other parameter. For example, if clusters are hospitals and subclusters are wards within hospitals, then patients within the same ward have one log odds ratio parameter, and patients from different wards have the other parameter.

ZFULL

specifies the full z-matrix. You must also specify a SAS data set containing the z-matrix with the ZDATA=data-set-name option. Each observation in the data set corresponds to one row of the z-matrix. You must specify the ZDATA data set as if all clusters are complete, that is, as if all clusters are the same size and there are no missing observations. The ZDATA data set has $K[n_{max}(n_{max} - 1)/2]$ observations, where $K$ is the number of clusters and $n_{max}$ is the maximum cluster size. If the members of cluster $i$ are ordered as $1, 2, \cdots, n$, then the rows of the z-matrix must be specified for pairs in the order $(1, 2), (1, 3), \cdots, (1, n), (2, 3), \cdots, (2, n), \cdots, (n - 1, n)$. The variables specified in the REPEATED statement for the SUBJECT effect must also be present in the ZDATA= data set to identify clusters. You must specify variables in the data set that define the columns of the z-matrix by the ZROW=variable-list option. If there are $q$ columns, ($q$ variables in variable-list), then there are $q$ log odds ratio parameters. You can optionally specify variables indicating the cluster pairs corresponding to each row of the z-matrix with the YPAIR=(variable1, variable2) option. If you specify this option, the data from the ZDATA data set is sorted within each cluster by variable1 and variable2. See Example 31.6 for an example of specifying a full z-matrix.

ZREP

replicated z-matrix. You specify z-matrix data exactly as you do for the ZFULL case, except that you specify only one complete cluster. The z-matrix for the one cluster is replicated for each cluster. The number of observations in the ZDATA data set is $\frac{n_{max}(n_{max} - 1)}{2}$, where $n_{max}$ is the...
size of a complete cluster (a cluster with no missing observations). See Example 31.6 for an example of specifying a replicated z-matrix.

\[ \text{LOGOR} = \text{ZREP}( \begin{pmatrix} 1 & 2 \\ 1 & 3 \\ 1 & 4 \\ 2 & 3 \\ 2 & 4 \\ 3 & 4 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 1 & 0 \\ 1 & 0 \\ 1 & 1 \\ 1 & 1 \\ 1 & 1 \end{pmatrix} ) \]

specifies the \( \frac{q \times 3}{2} = 6 \) rows of the z-matrix for a cluster of size 4 with \( q = 2 \) log odds ratio parameters. The log odds ratio for pairs (1 2), (1 3), (1 4) is \( \alpha_1 \), and the log odds ratio for pairs (2 3), (2 4), (3 4) is \( \alpha_1 + \alpha_2 \).

### Generalized Score Statistics

Boos (1992) and Rotnitzky and Jewell (1990) describe score tests applicable to testing \( L\beta = 0 \) in GEEs, where \( L \) is a user-specified \( r \times p \) contrast matrix or a contrast for a Type 3 test of hypothesis.

Let \( \tilde{\beta} \) be the regression parameters resulting from solving the GEE under the restricted model \( L\beta = 0 \), and let \( S(\tilde{\beta}) \) be the generalized estimating equation values at \( \tilde{\beta} \).

The generalized score statistic is

\[ T = S(\tilde{\beta})' \Sigma_m L'(L \Sigma_e L')^{-1} L \Sigma_m S(\tilde{\beta}) \]

where \( \Sigma_m \) is the model-based covariance estimate and \( \Sigma_e \) is the empirical covariance estimate. The \( p \)-values for \( T \) are computed based on the chi-square distribution with \( r \) degrees of freedom.

### Assessment of Models Based on Aggregates of Residuals (Experimental)

Lin, Wei, and Ying (2002) present graphical and numerical methods for model assessment based on the cumulative sums of residuals over certain coordinates (e.g., covariates or linear predictors) or some related aggregates of residuals. The distributions of these stochastic processes under the assumed model can be approximated by the distributions of certain zero-mean Gaussian processes whose realizations can be...
generated by simulation. Each observed residual pattern can then be compared, both graphically and numerically, with a number of realizations from the null distribution. Such comparisons enable you to assess objectively whether the observed residual pattern reflects anything beyond random fluctuation. These procedures are useful in determining appropriate functional forms of covariates and link function. You use the ASSESS|ASSESSMENT statement to perform this kind of model-checking with cumulative sums of residuals, moving sums of residuals, or LOWESS smoothed residuals. See Example 31.8 and Example 31.9 for examples of model assessment.

Let the model for the mean be

$$g(\mu_i) = x_i' \beta$$

where $\mu_i$ is the mean of the response $y_i$ and $x_i$ is the vector of covariates for the $i^{th}$ observation. Denote the raw residual resulting from fitting the model as

$$e_i = y_i - \hat{\mu}_i$$

and let $x_{ij}$ be the value of the $j^{th}$ covariate in the model for observation $i$. Then to check the functional form of the $j^{th}$ covariate, consider the cumulative sum of residuals with respect to $x_{ij}$

$$W_j(x) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} I(x_{ij} \leq x) e_i$$

where $I()$ is the indicator function. For any $x$, $W_j(x)$ is the sum of the residuals with values of $x_j$ less than or equal to $x$. Denote the score, or gradient vector by

$$U(\beta) = \sum_{i=1}^{n} h(x_i' \beta) x_i (y_i - \nu(x_i' \beta))$$

where $\nu(r) = g^{-1}(r)$, and

$$h(r) = \frac{1}{g'(\nu(r))V(\nu(r))}$$

Let $J$ be the Fisher information matrix

$$J(\beta) = -\frac{\partial U(\beta)}{\partial \beta'}$$

Define

$$\hat{W}_j(x) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \left[ I(x_{ij} \leq x) + \eta'(x; \hat{\beta}) J^{-1}(\hat{\beta}) x_i h(x_i' \hat{\beta}) \right] e_i Z_i$$
where
\[ \eta(x; \beta) = - \sum_{i=1}^{n} I(x_{ij} \leq x) \frac{\partial \nu(x_i' \beta)}{\partial \beta} \]

and \( Z_i \) are independent \( N(0, 1) \) random variables. Then the conditional distribution of \( \hat{W}_j(x) \), given \( (y_i, x_i), i = 1, \ldots, n \), under the null hypothesis \( H_0 \) that the model for the mean is correct, is the same asymptotically as \( n \to \infty \) as the unconditional distribution of \( W_j(x) \) (Lin, Wei, and Ying, 2002).

You can approximate realizations from the null hypothesis distribution of \( W_j(x) \) by repeatedly generating normal samples \( Z_i, i = 1, \ldots, n \) while holding \( (y_i, x_i), i = 1, \ldots, n \) at their observed values and computing \( \hat{W}_j(x) \) for each sample.

You can assess the functional form of covariate \( j \) by plotting a few realizations of \( \hat{W}_j(x) \) on the same plot as the observed \( W_j(x) \) and visually comparing to see how typical the observed \( W_j(x) \) is of the null distribution samples.

You can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let \( s_j \) be the observed value of \( S_j = \sup_x |W_j(x)| \). The \( p \)-value \( \Pr[S_j \geq s_j] \) is approximated by \( \Pr[\hat{S}_j \geq s_j] \), where \( \hat{S}_j = \sup_x |\hat{W}_j(x)| \). \( \Pr[\hat{S}_j \geq s_j] \) is estimated by generating realizations of \( \hat{W}_j(x) \) (1,000 is the default number of realizations).

You can check the link function instead of the \( j \)th covariate by using values of the linear predictor \( x_i' \beta \) in place of values of the \( j \)th covariate \( x_{ij} \). The graphical and numerical methods described above are then sensitive to inadequacies in the link function.

An alternative aggregate of residuals is the moving sum statistic
\[ W_j(x, b) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} I(x - b \leq x_{ij} \leq x) e_i \]

If you specify the keyword WINDOW(\( b \)), then the moving sum statistic with window size \( b \) is used instead of the cumulative sum of residuals, with \( I(x - b \leq x_{ij} \leq x) \) replacing \( I(x_{ij} \leq x) \) above.

If you specify the keyword LOWESS(\( f \)), LOWESS smoothed residuals are used in the formulas above, where \( f \) is the fraction of the data to be used at a given point. If \( f \) is not specified, \( f = \frac{1}{3} \) is used. Define, for data \( (Y_i, X_i), i = 1, \ldots, n \), \( r \) as the nearest integer to \( nf \) and \( h \) as the \( r \)th smallest among \( |X_i - x|, i = 1, \ldots, n \). Let
\[ K_i(x) = K\left( \frac{X_i - x}{h} \right) \]

where
\[ K(t) = \frac{70}{81}(1 - |t|^3)^3 I(-1 \leq t \leq 1) \]
Define
\[ w_i(x) = K_i(x)[S_2(x) - (X_i - x)S_1(x)] \]

where
\[ S_1(x) = \sum_{i=1}^{n} K_i(x)(X_i - x) \]
\[ S_2(x) = \sum_{i=1}^{n} K_i(x)(X_i - x)^2 \]

Then the LOWESS estimate of \( Y \) at \( x \) is defined by
\[ \hat{Y}(x) = \frac{1}{n} \sum_{i=1}^{n} w_i(x) \sum_{i=1}^{n} w_i(x) Y_i \]

LOWESS smoothed residuals for checking the functional form of the \( j \)th covariate are defined by replacing \( Y_i \) with \( e_i \) and \( X_i \) with \( x_{ij} \). To implement the graphical and numerical assessment methods, \( I(x_{ij} \leq x) \) is replaced with \( \frac{w_i(x)}{\sum_{i=1}^{n} w_i(x)} \) in the formulas for \( W_j(x) \) and \( \hat{W}_j(x) \).

You can perform the model checking described above for marginal models for dependent responses fit by generalized estimating equations (GEEs). Let \( y_{ik} \) denote the \( k \)th measurement on the \( i \)th cluster, \( i = 1, \ldots, K, k = 1, \ldots, n_i \), and \( x_{ik} \) the corresponding vector of covariates. The marginal mean of the response \( \mu_{ik} = E(y_{ik}) \) is assumed to depend on the covariate vector by
\[ g(\mu_{ik}) = x_{ik}'\beta \]

where \( g \) is the link function.

Define the vector of residuals for the \( i \)th cluster as
\[ e_i = (e_{i1}, \ldots, e_{in_i})' = (y_{i1} - \hat{\mu}_{i1}, \ldots, y_{in_i} - \hat{\mu}_{in_i})' \]

You use the following extension of \( W_j(x) \) defined above to check the functional form of the \( j \)th covariate:
\[ W_j(x) = \frac{1}{\sqrt{K}} \sum_{i=1}^{K} \sum_{k=1}^{n_i} I(x_{ikj} \leq x)e_{ik} \]

where \( x_{ikj} \) is the \( j \)th component of \( x_{ik} \).
The null distribution of $W_j(x)$ can be approximated by the conditional distribution of

$$\tilde{W}_j(x) = \frac{1}{\sqrt{K}} \sum_{i=1}^{K} \left\{ \sum_{k=1}^{n_i} I(x_{ikj} \leq x) e_{ik} + \eta'(x, \hat{\beta}) I_0^{-1} \hat{D}_i' \hat{V}_i^{-1} e_i \right\} Z_i$$

where $\hat{D}_i$ and $\hat{V}_i$ are defined as in the section “Generalized Estimating Equations” on page 1672 with the unknown parameters replaced by their estimated values,

$$\eta(x, \beta) = - \sum_{i=1}^{K} \sum_{k=1}^{n_i} I(x_{ikj} \leq x) \frac{\partial \mu_{ik}}{\partial \beta}$$

$$I_0 = \sum_{i=1}^{K} \hat{D}_i' \hat{V}_i^{-1} \hat{D}_i$$

and $Z_i, i = 1, \ldots, K$, are independent $N(0, 1)$ random variables. You replace $x_{ikj}$ with the linear predictor $x_{ikj}' \hat{\beta}$ in the preceding formulas to check the link function.

**Displayed Output**

The following output is produced by the GENMOD procedure. Note that some of the tables are optional and appear only in conjunction with the REPEATED statement and its options or with options in the MODEL statement. For details, see the section “ODS Table Names” on page 1693.

**Model Information**

PROC GENMOD displays the following model information:

- data set name
- response distribution
- link function
- response variable name
- offset variable name
- frequency variable name
- scale weight variable name
- number of observations used
- number of events if events/trials format is used for response
- number of trials if events/trials format is used for response
- sum of frequency weights
- number of missing values in data set
- number of invalid observations (for example, negative or 0 response values with gamma distribution or number of observations with events greater than trials with binomial distribution)
Class Level Information

If you use classification variables in the model, PROC GENMOD displays the levels of classification variables specified in the CLASS statement and in the MODEL statement. The levels are displayed in the same sorted order used to generate columns in the design matrix.

Response Profile

If you specify an ordinal model for the multinomial distribution, a table titled “Response Profile” is displayed containing the ordered values of the response variable and the number of occurrences of the values used in the model.

Iteration History for Parameter Estimates

If you specify the ITPRINT model option, PROC GENMOD displays a table containing the following for each iteration in the Newton-Raphson procedure for model fitting:

- iteration number
- ridge value
- log likelihood
- values of all parameters in the model

Criteria for Assessing Goodness of Fit

PROC GENMOD displays the following criteria for assessing goodness of fit:

- degrees of freedom for deviance and Pearson’s chi-square, equal to the number of observations minus the number of regression parameters estimated
- deviance
- deviance divided by degrees of freedom
- scaled deviance
- scaled deviance divided by degrees of freedom
- Pearson’s chi-square
- Pearson’s chi-square divided by degrees of freedom
- scaled Pearson’s chi-square
- scaled Pearson’s chi-square divided by degrees of freedom
- log likelihood

Last Evaluation of the Gradient

If you specify the model option ITPRINT, the GENMOD procedure displays the last evaluation of the gradient vector.
Last Evaluation of the Hessian

If you specify the model option ITPRINT, the GENMOD procedure displays the last evaluation of the Hessian matrix.

Analysis of (Initial) Parameter Estimates

The “Analysis of (Initial) Parameter Estimates” table contains the results from fitting a generalized linear model to the data. If you specify the REPEATED statement, these GLM parameter estimates are used as initial values for the GEE solution. For each parameter in the model, PROC GENMOD displays the following:

- the parameter name
  - the variable name for continuous regression variables
  - the variable name and level for classification variables and interactions involving classification variables
  - SCALE for the scale variable related to the dispersion parameter
- degrees of freedom for the parameter
- estimate value
- standard error
- Wald chi-square value
- $p$-value based on the chi-square distribution
- confidence limits (Wald or profile likelihood) for parameters

Estimated Covariance Matrix

If you specify the model option COVB, the GENMOD procedure displays the estimated covariance matrix, defined as the inverse of the information matrix at the final iteration. This is based on the expected information matrix if the EXPECTED option is specified in the MODEL statement. Otherwise, it is based on the Hessian matrix used at the final iteration. This is, by default, the observed Hessian unless altered by the SCORING option in the MODEL statement.

Estimated Correlation Matrix

If you specify the CORRB model option, PROC GENMOD displays the estimated correlation matrix. This is based on the expected information matrix if the EXPECTED option is specified in the MODEL statement. Otherwise, it is based on the Hessian matrix used at the final iteration. This is, by default, the observed Hessian unless altered by the SCORING option in the MODEL statement.

Iteration History for LR Confidence Intervals

If you specify the ITPRINT and LRCI model options, PROC GENMOD displays an iteration history table for profile likelihood-based confidence intervals. For each parameter in the model, PROC GENMOD displays the following:
listed Output • 1687

- parameter identification number
- iteration number
- log likelihood value
- parameter values

**Likelihood Ratio-Based Confidence Intervals for Parameters**

If you specify the LRCI and the ITPRINT options in the MODEL statement, a table is displayed summarizing profile likelihood-based confidence intervals for all parameters. The table contains the following for each parameter in the model:

- confidence coefficient
- parameter identification number
- lower and upper endpoints of confidence intervals for the parameter
- values of all other parameters at the solution

**LR Statistics for Type 1 Analysis**

If you specify the TYPE1 model option, a table containing the following is displayed for each effect in the model:

- name of effect
- deviance for the model including the effect and all previous effects
- degrees of freedom for the effect
- likelihood ratio statistic for testing the significance of the effect
- p-value computed from the chi-square distribution with effect degrees of freedom

If you specify either the SCALE=DEVIANECE or SCALE=PEARSON option in the MODEL statement, columns containing the following are displayed:

- name of effect
- deviance for the model including the effect and all previous effects
- numerator degrees of freedom
- denominator degrees of freedom
- chi-square statistic for testing the significance of the effect
- p-value computed from the chi-square distribution with numerator degrees of freedom
- F statistic for testing the significance of the effect
- p-value based on the F distribution
Iteration History for Type 3 Contrasts

If you specify the model options ITPRINT and TYPE3, an iteration history table is displayed for fitting the model with Type 3 contrast constraints for each effect. The table contains the following:

- effect name
- iteration number
- ridge value
- log likelihood
- values of all parameters

LR Statistics for Type 3 Analysis

If you specify the TYPE3 model option, a table containing the following is displayed for each effect in the model:

- name of the effect
- likelihood ratio statistic for testing the significance of the effect
- degrees of freedom for effect
- \( p \)-value computed from the chi-square distribution

If you specify either the SCALE=DEVIANCE or SCALE=PEARSON option in the MODEL statement, columns containing the following are displayed:

- name of the effect
- likelihood ratio statistic for testing the significance of the effect
- \( F \) statistic for testing the significance of the effect
- numerator degrees of freedom
- denominator degrees of freedom
- \( p \)-value based on the \( F \) distribution
- \( p \)-value computed from the chi-square distribution with numerator degrees of freedom

Wald Statistics for Type 3 Analysis

If you specify the TYPE3 and WALD model options, a table containing the following is displayed for each effect in the model:

- name of effect
- degrees of freedom for effect
- Wald statistic for testing the significance of the effect
- \( p \)-value computed from the chi-square distribution
**Parameter Information**

If you specify the ITPRINT, COVB, CORRB, WALDCI, or LRCI option in the MODEL statement, or if you specify a CONTRAST statement, a table is displayed that identifies parameters with numbers, rather than names, for use in tables and matrices where a compact identifier for parameters is helpful. For each parameter, the table contains the following:

- a number that identifies the parameter
- the parameter name, including level information for effects containing classification variables

**Observation Statistics**

If you specify the OBSTATS option in the MODEL statement, PROC GENMOD displays a table containing miscellaneous statistics. For each observation in the input data set, the following are displayed:

- the value of the response variable, denoted by the variable name
- the predicted value of the mean, denoted by PRED
- the value of the linear predictor, denoted by XBETA. The value of an OFFSET variable is added to the linear predictor.
- the estimated standard error of the linear predictor, denoted by STD
- the value of the negative of the weight in the Hessian matrix at the final iteration, denoted by HESSWGT. This is the expected weight if the EXPECTED option is specified in the MODEL statement. Otherwise, it is the weight used in the final iteration. That is, it is the observed weight unless the SCORING= option has been specified.
- approximate lower and upper endpoints for a confidence interval for the predicted value of the mean, denoted by LOWER and UPPER
- raw residual, denoted by RESRAW
- Pearson residual, denoted by RESCHI
- deviance residual, denoted by RESDEV
- standardized Pearson residual, denoted by STDRESCHI
- standardized deviance residual, denoted by STDRESDEV
- likelihood residual, denoted by RESLIK

**ESTIMATE Statement Results**

If you specify a REPEATED statement, the ESTIMATE statement results apply to the specified GEE model. Otherwise, they apply to the specified generalized linear model.

The following are displayed for each ESTIMATE statement:
Chapter 31. The GENMOD Procedure

- contrast label
- estimated value of the contrast
- standard error of the estimate
- significance level $\alpha$
- $(1 - \alpha) \times 100\%$ confidence intervals for contrast
- Wald chi-square statistic for the contrast
- $p$-value computed from the chi-square distribution

If you specify the EXP option, an additional row is displayed with statistics for the exponentiated value of the contrast.

**CONTRAST Coefficients**

If you specify the CONTRAST or ESTIMATE statement and you specify the E option, a table titled “Coefficients For Contrast label” is displayed, where label is the label specified in the CONTRAST statement. The table contains the following:

- the contrast label
- the rows of the contrast matrix

**Iteration History for Contrasts**

If you specify the ITPRINT option, an iteration history table is displayed for fitting the model with contrast constraints for each effect. The table contains the following for each contrast defined in a CONTRAST statement:

- contrast label
- iteration number
- ridge value
- log likelihood
- values of all parameters

**CONTRAST Statement Results**

If you specify a REPEATED statement, the CONTRAST statement results apply to the specified GEE model. Otherwise, they apply to the specified generalized linear model.

The following are displayed for each CONTRAST statement:

- contrast label
- degrees of freedom for the contrast
- likelihood ratio, score, or Wald statistic for testing the significance of the contrast. Score statistics are used in GEE models, likelihood ratio statistics are used in generalized linear models, and Wald statistics are used in both.
• \( p \)-value computed from the chi-square distribution
• the type of statistic computed for this contrast: Wald, LR, or score

If you specify either the SCALE=DEViance or SCALE=PEARson option for generalized linear models, columns containing the following are displayed:

• contrast label
• likelihood ratio statistic for testing the significance of the contrast
• \( F \) statistic for testing the significance of the contrast
• numerator degrees of freedom
• denominator degrees of freedom
• \( p \)-value based on the \( F \) distribution
• \( p \)-value computed from the chi-square distribution with numerator degrees of freedom

**LSMEANS Coefficients**

If you specify the LSMEANS statement and you specify the E option, a table titled “Coefficients for effect Least Squares Means” is displayed, where effect is the effect specified in the LSMEANS statement. The table contains the following:

• the effect names
• the rows of least squares means coefficients

**Least Squares Means**

If you specify the LSMEANS statement a table titled “Least Squares Means” is displayed. The table contains the following:

• the effect names
• for each level of each effect,
  – the least squares mean estimate
  – standard error
  – chi-square value
  – \( p \)-value computed from the chi-square distribution

If you specify the DIFF option, a table titled “Differences of Least Squares Means” is displayed containing corresponding statistics for the differences between the least squares means for the levels of each effect.
**GEE Model Information**

If you specify the `REPEATED` statement, the following are displayed:

- correlation structure of the working correlation matrix or the log odds ratio structure
- within-subject effect
- subject effect
- number of clusters
- correlation matrix dimension
- minimum and maximum cluster size

**Log Odds Ratio Parameter Information**

If you specify the `REPEATED` statement and specify a log odds ratio model for binary data with the `LOGOR=` option, then a table is displayed showing the correspondence between data pairs and log odds ratio model parameters.

**Iteration History for GEE Parameter Estimates**

If you specify the `REPEATED` statement and the `MODEL` statement option `ITPRINT`, an iteration history table for GEE parameter estimates is displayed. The table contains the following:

- parameter identification number
- iteration number
- values of all parameters

**Last Evaluation of the Generalized Gradient and Hessian**

If you specify the `REPEATED` statement and select `ITPRINT` as a model option, PROC GENMOD displays the last generalized gradient and Hessian matrix in the GEE iterative parameter estimation process.

**GEE Parameter Estimate Covariance Matrices**

If you specify the `REPEATED` statement and the `COVB` option, PROC GENMOD displays both model-based and empirical parameter estimate covariance matrices.

**GEE Parameter Estimate Correlation Matrices**

If you specify the `REPEATED` statement and the `CORRB` option, PROC GENMOD displays both model-based and empirical parameter estimate covariance matrices.
**GEE Working Correlation Matrix**

If you specify the REPEATED statement and the CORRW option, PROC GENMOD displays the exchangeable working correlation matrix.

**Analysis of GEE Parameter Estimates**

If you specify the REPEATED statement, PROC GENMOD uses empirical standard error estimates to compute and display the following for each parameter in the model:

- the parameter name
  - the variable name for continuous regression variables
  - the variable name and level for classification variables and interactions involving classification variables
  - “Scale” for the scale variable related to the dispersion parameter
- parameter estimate
- standard error
- 95% confidence interval
- $Z$ score and $p$-value

If you specify the MODELSE option in the REPEATED statement, a table based on model-based standard errors is also produced.

**GEE Observation Statistics**

If you specify the OBSTATS option in the REPEATED statement, PROC GENMOD displays a table containing miscellaneous statistics. For each observation in the input data set, the following are displayed:

- the value of the response variable and all other variables in the model, denoted by the variable names
- the predicted value of the mean, denoted by PRED
- the value of the linear predictor, denoted by XBETA
- the standard error of the linear predictor, denoted by STD
- confidence limits for the predicted values, denoted by LOWER and UPPER
- raw residual, denoted by RESRAW
- Pearson residual, denoted by RESCHI

**ODS Table Names**

PROC GENMOD assigns a name to each table that it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”
### Table 31.3. ODS Tables Produced in PROC GENMOD

This section describes the use of ODS for creating statistical graphs with the GENMOD procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the ASSESS statement and options. For more information on the ASSESS statement, see the “ASSESS Statement” section on page 1627. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”
**ODS Graph Names**

PROC GENMOD assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 31.4.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 31.4.

**Examples**

The following examples illustrate some of the capabilities of the GENMOD procedure. These are not intended to represent definitive analyses of the data sets presented here. You should refer to the texts cited in the “References” section on page 1728 for guidance on complete analysis of data using generalized linear models.

**Example 31.1. Logistic Regression**

In an experiment comparing the effects of five different drugs, each drug is tested on a number of different subjects. The outcome of each experiment is the presence or absence of a positive response in a subject. The following artificial data represent the number of responses \( r \) in the \( n \) subjects for the five different drugs, labeled A through E. The response is measured for different levels of a continuous covariate \( x \) for each drug. The drug type and the continuous covariate \( x \) are explanatory variables in this experiment. The number of responses \( r \) is modeled as a binomial random variable for each combination of the explanatory variable values, with the binomial number of trials parameter equal to the number of subjects \( n \) and the binomial probability equal to the probability of a response.

The following DATA step creates the data set.

```plaintext
data drug;
  input drug$ x r n @@;
datalines;
  A .1 10 A .23 2 1 9
  B .2 3 13 B .3 4 15 B .45 5 16 B .78 5 13
  C .04 0 10 C .15 0 11 C .56 1 12 C .7 2 12
  D .34 5 10 D .6 5 9 D .7 8 10
  E .2 12 20 E .34 15 20 E .56 13 15 E .8 17 20
;
run;
```
A logistic regression for these data is a generalized linear model with response equal to the binomial proportion \( r/n \). The probability distribution is binomial, and the link function is logit. For these data, \( \text{drug} \) and \( x \) are explanatory variables. The probit and the complementary log-log link functions are also appropriate for binomial data.

PROC GENMOD performs a logistic regression on the data in the following SAS statements:

```sas
proc genmod data=drug;
   class drug;
   model r/n = x drug / dist = bin
                      link = logit
       lrci;
run;
```

Since these data are binomial, you use the `events/trials` syntax to specify the response in the MODEL statement. Profile likelihood confidence intervals for the regression parameters are computed using the LRCI option.

General model and data information is produced in Output 31.1.1.

**Output 31.1.1.** Model Information

```
The GENMOD Procedure

Model Information

Data Set WORK.DRUG
Distribution Binomial
Link Function Logit
Response Variable (Events) r
Response Variable (Trials) n
```

The five levels of the CLASS variable DRUG are displayed in Output 31.1.2.

**Output 31.1.2.** Class Variable Levels

```
Class Level Information

Class  Levels  Values
  drug   5     A B C D E
```

In the “Criteria For Assessing Goodness Of Fit” table displayed in Output 31.1.3, the value of the deviance divided by its degrees of freedom is less than 1. A \( p \)-value is not computed for the deviance; however, a deviance that is approximately equal to its degrees of freedom is a possible indication of a good model fit. Asymptotic distribution theory applies to binomial data as the number of binomial trials parameter \( n \) becomes large for each combination of explanatory variables. McCullagh and
Nelder (1989) caution against the use of the deviance alone to assess model fit. The model fit for each observation should be assessed by examination of residuals. The OBSTATS option in the MODEL statement produces a table of residuals and other useful statistics for each observation.

**Output 31.1.3. Goodness of Fit Criteria**

In the “Analysis Of Parameter Estimates” table displayed in **Output 31.1.4**, chi-square values for the explanatory variables indicate that the parameter values other than the intercept term are all significant. The scale parameter is set to 1 for the binomial distribution. When you perform an overdispersion analysis, the value of the overdispersion parameter is indicated here. See the the section “Overdispersion” on page 1659 for a discussion of overdispersion.

</tr>
</tbody>
</table>

**NOTE:** The scale parameter was held fixed.

The preceding table contains the profile likelihood confidence intervals for the explanatory variable parameters requested with the LRCI option. Wald confidence intervals are displayed by default. Profile likelihood confidence intervals are considered to be more accurate than Wald intervals (refer to Aitkin et al. 1989), especially with small sample sizes. You can specify the confidence coefficient with the ALPHA= option in the MODEL statement. The default value of 0.05, corresponding to 95% confidence limits, is used here. See the section “Confidence Intervals for Parameters” on page 1666 for a discussion of profile likelihood confidence intervals.
Example 31.2. Normal Regression, Log Link

Consider the following data, where $x$ is an explanatory variable, and $y$ is the response variable. It appears that $y$ varies nonlinearly with $x$ and that the variance is approximately constant. A normal distribution with a log link function is chosen to model these data; that is, $\log(\mu_i) = x_i'\beta$ so that $\mu_i = \exp(x_i'\beta)$.

```sas
data nor;
  input x y;
datalines;
  0 5
  0 7
  0 9
  1 7
  1 10
  1 8
  2 11
  2 9
  3 16
  3 13
  3 14
  4 25
  4 24
  5 34
  5 32
  5 30
;
run;
```

The following SAS statements produce the analysis with the normal distribution and log link:

```sas
proc genmod data=nor;
  model y = x / dist = normal link = log;
  output out = Residuals
    pred = Pred
    resraw = Resraw
    reschi = Reschi
    resdev = Resdev
    stdreschi = Stdreschi
    stdresdev = Stdresdev
    reslik = Reslik;
run;
```

The OUTPUT statement is specified to produce a data set that contains predicted values and residuals for each observation. This data set can be useful for further analysis, such as residual plotting.

The output from these statements is displayed in Output 31.2.1.

The data set of predicted values and residuals (Output 31.2.2) is created by the OUTPUT statement. With this data set, you can construct residual plots using the GPLOT procedure to aid in assessing model fit. Note that raw, Pearson, and deviance residuals are equal in this example. This is a characteristic of the normal distribution and is not true in general for other distributions.

Example 31.3. Gamma Distribution Applied to Life Data

Life data are sometimes modeled with the gamma distribution. Although PROC GENMOD does not analyze censored data or provide other useful lifetime distributions such as the Weibull or lognormal, it can be used for modeling complete (uncensored) data with the gamma distribution, and it can provide a statistical test for the exponential distribution against other gamma distribution alternatives. Refer to Lawless (1982) or Nelson (1982) for applications of the gamma distribution to life data.

The following data represent failure times of machine parts, some of which are manufactured by manufacturer A and some by manufacturer B.

data A;
  input lifetime@@;
mfg = ‘A’;
datalines;
  620 470 260 89 388 242
  103 100 39 460 284 1285
  218 393 106 158 152 477
  403 103 69 158 818 947
  399 1274 32 12 134 660
  548 381 203 871 193 531
  317 85 1410 250 41 1101
  32 421 32 343 376 1512
  1792 47 95 76 515 72
The following SAS statements use PROC GENMOD to compute Type 3 statistics to test for differences between the two manufacturers in machine part life. Type 3 statistics are identical to Type 1 statistics in this case, since there is only one effect in the model. The log link function is selected to ensure that the mean is positive.

```sas
proc genmod data = lifdat;
  class mfg;
  model lifetime = mfg / dist=gamma
    link=log
    type3;
run;
```

The output from these statements is displayed in Output 31.3.1.

</tr>
</tbody>
</table>

**NOTE:** The scale parameter was estimated by maximum likelihood.

Интерпет — это оцененный логарифм среднего значения распределения гамма, поэтому средняя длительность работы составляет

\[
\mu = \exp(\text{INTERCEPT}) = \exp(6.1391) = 463.64
\]

Значение SCALE параметра в процедуре GENMOD является инверсией параметра дисперсии гамма-распределения, и его иногда называют параметром индекса гамма. См. раздел "Распределение вероятности ответов" на странице 1650 для определения гамма-распределения плотности вероятности. Значение 1 для индекса параметра соответствует экспоненциальному распределению. Оцененное значение параметра дисперсии составляет 0.8274. Интервал доверительной вероятности по профилю площади для параметра дисперсии составляет (0.6959, 0.9762), который не содержит 1. Гипотеза о распределении экспоненциальной для данных отвергается на уровне 0.05. Доверительный интервал для средней длительности составляет

\[
(\exp(5.99), \exp(6.30)) = (399.57, 542.18)
\]

### Example 31.4. Ordinal Model for Multinomial Data

Этот пример иллюстрирует, как можно использовать процедуру GENMOD, чтобы построить модель на данных, измеренных на порядковой шкале. Следующие строки создают SAS-датасет с именем icecream. Данный датасет содержит результаты гипотетического теста вкуса трех брендов мороженого. Три бренды оцениваются по пятибалльной шкале от очень хороший (vg) до очень плохо (vb). Анализ выполняется, чтобы оценить различия в оценках для этих трех брендов. Приведенное значение в переменной taste содержит оценки, а переменная brand содержит бренды, которые тестировали. Параметр count содержит количество тестеров, оценивших каждый бренд в каждой категории.

Следующие строки создают датасет icecream.
The following statements fit a cumulative logit model to the ordinal data with the variable taste as the response and the variable brand as a covariate. The variable count is used as a FREQ variable.

```plaintext
proc genmod rorder=data;
  freq count;
  class brand;
  model taste = brand / dist=multinomial
                   link=cumlogit
                   aggregate=brand
                   type1;

  estimate 'LogOR12' brand 1 -1 / exp;
  estimate 'LogOR13' brand 1 0 -1 / exp;
  estimate 'LogOR23' brand 0 1 -1 / exp;
run;
```

The AGGREGATE=BRAND option in the MODEL statement specifies the variable brand as defining multinomial populations for computing deviances and Pearson chi-squares. The RORDER=DATA option specifies that the taste variable levels be ordered by their order of appearance in the input data set, that is, from very good (vg) to very bad (vb). By default, the response is sorted in increasing ASCII order. Always check the “Response Profiles” table to verify that response levels are appropriately ordered. The TYPE1 option requests a Type 1 test for the significance of the covariate brand.

If \( \gamma_j(x) = \Pr(\text{taste} \leq j) \) is the cumulative probability of the \( j \)th or lower taste category, then the odds ratio comparing \( x_1 \) to \( x_2 \) is as follows:

\[
\frac{\gamma_j(x_1)/(1 - \gamma_j(x_1))}{\gamma_j(x_2)/(1 - \gamma_j(x_2))} = \exp[(x_1 - x_2)'\beta]
\]
Refer to McCullagh and Nelder (1989, Chapter 5) for details on the cumulative logit model. The ESTIMATE statements compute log odds ratios comparing each of brands. The EXP option in the ESTIMATE statements exponentiates the log odds ratios to form odds ratio estimates. Standard errors and confidence intervals are also computed.

Output 31.4.1 displays general information about the model and data, the levels of the CLASS variable brand, and the total number of occurrences of the ordered levels of the response variable taste.

Output 31.4.2 displays estimates of the intercept terms and covariates and associated statistics. The intercept terms correspond to the four cumulative logits defined on the taste categories in the order shown in Output 31.4.1. That is, Intercept1 is the intercept for the first cumulative logit, \( \log \left( \frac{p_1}{1-p_1} \right) \), Intercept2 is the intercept for the second cumulative logit \( \log \left( \frac{p_1+p_2}{1-(p_1+p_2)} \right) \), and so forth.

**NOTE:** The scale parameter was held fixed.

The Type 1 test displayed in Output 31.4.3 indicates that Brand is highly significant; that is, there are significant differences in the brands. The log odds ratios and odds ratios in the “ESTIMATE Statement Results” table indicate the relative differences between the brands. For example, the odds ratio of 2.8 in the “Exp(LogOR12)” row indicates that the odds of brand 1 being in lower taste categories is 2.8 times the odds of brand 2 being in lower taste categories. Since, in this ordering, the lower categories represent the more favorable taste results, this indicates that brand 1 scored significantly better than brand 2. This is also apparent from the data in this example.

Example 31.5. GEE for Binary Data with Logit Link Function

Table 31.5 displays a partial listing of a SAS data set of clinical trial data comparing two treatments for a respiratory disorder. See “Gee Model for Binary Data” in the SAS/STAT Sample Program Library for the complete data set. These data are from Stokes, Davis, and Koch (1995), where a SAS macro is used to fit a GEE model. A GEE model is fit, using the REPEATED statement in the GENMOD procedure.

Table 31.5. Respiratory Disorder Data

Patients in each of two centers are randomly assigned to groups receiving the active treatment or a placebo. During treatment, respiratory status (coded here as 0=poor, 1=good) is determined for each of four visits. The variables center, treatment, sex, and baseline (baseline respiratory status) are classification variables with two levels. The variable age (age at time of entry into the study) is a continuous variable.

Explanatory variables in the model are intercept \((x_{ij1})\), treatment \((x_{ij2})\), center \((x_{ij3})\), sex \((x_{ij4})\), age \((x_{ij6})\), and baseline \((x_{ij6})\), so that \(x'_{ij} = [x_{ij1}, x_{ij2}, \ldots, x_{ij6}]\) is the vector of explanatory variables. Indicator variables for the classification explanatory variables can be automatically generated by listing them in the CLASS statement in PROC GENMOD. However, in order to be consistent with the analysis in Stokes, Davis, and Koch (1995), the four classification explanatory variables are coded as follows:

\[
\begin{align*}
  x_{ij2} & = \begin{cases} 
  0 & \text{placebo} \\
  1 & \text{active} 
  \end{cases} \\
  x_{ij3} & = \begin{cases} 
  0 & \text{center 1} \\
  1 & \text{center 2} 
  \end{cases} \\
  x_{ij4} & = \begin{cases} 
  0 & \text{male} \\
  1 & \text{female} 
  \end{cases} \\
  x_{ij6} & = \begin{cases} 
  0 & \text{poor} \\
  1 & \text{good} 
  \end{cases}
\end{align*}
\]
Suppose $y_{ij}$ represents the respiratory status of patient $i$ at the $j$th visit, $j = 1, \ldots, 4$, and $\mu_{ij} = E(y_{ij})$ represents the mean of the respiratory status. Since the response data are binary, you can use the variance function for the binomial distribution $v(\mu_{ij}) = \mu_{ij}(1 - \mu_{ij})$ and the logit link function $g(\mu_{ij}) = \log(\mu_{ij}/(1 - \mu_{ij}))$. The model for the mean is $g(\mu_{ij}) = x_{ij}^T\beta$, where $\beta$ is a vector of regression parameters to be estimated.

Further manipulation of the data set creates an observation for each visit with the respiratory status at each visit represented by the binary variable `outcome` and indicator variables for treatment (active), center (center2), and sex (female). A partial listing of the resulting data set is shown in Output 31.5.1.

</tbody>
</table>

The GEE solution is requested with the REPEATED statement in the GENMOD procedure. The option SUBJECT=ID(CENTER) specifies that the observations in a single cluster are uniquely identified by `center` and `id` within `center`. The option TYPE=UNSTR specifies the unstructured working correlation structure. The MODEL statement specifies the regression model for the mean with the binomial distribution variance function.

```
proc genmod data=resp descend;
  class id center;
  model outcome=center2 active female age baseline / dist=bin;
  repeated subject=id(center) / corr=unstr corrw;
run;
```

These statements first produce the usual output (not shown) for fitting the generalized linear (GLM) model specified in the MODEL statement. The parameter estimates from the GLM model are used as initial values for the GEE solution. The
DESCEND option in the PROC GENMOD statement specifies that the probability that outcome = 1 be modeled. If the DESCEND option had not been specified, the probability that outcome = 0 would be modeled by default.

Information about the GEE model is displayed in Output 31.5.2. The results of GEE model fitting are displayed in Output 31.5.3. If you specify no other options, the standard errors, confidence intervals, Z scores, and p-values are based on empirical standard error estimates. You can specify the MODELSE option in the REPEATED statement to create a table based on model-based standard error estimates.

The non-significance of age and female make them candidates for omission from the model.
Example 31.6. Log Odds Ratios and the ALR Algorithm

Since the respiratory data in Example 31.5 are binary, you can use the ALR algorithm to model the log odds ratios instead of using working correlations to model associations. Here, a "fully parameterized cluster" model for the log odds ratio is fit. That is, there is a log odds ratio parameter for each unique pair of responses within clusters, and all clusters are parameterized identically. The following statements fit the same regression model for the mean as in Example 31.5 but use a regression model for the log odds ratios instead of a working correlation. The LOGOR=FULLCLUST option specifies a fully parameterized log odds ratio model.

```plaintext
proc genmod data=resp descend;
class id center;
model outcome=center2 active female age baseline / dist=bin;
   repeated subject=id(center) / logor=fullclust;
run;
```

The results of fitting the model are displayed in Output 31.6.1 along with a table that shows the correspondence between the log odds ratio parameters and the within cluster pairs.

**Output 31.6.1.** Results of Model Fitting

| Parameter  | Group | Estimate | Standard Error | 95% Confidence Limits | Z  | Pr > | | |
|------------|-------|----------|----------------|-----------------------|----|-----|---|

You can fit the same model by fully specifying the $z$-matrix. The following statements create a data set containing the full $z$-matrix.

```sas
data zin;
  keep id center z1-z6 y1 y2;
  array zin(6) z1-z6;
  set resp ;
  by center id;
  if first.id
    then do;
      t = 0;
      do m = 1 to 4;
        do n = m+1 to 4;
          do j = 1 to 6;
            zin(j) = 0;
          end;
          y1 = m;
          y2 = n;
          t + 1;
          zin(t) = 1;
          output;
        end;
      end;
    end;
  end;
run;
```

```sas
proc print data=zin (obs=12);
```

Output 31.6.2 displays the full $z$-matrix for the first two clusters. The $z$-matrix is identical for all clusters in this example.

```

The following statements fit the model for fully parameterized clusters by fully specifying the $z$-matrix. The results are identical to those shown previously.
Example 31.7. Log-Linear Model for Count Data

These data, from Thall and Vail (1990), are concerned with the treatment of people suffering from epileptic seizure episodes. These data are also analyzed in Diggle, Liang, and Zeger (1994). The data consist of the number of epileptic seizures in an eight-week baseline period, before any treatment, and in each of four two-week treatment periods, in which patients received either a placebo or the drug Progabide in addition to other therapy. A portion of the data is displayed in Table 31.6. See “Gee Model for Count Data, Exchangeable Correlation” in the SAS/STAT Sample Program Library for the complete data set.

<table>

<td>0</td>
<td>4</td>
<td>3</td>
<td>0</td>
</tr>
</tbody>
</table>

Model the data as a log-linear model with $V(\mu) = \mu$ (the Poisson variance function) and

$$\log(E(Y_{ij})) = \beta_0 + x_{i1}\beta_1 + x_{i2}\beta_2 + x_{i1}x_{i2}\beta_3 + \log(t_{ij})$$

where

- $Y_{ij} =$ number of epileptic seizures in interval $j$
- $t_{ij} =$ length of interval $j$
Chapter 31. The GENMOD Procedure

\[ x_{i1} = \begin{cases} 1 : \text{weeks 8\textendash}16 \text{ (treatment)} \\
0 : \text{weeks 0\textendash}8 \text{ (baseline)} \end{cases} \]

\[ x_{i2} = \begin{cases} 1 : \text{progabide group} \\
0 : \text{placebo group} \end{cases} \]

The correlations between the counts are modeled as \( r_{ij} = \alpha, \ i \neq j \) (exchangeable correlations). For comparison, the correlations are also modeled as independent (identity correlation matrix). In this model, the regression parameters have the interpretation in terms of the log seizure rate displayed in Table 31.7.

<table>
<thead>
<tr>
<th>Treatment</th>
<th>Visit</th>
<th>( \log(E(Y_{ij})/t_{ij}) )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Placebo</td>
<td>Baseline 1-4</td>
<td>( \beta_0 )</td>
</tr>
<tr>
<td>Progabide</td>
<td>Baseline 1-4</td>
<td>( \beta_0 + \beta_1 )</td>
</tr>
</tbody>
</table>

The difference between the log seizure rates in the pretreatment (baseline) period and the treatment periods is \( \beta_1 \) for the placebo group and \( \beta_1 + \beta_3 \) for the Progabide group. A value of \( \beta_3 < 0 \) indicates a reduction in the seizure rate.

Output 31.7.1 is a listing of the first 14 observations of the data, which are arranged as one visit per observation:

</tbody>
</table>

Some further data manipulations create an observation for the baseline measures, a log time interval variable for use as an offset, and an indicator variable for whether the observation is for a baseline measurement or a visit measurement. Patient 207 is deleted as an outlier, as in the Diggle, Liang, and Zeger (1994) analysis.
The GEE solution is requested by using the REPEATED statement in the GENMOD procedure. The SUBJECT=ID option indicates that the id variable describes the observations for a single cluster, and the CORRW option displays the working correlation matrix. The TYPE= option specifies the correlation structure; the value EXCH indicates the exchangeable structure.

```
proc genmod data=new;
  class id;
  model y=x1 | trt / d=poisson offset=ltime;
  repeated subject=id / corrw covb type=exch;
run;
```

These statements first produce the usual output from fitting a generalized linear model (GLM) to these data. The estimates are used as initial values for the GEE solution. Information about the GEE model is displayed in Output 31.7.3. The results of fitting the model are displayed in Output 31.7.4. Compare these with the model of independence displayed in Output 31.7.2. The parameter estimates are nearly identical, but the standard errors for the independence case are underestimated. The coefficient of the interaction term, $\beta_3$, is highly significant under the independence model and marginally significant with the exchangeable correlations model.

</tbody>
</table>

If you specify the COVB option, you produce both the model-based (naive) and the empirical (robust) covariance matrices. Output 31.7.6 contains these estimates.
Output 31.7.6. Covariance Matrices

Covariance Matrix (Model-Based)

\[
\begin{array}{cccc}
\text{Prm1} & \text{Prm2} & \text{Prm3} & \text{Prm4} \\
\text{Prm1} & 0.01223 & 0.001520 & -0.01223 & -0.001520 \\
\text{Prm2} & 0.001520 & 0.01519 & -0.001520 & -0.01519 \\
\text{Prm3} & -0.01223 & -0.001520 & 0.02495 & 0.005427 \\
\text{Prm4} & -0.001520 & -0.01519 & 0.005427 & 0.03748 \\
\end{array}
\]

Covariance Matrix (Empirical)

\[
\begin{array}{cccc}
\text{Prm1} & \text{Prm2} & \text{Prm3} & \text{Prm4} \\
\text{Prm1} & 0.02476 & -0.001152 & -0.02476 & 0.001152 \\
\text{Prm2} & -0.001152 & 0.01348 & 0.001152 & -0.01348 \\
\text{Prm3} & -0.02476 & 0.001152 & 0.03751 & -0.002999 \\
\text{Prm4} & 0.001152 & -0.01348 & -0.002999 & 0.02931 \\
\end{array}
\]

The two covariance estimates are similar, indicating an adequate correlation model.

Example 31.8. Model Assessment of Multiple Regression Using Aggregates of Residuals (Experimental)

Neter et al. (1996, Section 8.2) describe a study of 54 patients undergoing a certain kind of liver operation in a surgical unit. The data consist of the survival time and certain covariates. After a model selection procedure, they arrived at the following model

\[ Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \epsilon \]

where \( Y \) is the logarithm (base 10) of the survival time, \( X_1, X_2, X_3 \) are blood-clotting score, prognostic index, and enzyme function, and \( \epsilon \) is a normal error term. A listing of the SAS data set containing the data is shown in Output 31.8.1. The variables \( Y, X_1, X_2, X_3 \) correspond to \( Y, X_1, X_2, X_3 \), and \( \text{LogX1} \) is \( \log(X_1) \). The GENMOD fit of the model is shown in Output 31.8.2. The analysis first focuses on the adequacy of the functional form of \( X_1 \), blood-clotting score.

</tr>
</tbody>
</table>

NOTE: The scale parameter was estimated by the square root of Pearson’s Chi-Square/DOF.

In order to assess the adequacy of the fitted multiple regression model, the ASSESS statement in the following SAS statements was used to create the plots of cumulative residuals against X1 shown in Output 31.8.3 and Output 31.8.4 and the summary table in Output 31.8.5. The RESAMPLE= keyword specifies that a p-value be computed based on a sample of 10,000 simulated residual paths. A random number seed is specified by the SEED= keyword for reproducibility. If you do not specify the seed, one is derived from the time of day. The keyword CRPANEL specifies that the panel of four cumulative residual plots shown in Output 31.8.4 be created, each with two simulated paths. The single residual plot with 20 simulated paths in Output 31.8.3 is created by default.

```sas
ods html;
ods graphics on;
proc genmod data=Surg;
  model Y = X1 X2 X3 / scale=Pearson;
  assess var=(X1) / resample=10000
           seed=603708000
           crpanel ;
run;
ods graphics off;
ods html close;
```

These graphical displays are requested by specifying the experimental ODS GRAPHICS statement and the experimental ASSESS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GENMOD procedure, see the “ODS Graphics” section on page 1695.
Output 31.8.3. Cumulative Residual Plot for Linear X1 Fit (Experimental)
Output 31.8.4. Cumulative Residual Panel Plot for Linear X1 Fit (Experimental)

Output 31.8.5. Summary of Model Assessment

<table>
<thead>
<tr>
<th>Assessment Variable</th>
<th>Maximum Absolute Value</th>

</thead>
<tbody>
<tr>
<td>X1</td>
<td>0.0380</td>
<td>10000</td>
<td>603708000</td>
<td>0.1084</td>
</tr>
</tbody>
</table>

The $p$-value of 0.1084 reported on Output 31.8.3 and Output 31.8.5 suggests that a more adequate model may be possible. The observed cumulative residuals on Output 31.8.3 and Output 31.8.4, represented by the heavy lines, seem atypical of the simulated curves, represented by the light lines, reinforcing the conclusion that a more appropriate functional form for X1 is possible.
The cumulative residual plots in Output 31.8.6 provide guidance in determining a more appropriate functional form. The four curves were created from simple forms of model misspecification using simulated data. The mean models of the data and the fitted model are shown in Table 31.9.

**Output 31.8.6.** Typical Cumulative Residual Patterns

![Cumulative Residual Patterns](image_url)

**Table 31.9.** Model Misspecifications

<table>
<thead>

</tr>
<tr>
<td>(c)</td>
<td>X + X^2 + X^3</td>
<td>X + X^2</td>
</tr>
<tr>
<td>(d)</td>
<td>I(X &gt; 5)</td>
<td>X</td>
</tr>
</tbody>
</table>

The observed cumulative residual pattern in Output 31.8.3 and Output 31.8.4 most resembles the behavior of the curve in plot (a) of Output 31.8.6, indicating that log(X₁) might be a more appropriate term in the model than X₁.

The following SAS statements fit a model with LogX1 in place of X1 and request a model assessment.
The revised model fit is shown in Output 31.8.7, the \( p \)-value from the simulation is 0.4777, and the cumulative residuals plotted on Output 31.8.8 show no systematic trend. The log-transformation for \( X_1 \) is more appropriate. Under the revised model, the \( p \)-values for testing the functional forms of \( X_2 \) and \( X_3 \) are 0.20 and 0.63, and the \( p \)-value for testing the linearity of the model is 0.65. Thus, the revised model seems reasonable.

Example 31.9. Assessment of a Marginal Model for Dependent Data Using Aggregates of Residuals (Experimental)

This example illustrates the use of cumulative residuals to assess the adequacy of a marginal model for dependent data fit by generalized estimating equations (GEEs). The assessment methods are applied to CD4 count data from an AIDS clinical trial reported by Fischl et al. (1990), and reanalyzed by Lin, Wei, and Ying (2002). The study randomly assigned 360 HIV patients to AZT and 351 to placebo. CD4 counts were measured repeatedly over the course of the study. The data used here are the 4328 measurements taken in the first 40 weeks of the study.

The analysis focuses on the time trend of the response. The first model considered is

\[ E(y_{ik}) = \beta_0 + \beta_1 T_{ik} + \beta_2 T_{ik}^2 + \beta_3 R_i T_{ik} + \beta_4 R_i T_{ik}^2 \]

where \( T_{ik} \) is the time (in weeks) of the \( k \)th measurement on the \( i \)th patient, \( y_{ik} \) is the CD4 count at \( T_{ik} \) for the \( i \)th patient, and \( R_i \) is the indicator of AZT for the \( i \)th patient. Normal errors and an independent working correlation are assumed.
The following SAS statements fit the preceding model, create the cumulative residual plot in Output 31.9.1, and compute a p-value for the model.

These graphical displays are requested by specifying the experimental ODS GRAPHICS statement and the experimental ASSESS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GENMOD procedure, see the “ODS Graphics” section on page 1695.

Here, the SAS data set variables Time, Time2, TrtTime, and TrtTime2 correspond to $T_{ik}$, $T_{ik}^2$, $R_i T_{ik}$, and $R_i T_{ik}^2$, respectively. The variable Id identifies individual patients.

```sas
ods html;
ods graphics on;

proc genmod data=cd4;
   class Id;
   model Y = Time Time2 TrtTime TrtTime2;
   repeated sub=Id;
   assess var=(Time) / resample
       seed=603708000;
run;

ods graphics off;
ods html close;
```
Output 31.9.1. Cumulative Residual Plot for Quadratic Time Fit (Experimental)

The cumulative residual plot in Output 31.9.1 displays cumulative residuals versus time for the model and 20 simulated realizations. The associated $p$-value, also shown on Output 31.9.1, is 0.18. These results indicate that a more satisfactory model might be possible. The observed cumulative residual pattern most resembles plot (c) in Output 31.8.6, suggesting cubic time trends.

The following SAS statements fit the model, create the plot in Output 31.9.2, and compute a $p$-value for a model with the additional terms $T_{ik}^3$ and $R_i T_{ik}^3$.

```sas
ods html;
ods graphics on;
proc genmod data=cd4;
   class Id;
   model Y = Time Time2 Time3 TrtTime TrtTime2 TrtTime3;
   repeated sub=Id;
   assess var=(Time) / resample
       seed=603708000;
run;
ods graphics off;
ods html close;
```
The observed cumulative residual pattern appears more typical of the simulated realizations, and the $p$-value is 0.45, indicating that the model with cubic time trends is more appropriate.

Chapter 32
The GLM Procedure

Overview

The GLM procedure uses the method of least squares to fit general linear models. Among the statistical methods available in PROC GLM are regression, analysis of variance, analysis of covariance, multivariate analysis of variance, and partial correlation.

PROC GLM analyzes data within the framework of General linear models. PROC GLM handles models relating one or several continuous dependent variables to one or several independent variables. The independent variables may be either classification variables, which divide the observations into discrete groups, or continuous variables. Thus, the GLM procedure can be used for many different analyses, including:

- simple regression
- multiple regression
- analysis of variance (ANOVA), especially for unbalanced data
- analysis of covariance
- response-surface models
- weighted regression
- polynomial regression
- partial correlation
- multivariate analysis of variance (MANOVA)
- repeated measures analysis of variance

PROC GLM Features

The following list summarizes the features in PROC GLM:

- PROC GLM enables you to specify any degree of interaction (crossed effects) and nested effects. It also provides for polynomial, continuous-by-class, and continuous-nesting-class effects.
- Through the concept of estimability, the GLM procedure can provide tests of hypotheses for the effects of a linear model regardless of the number of missing cells or the extent of confounding. PROC GLM displays the Sum of Squares (SS) associated with each hypothesis tested and, upon request, the form of the estimable functions employed in the test. PROC GLM can produce the general form of all estimable functions.
• The REPEATED statement enables you to specify effects in the model that represent repeated measurements on the same experimental unit for the same response, providing both univariate and multivariate tests of hypotheses.

• The RANDOM statement enables you to specify random effects in the model; expected mean squares are produced for each Type I, Type II, Type III, Type IV, and contrast mean square used in the analysis. Upon request, $F$ tests using appropriate mean squares or linear combinations of mean squares as error terms are performed.

• The ESTIMATE statement enables you to specify an $L$ vector for estimating a linear function of the parameters $L\beta$.

• The CONTRAST statement enables you to specify a contrast vector or matrix for testing the hypothesis that $L\beta = 0$. When specified, the contrasts are also incorporated into analyses using the MANOVA and REPEATED statements.

• The MANOVA statement enables you to specify both the hypothesis effects and the error effect to use for a multivariate analysis of variance.

• PROC GLM can create an output data set containing the input dataset in addition to predicted values, residuals, and other diagnostic measures.

• PROC GLM can be used interactively. After specifying and running a model, a variety of statements can be executed without recomputing the model parameters or sums of squares.

• For analysis involving multiple dependent variables but not the MANOVA or REPEATED statements, a missing value in one dependent variable does not eliminate the observation from the analysis for other dependent variables. PROC GLM automatically groups together those variables that have the same pattern of missing values within the data set or within a BY group. This ensures that the analysis for each dependent variable brings into use all possible observations.

• Experimental graphics are now available with the GLM procedure. For more information, see the “ODS Graphics” section on page 1846.

**PROC GLM Contrasted with Other SAS Procedures**

As described previously, PROC GLM can be used for many different analyses and has many special features not available in other SAS procedures. However, for some types of analyses, other procedures are available. As discussed in the “PROC GLM for Unbalanced ANOVA” and “PROC GLM for Quadratic Least Squares Regression” sections (beginning on page 1735), sometimes these other procedures are more efficient than PROC GLM. The following procedures perform some of the same analyses as PROC GLM:

- **ANOVA** performs analysis of variance for balanced designs. The ANOVA procedure is generally more efficient than PROC GLM for these designs.
PROC GLM for Unbalanced ANOVA

**MIXED**
fits mixed linear models by incorporating covariance structures in the model fitting process. Its RANDOM and REPEATED statements are similar to those in PROC GLM but offer different functionalities.

**NESTED**
performs analysis of variance and estimates variance components for nested random models. The NESTED procedure is generally more efficient than PROC GLM for these models.

**NPAR1WAY**
performs nonparametric one-way analysis of rank scores. This can also be done using the RANK procedure and PROC GLM.

**REG**
performs simple linear regression. The REG procedure allows several MODEL statements and gives additional regression diagnostics, especially for detection of collinearity. PROC REG also creates plots of model summary statistics and regression diagnostics.

**RSREG**
performs quadratic response-surface regression, and canonical and ridge analysis. The RSREG procedure is generally recommended for data from a response surface experiment.

**TTEST**
comparisons the means of two groups of observations. Also, tests for equality of variances for the two groups are available. The TTEST procedure is usually more efficient than PROC GLM for this type of data.

**VARCOMP**
estimates variance components for a general linear model.

---

**Getting Started**

**PROC GLM for Unbalanced ANOVA**

*Analysis of variance*, or ANOVA, typically refers to partitioning the variation in a variable’s values into variation between and within several groups or classes of observations. The GLM procedure can perform simple or complicated ANOVA for balanced or unbalanced data.

This example discusses a $2 \times 2$ ANOVA model. The experimental design is a full factorial, in which each level of one treatment factor occurs at each level of the other treatment factor. The data are shown in a table and then read into a SAS data set.

```
   A
  1  2
1 12 20
B
  14 18
2  11 17
```
title 'Analysis of Unbalanced 2-by-2 Factorial';
data exp;
  input A $ B $ Y @@;
datalines;

Note that there is only one value for the cell with A='A2' and B='B2'. Since one cell contains a different number of values from the other cells in the table, this is an unbalanced design.

The following PROC GLM invocation produces the analysis.

```sas
proc glm;
  class A B;
  model Y=A B A*B;
run;
```

Both treatments are listed in the CLASS statement because they are classification variables. A*B denotes the interaction of the A effect and the B effect. The results are shown in Figure 32.1 and Figure 32.2.

---

Figure 32.2. ANOVA Table and Tests of Effects

The degrees of freedom may be used to check your data. The Model degrees of freedom for a $2 \times 2$ factorial design with interaction are $(ab - 1)$, where $a$ is the number of levels of $A$ and $b$ is the number of levels of $B$; in this case, $(2 \times 2 - 1) = 3$. The Corrected Total degrees of freedom are always one less than the number of observations used in the analysis; in this case, $7 - 1 = 6$.

The overall $F$ test is significant ($F = 15.29, p = 0.0253$), indicating strong evidence that the means for the four different $A \times B$ cells are different. You can further analyze this difference by examining the individual tests for each effect.

Four types of estimable functions of parameters are available for testing hypotheses in PROC GLM. For data with no missing cells, the Type III and Type IV estimable functions are the same and test the same hypotheses that would be tested if the data were balanced. Type I and Type III sums of squares are typically not equal when the data are unbalanced; Type III sums of squares are preferred in testing effects in unbalanced cases because they test a function of the underlying parameters that is independent of the number of observations per treatment combination.

According to a significance level of 5% ($\alpha = 0.05$), the $A*B$ interaction is not significant ($F = 0.20, p = 0.6850$). This indicates that the effect of $A$ does not depend on the level of $B$ and vice versa. Therefore, the tests for the individual effects are valid,
showing a significant A effect \( (F = 33.80, p = 0.0101) \) but no significant B effect \( (F = 5.00, p = 0.1114) \).

**PROC GLM for Quadratic Least Squares Regression**

In polynomial regression, the values of a dependent variable (also called a response variable) are described or predicted in terms of polynomial terms involving one or more independent or explanatory variables. An example of quadratic regression in PROC GLM follows. These data are taken from Draper and Smith (1966, p. 57). Thirteen specimens of 90/10 Cu-Ni alloys are tested in a corrosion-wheel setup in order to examine corrosion. Each specimen has a certain iron content. The wheel is rotated in salt sea water at 30 ft/sec for 60 days. Weight loss is used to quantify the corrosion. The \( \text{fe} \) variable represents the iron content, and the \( \text{loss} \) variable denotes the weight loss in milligrams/square decimeter/day in the following DATA step.

```
title 'Regression in PROC GLM';
data iron;
    input fe loss @@;
datalines;
  0.01 127.6  0.48 124.0  0.71 110.8  0.95 103.9
  1.19 101.5  0.01 130.1  0.48 122.0  1.44 92.3
  0.71 113.1  1.96 83.7  0.01 128.0  1.44 91.4
  1.96 86.2
;
```

The GPLOT procedure is used to request a scatter plot of the response variable versus the independent variable.

```
symbol1 c=blue;
proc gplot;
    plot loss*fe / vm=1;
run;
```

The plot in Figure 32.3 displays a strong negative relationship between iron content and corrosion resistance, but it is not clear whether there is curvature in this relationship.
The following statements fit a quadratic regression model to the data. This enables you to estimate the linear relationship between iron content and corrosion resistance and test for the presence of a quadratic component. The intercept is automatically fit unless the NOINT option is specified.

```plaintext
proc glm;
  model loss=fe fe*fe;
run;
```

The CLASS statement is omitted because a regression line is being fitted. Unlike PROC REG, PROC GLM allows polynomial terms in the MODEL statement.

**Figure 32.4.** Class Level Information

The preliminary information in Figure 32.4 informs you that the GLM procedure has been invoked and states the number of observations in the data set. If the model involves classification variables, they are also listed here, along with their levels.
Figure 32.5 shows the overall ANOVA table and some simple statistics. The degrees of freedom can be used to check that the model is correct and that the data have been read correctly. The Model degrees of freedom for a regression is the number of parameters in the model minus 1. You are fitting a model with three parameters in this case,

\[
\text{loss} = \beta_0 + \beta_1 \times (\text{fe}) + \beta_2 \times (\text{fe})^2 + \text{error}
\]

so the degrees of freedom are \(3 - 1 = 2\). The Corrected Total degrees of freedom are always one less than the number of observations used in the analysis.

**Figure 32.6.** Tests of Effects and Parameter Estimates

The $t$ tests provided are equivalent to the Type III $F$ tests. The quadratic term is not significant ($F = 0.28, p = 0.6107; t = 0.53, p = 0.6107$) and thus can be removed from the model; the linear term is significant ($F = 35.64, p = 0.0001; t = -5.97, p = 0.0001$). This suggests that there is indeed a straight line relationship between $\text{loss}$ and $\text{fe}$.

Fitting the model without the quadratic term provides more accurate estimates for $\beta_0$ and $\beta_1$. PROC GLM allows only one MODEL statement per invocation of the procedure, so the PROC GLM statement must be issued again. The statements used to fit the linear model are

```
proc glm;
   model loss=fe;
run;
```

**Figure 32.7** displays the output produced by these statements. The linear term is still significant ($F = 352.27, p < 0.0001$). The estimated model is now

\[
\text{loss} = 129.79 - 24.02 \times \text{fe}
\]

Figure 32.7. Linear Model Output

Syntax

The following statements are available in PROC GLM.

PROC GLM < options >;
  CLASS variables < / option > ;
  MODEL dependents=independents < / options > ;
  ABSORB variables ;
  BY variables ;
  FREQ variable ;
  ID variables ;
  WEIGHT variable ;
  CONTRAST 'label' effect values < . . . effect values > < / options > ;
  ESTIMATE 'label' effect values < . . . effect values > < / options > ;
  LSMEANS effects < / options > ;
  MANOVA < test-options > < / detail-options > ;
Although there are numerous statements and options available in PROC GLM, many applications use only a few of them. Often you can find the features you need by looking at an example or by quickly scanning through this section.

To use PROC GLM, the PROC GLM and MODEL statements are required. You can specify only one MODEL statement (in contrast to the REG procedure, for example, which allows several MODEL statements in the same PROC REG run). If your model contains classification effects, the classification variables must be listed in a CLASS statement, and the CLASS statement must appear before the MODEL statement. In addition, if you use a CONTRAST statement in combination with a MANOVA, RANDOM, REPEATED, or TEST statement, the CONTRAST statement must be entered first in order for the contrast to be included in the MANOVA, RANDOM, REPEATED, or TEST analysis.

The following table summarizes the positional requirements for the statements in the GLM procedure.

</table>

The rest of this section gives detailed syntax information for each of these statements, beginning with the PROC GLM statement. The remaining statements are covered in alphabetical order.

PROC GLM Statement

PROC GLM < options > ;

The PROC GLM statement starts the GLM procedure. You can specify the following options in the PROC GLM statement:

ALPHA=p
specifies the level of significance p for $100(1 - p)$% confidence intervals. The value must be between 0 and 1; the default value of $p = 0.05$ results in 95% intervals. This value is used as the default confidence level for limits computed by the following options.

<table>
<thead>
<tr>
<th>Statement</th>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td>LSMEANS</td>

<td>CLM CLDIFF</td>
</tr>
<tr>
<td>MODEL</td>
<td>CLI CLM CLPARK</td>
</tr>
<tr>
<td>OUTPUT</td>
<td>UCL= LCL= UCLM= LCLM=</td>
</tr>
</tbody>
</table>

You can override the default in each of these cases by specifying the ALPHA= option for each statement individually.

DATA=SAS-data-set
names the SAS data set used by the GLM procedure. By default, PROC GLM uses the most recently created SAS data set.

MANOVA
requests the multivariate mode of eliminating observations with missing values. If any of the dependent variables have missing values, the procedure eliminates that observation from the analysis. The MANOVA option is useful if you use PROC GLM in interactive mode and plan to perform a multivariate analysis.
MULTIPASS
requests that PROC GLM reread the input data set when necessary, instead of writing the necessary values of dependent variables to a utility file. This option decreases disk space usage at the expense of increased execution times, and is useful only in rare situations where disk space is at an absolute premium.

NAMELEN=n
specifies the length of effect names in tables and output data sets to be n characters long, where n is a value between 20 and 200 characters. The default length is 20 characters.

NOPRINT
suppresses the normal display of results. The NOPRINT option is useful when you want only to create one or more output data sets with the procedure. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the sorting order for the levels of all classification variables (specified in the CLASS statement). This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use CONTRAST or ESTIMATE statements. Note that the ORDER= option applies to the levels for all classification variables. The exception is the default ORDER=FORMATTED for numeric variables for which you have supplied no explicit format. In this case, the levels are ordered by their internal value. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the affected classification variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or ORDER=INTERNAL to get the more natural ordering. The following table shows how PROC GLM interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

By default, ORDER=FORMATTED. For FORMATTED and INTERNAL, the sort order is machine dependent. For more information on sorting order, see the chapter

**OUTSTAT=SAS-data-set**
	names an output data set that contains sums of squares, degrees of freedom, $F$ statistics, and probability levels for each effect in the model, as well as for each CONTRAST that uses the overall residual or error mean square (MSE) as the denominator in constructing the $F$ statistic. If you use the CANONICAL option in the MANOVA statement and do not use an M= specification in the MANOVA statement, the data set also contains results of the canonical analysis. See the section “Output Data Sets” on page 1840 for more information.

**ABSORB Statement**

```
ABSORB variables;
```

Absorption is a computational technique that provides a large reduction in time and memory requirements for certain types of models. The *variables* are one or more variables in the input data set.

For a main effect variable that does not participate in interactions, you can absorb the effect by naming it in an ABSORB statement. This means that the effect can be adjusted out before the construction and solution of the rest of the model. This is particularly useful when the effect has a large number of levels.

Several variables can be specified, in which case each one is assumed to be nested in the preceding variable in the ABSORB statement.

**Note:** When you use the ABSORB statement, the data set (or each BY group, if a BY statement appears) must be sorted by the variables in the ABSORB statement. The GLM procedure cannot produce predicted values or least-squares means (LS-means) or create an output data set of diagnostic values if an ABSORB statement is used. If the ABSORB statement is used, it must appear before the first RUN statement or it is ignored.

When you use an ABSORB statement and also use the INT option in the MODEL statement, the procedure ignores the option but computes the uncorrected total sum of squares (SS) instead of the corrected total sums of squares.

See the “Absorption” section on page 1799 for more information.

**BY Statement**

```
BY variables;
```

You can specify a BY statement with PROC GLM to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the GLM procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

Since sorting the data changes the order in which PROC GLM reads observations, the sorting order for the levels of the classification variables may be affected if you have also specified ORDER=DATA in the PROC GLM statement. This, in turn, affects specifications in CONTRAST and ESTIMATE statements.

If you specify the BY statement, it must appear before the first RUN statement or it is ignored. When you use a BY statement, the interactive features of PROC GLM are disabled.

When both BY and ABSORB statements are used, observations must be sorted first by the variables in the BY statement, and then by the variables in the ABSORB statement.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Contents. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

### CLASS Statement

```
CLASS variables < / option >;
```

The CLASS statement names the classification variables to be used in the model. Typical class variables are TREATMENT, SEX, RACE, GROUP, and REPLICA TION. If you specify the CLASS statement, it must appear before the MODEL statement.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option on the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the SAS Procedures Guide, and the discussions for the FORMAT statement and SAS formats in SAS Language Reference: Dictionary.

The GLM procedure displays a table summarizing the class variables and their levels, and you can use this to check the ordering of levels and, hence, of the corresponding parameters for main effects. If you need to check the ordering of parameters for interaction effects, use the E option in the MODEL, CONTRAST, ESTIMATE, and LSMEANS statements. See the “Parameterization of PROC GLM Models” section on page 1787 for more information.
CONTRAST Statement

You can specify the following option in the CLASS statement after a slash(/):

**TRUNCATE**

specifies that class levels should be determined using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

---

## CONTRAST Statement

```plaintext
CONTRAST  'label' effect values < ... effect values > < / options > ;
```

The CONTRAST statement enables you to perform custom hypothesis tests by specifying an \( L \) vector or matrix for testing the univariate hypothesis \( L\beta = 0 \) or the multivariate hypothesis \( LBM = 0 \). Thus, to use this feature you must be familiar with the details of the model parameterization that PROC GLM uses. For more information, see the “Parameterization of PROC GLM Models” section on page 1787. All of the elements of the \( L \) vector may be given, or if only certain portions of the \( L \) vector are given, the remaining elements are constructed by PROC GLM from the context (in a manner similar to rule 4 discussed in the “Construction of Least-Squares Means” section on page 1820).

There is no limit to the number of CONTRAST statements you can specify, but they must appear after the MODEL statement. In addition, if you use a CONTRAST statement and a MANOVA, REPEATED, or TEST statement, appropriate tests for contrasts are carried out as part of the MANOVA, REPEATED, or TEST analysis. If you use a CONTRAST statement and a RANDOM statement, the expected mean square of the contrast is displayed. As a result of these additional analyses, the CONTRAST statement must appear before the MANOVA, REPEATED, RANDOM, or TEST statement.

In the CONTRAST statement,

- **label** identifies the contrast on the output. A label is required for every contrast specified. Labels must be enclosed in quotes.
- **effect** identifies an effect that appears in the MODEL statement, or the INTERCEPT effect. The INTERCEPT effect can be used when an intercept is fitted in the model. You do not need to include all effects that are in the MODEL statement.
- **values** are constants that are elements of the \( L \) vector associated with the effect.

You can specify the following options in the CONTRAST statement after a slash(/):

- **E** displays the entire \( L \) vector. This option is useful in confirming the ordering of parameters for specifying \( L \).
**E=effect**
specifies an error term, which must be one of the effects in the model. The procedure uses this effect as the denominator in $F$ tests in univariate analysis. In addition, if you use a MANOVA or REPEATED statement, the procedure uses the effect specified by the `E=` option as the basis of the $E$ matrix. By default, the procedure uses the overall residual or error mean square (MSE) as an error term.

**ETYPE=n**
specifies the type (1, 2, 3, or 4, corresponding to Type I, II, III, and IV tests, respectively) of the $E=$ effect. If the $E=$ option is specified and the `ETYPE=` option is not, the procedure uses the highest type computed in the analysis.

**SINGULAR=number**
tunes the estimability checking. If $\text{ABS}(L - LH) > C \times \text{number}$ for any row in the contrast, then $L$ is declared nonestimable. $H$ is the $(X'X)^{-1}X'X$ matrix, and $C$ is $\text{ABS}(L)$ except for rows where $L$ is zero, and then it is 1. The default value for the `SINGULAR=` option is $10^{-4}$. Values for the `SINGULAR=` option must be between 0 and 1.

As stated previously, the CONTRAST statement enables you to perform custom hypothesis tests. If the hypothesis is testable in the univariate case, $\text{SS}(H_0; L\beta = 0)$ is computed as

$$(Lb)'(L(X'X)^{-1}L')^{-1}(Lb)$$

where $b = (X'X)^{-1}X'y$. This is the sum of squares displayed on the analysis-of-variance table.

For multivariate testable hypotheses, the usual multivariate tests are performed using

$$H = M'(LB)'(L(X'X)^{-1}L')^{-1}(LB)M$$

where $B = (X'X)^{-1}X'Y$ and $Y$ is the matrix of multivariate responses or dependent variables. The degrees of freedom associated with the hypothesis is equal to the row rank of $L$. The sum of squares computed in this situation is equivalent to the sum of squares computed using an $L$ matrix with any row deleted that is a linear combination of previous rows.

Multiple-degree-of-freedom hypotheses can be specified by separating the rows of the $L$ matrix with commas.

For example, for the model

```plaintext
proc glm;
  class A B;
  model Y=A B;
run;
```
with A at 5 levels and B at 2 levels, the parameter vector is

\[(\mu \alpha_1 \alpha_2 \alpha_3 \alpha_4 \alpha_5 \beta_1 \beta_2)\]

To test the hypothesis that the pooled A linear and A quadratic effect is zero, you can use the following L matrix:

\[L = \begin{bmatrix}
0 & -2 & -1 & 0 & 1 & 2 & 0 & 0 \\
0 & 2 & -1 & -2 & -1 & 2 & 0 & 0
\end{bmatrix}\]

The corresponding CONTRAST statement is

\text{contrast} 'A LINEAR & QUADRATIC'
\quad a -2 -1 0 1 2,
\quad a 2 -1 -2 -1 2;

If the first level of A is a control level and you want a test of control versus others, you can use this statement:

\text{contrast} 'CONTROL VS OTHERS' a -1 0.25 0.25 0.25 0.25;

See the following discussion of the ESTIMATE statement and the “Specification of ESTIMATE Expressions” section on page 1801 for rules on specification, construction, distribution, and estimability in the CONTRAST statement.

**ESTIMATE Statement**

**ESTIMATE** 'label' effect values < ... effect values > < / options > ;

The ESTIMATE statement enables you to estimate linear functions of the parameters by multiplying the vector L by the parameter estimate vector b resulting in \(Lb\). All of the elements of the L vector may be given, or, if only certain portions of the L vector are given, the remaining elements are constructed by PROC GLM from the context (in a manner similar to rule 4 discussed in the “Construction of Least-Squares Means” section on page 1820).

The linear function is checked for estimability. The estimate Lb, where \(b = (X'X)^{-1}X'y\), is displayed along with its associated standard error, \(\sqrt{L(X'X)^{-1}L's^2}\), and t test. If you specify the CLPARAM option in the MODEL statement (see page 1771), confidence limits for the true value are also displayed.

There is no limit to the number of ESTIMATE statements that you can specify, but they must appear after the MODEL statement. In the ESTIMATE statement,

\textit{label} identifies the estimate on the output. A label is required for every contrast specified. Labels must be enclosed in quotes.
effect identifies an effect that appears in the MODEL statement, or the INTERCEPT effect. The INTERCEPT effect can be used as an effect when an intercept is fitted in the model. You do not need to include all effects that are in the MODEL statement.

values are constants that are the elements of the L vector associated with the preceding effect. For example,

```
estimate 'A1 VS A2' A 1 -1;
```

forms an estimate that is the difference between the parameters estimated for the first and second levels of the CLASS variable A.

You can specify the following options in the ESTIMATE statement after a slash:

**DIVISOR=number**

specifies a value by which to divide all coefficients so that fractional coefficients can be entered as integer numerators. For example, you can use

```
estimate '1/3(A1+A2) - 2/3A3' a 1 1 -2 / divisor=3;
```

instead of

```
estimate '1/3(A1+A2) - 2/3A3' a 0.33333 0.33333 -0.66667;
```

**E**

displays the entire L vector. This option is useful in confirming the ordering of parameters for specifying L.

**SINGULAR=number**

tunes the estimability checking. If \( \text{ABS}(L - LH) > C \times \text{number} \), then the L vector is declared nonestimable. \( H \) is the \((X'X)^{-1}X'X\) matrix, and \( C \) is \( \text{ABS}(L) \) except for rows where \( L \) is zero, and then it is 1. The default value for the SINGULAR= option is \( 10^{-4} \). Values for the SINGULAR= option must be between 0 and 1.

See also the “Specification of ESTIMATE Expressions” section on page 1801.

---

**FREQ Statement**

```
FREQ variable ;
```

The FREQ statement names a variable that provides frequencies for each observation in the DATA= data set. Specifically, if \( n \) is the value of the FREQ variable for a given observation, then that observation is used \( n \) times.

The analysis produced using a FREQ statement reflects the expanded number of observations. For example, means and total degrees of freedom reflect the expanded number of observations. You can produce the same analysis (without the FREQ statement) by first creating a new data set that contains the expanded number of observations. For example, if the value of the FREQ variable is 5 for the first observation,
the first 5 observations in the new data set are identical. Each observation in the old data set is replicated \( n_i \) times in the new data set, where \( n_i \) is the value of the FREQ variable for that observation.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

If you specify the FREQ statement, it must appear before the first RUN statement or it is ignored.

**ID Statement**

```
ID variables;
```

When predicted values are requested as a MODEL statement option, values of the variables given in the ID statement are displayed beside each observed, predicted, and residual value for identification. Although there are no restrictions on the length of ID variables, PROC GLM may truncate the number of values listed in order to display them on one line. The GLM procedure displays a maximum of five ID variables.

If you specify the ID statement, it must appear before the first RUN statement or it is ignored.

**LSMEANS Statement**

```
LSMEANS effects < / options >;
```

Least-squares means (LS-means) are computed for each effect listed in the LSMEANS statement. You may specify only classification effects in the LSMEANS statement—that is, effects that contain only classification variables. You may also specify options to perform multiple comparisons. In contrast to the MEANS statement, the LSMEANS statement performs multiple comparisons on interactions as well as main effects.

LS-means are predicted population margins; that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs. Each LS-mean is computed as \( L^T b \) for a certain column vector \( L \), where \( b \) is the vector of parameter estimates—that is, the solution of the normal equations. For further information, see the section “Construction of Least-Squares Means” on page 1820.

Multiple effects can be specified in one LSMEANS statement, or multiple LSMEANS statements can be used, but they must all appear after the MODEL statement. For example,

```
proc glm;
   class A B;
   model Y=A B A*B;
   lsmeans A B A*B;
run;
```
LS-means are displayed for each level of the A, B, and A*B effects.

You can specify the following options in the LSMEANS statement after a slash:

\begin{verbatim}
ADJUST=BON
ADJUST=DUNNETT
ADJUST=SCHEFFE
ADJUST=SIDAK
ADJUST=SIMULATE <(simoptions)>
ADJUST=SMM | GT2
ADJUST=TUKEY
ADJUST=T
\end{verbatim}

requests a multiple comparison adjustment for the \(p\)-values and confidence limits for the differences of LS-means. The ADJUST= option modifies the results of the TDIFF and PDIFF options; thus, if you omit the TDIFF or PDIFF option then the ADJUST= option has no effect. By default, PROC GLM analyzes all pairwise differences unless you specify ADJUST=DUNNETT, in which case PROC GLM analyzes all differences with a control level. The default is ADJUST=T, which really signifies no adjustment for multiple comparisons.

The BON (Bonferroni) and SIDAK adjustments involve correction factors described in the “Multiple Comparisons” section on page 1806 and in Chapter 48, “The MULTTEST Procedure.” When you specify ADJUST=TUKEY and your data are unbalanced, PROC GLM uses the approximation described in Kramer (1956) and identifies the adjustment as “Tukey-Kramer” in the results. Similarly, when you specify ADJUST=DUNNETT and the LS-means are correlated, PROC GLM uses the factor-analytic covariance approximation described in Hsu (1992) and identifies the adjustment as “Dunnett-Hsu” in the results. The preceding references also describe the SCHEFFE and SMM adjustments.

The SIMULATE adjustment computes the adjusted \(p\)-values from the simulated distribution of the maximum or maximum absolute value of a multivariate \(t\) random vector. The simulation estimates \(q\), the true \((1 - \alpha)\)th quantile, where \(1 - \alpha\) is the confidence coefficient. The default \(\alpha\) is the value of the ALPHA= option in the PROC GLM statement or 0.05 if that option is not specified. You can change this value with the ALPHA= option in the LSMEANS statement.

The number of samples for the SIMULATE adjustment is set so that the tail area for the simulated \(q\) is within a certain accuracy radius \(\gamma\) of \(1 - \alpha\) with an accuracy confidence of \(100(1 - \epsilon)\%\). In equation form,

\[
P(|F(\hat{q}) - (1 - \alpha)| \leq \gamma) = 1 - \epsilon
\]

where \(\hat{q}\) is the simulated \(q\) and \(F\) is the true distribution function of the maximum; refer to Edwards and Berry (1987) for details. By default, \(\gamma = 0.005\) and \(\epsilon = 0.01\) so that the tail area of \(\hat{q}\) is within 0.005 of 0.95 with 99\% confidence.

You can specify the following simoptions in parentheses after the ADJUST=SIMULATE option.
**ACC=**value specifies the target accuracy radius $\gamma$ of a $100(1-\epsilon)$% confidence interval for the true probability content of the estimated $(1-\alpha)$th quantile. The default value is ACC=0.005. Note that, if you also specify the CVADJUST simoption, then the actual accuracy radius will probably be substantially less than this target.

**CVADJUST** specifies that the quantile should be estimated by the control variate adjustment method of Hsu and Nelson (1998) instead of simply as the quantile of the simulated sample. Specifying the CVADJUST option typically has the effect of significantly reducing the accuracy radius $\gamma$ of a $100 \times (1-\epsilon)$% confidence interval for the true probability content of the estimated $(1-\alpha)$th quantile. The control-variate-adjusted quantile estimate takes roughly twice as long to compute, but it is typically much more accurate than the sample quantile.

**EPS=**value specifies the value $\epsilon$ for a $100 \times (1-\epsilon)$% confidence interval for the true probability content of the estimated $(1-\alpha)$th quantile. The default value for the accuracy confidence is 99%, corresponding to EPS=0.01.

**NSAMP=**n specifies the sample size for the simulation. By default, $n$ is set based on the values of the target accuracy radius $\gamma$ and accuracy confidence $100 \times (1-\epsilon)$ true probability content of the estimated $(1-\alpha)$th quantile. With the default values for $\gamma$, $\epsilon$, and $\alpha$ (0.005, 0.01, and 0.05, respectively), NSAMP=12604 by default.

**REPORT** specifies that a report on the simulation should be displayed, including a listing of the parameters, such as $\gamma$, $\epsilon$, and $\alpha$ as well as an analysis of various methods for estimating or approximating the quantile.

**SEED=**number specifies an integer used to start the pseudo-random number generator for the simulation. If you do not specify a seed, or specify a value less than or equal to zero, the seed is by default generated from reading the time of day from the computer’s clock.

**ALPHA=**p specifies the level of significance $p$ for $100(1-p)$% confidence intervals. This option is useful only if you also specify the CL option, and, optionally, the PDIFF option. By default, $p$ is equal to the value of the ALPHA= option in the PROC GLM statement or 0.05 if that option is not specified. This value is used to set the endpoints for confidence intervals for the individual means as well as for differences between means.

**AT** variable = value
**AT** (variable-list) = (value-list)
**AT MEANS**

enables you to modify the values of the covariates used in computing LS-means. By default, all covariate effects are set equal to their mean values for computation of standard LS-means. The AT option enables you to set the covariates to whatever values
you consider interesting. For more information, see the section “Setting Covariate Values” on page 1821.

**BYLEVEL**
requests that PROC GLM process the OM data set by each level of the LS-mean effect in question. For more details, see the entry for the OM option in this section.

**CL**
requests confidence limits for the individual LS-means. If you specify the PDIFF option, confidence limits for differences between means are produced as well. You can control the confidence level with the ALPHA= option. Note that, if you specify an ADJUST= option, the confidence limits for the differences are adjusted for multiple inference but the confidence intervals for individual means are not adjusted.

**COV**
includes variances and covariances of the LS-means in the output data set specified in the OUT= option in the LSMEANS statement. Note that this is the covariance matrix for the LS-means themselves, not the covariance matrix for the differences between the LS-means, which is used in the PDIFF computations. If you omit the OUT= option, the COV option has no effect. When you specify the COV option, you can specify only one effect in the LSMEANS statement.

**E**
displays the coefficients of the linear functions used to compute the LS-means.

**E=effect**
specifies an effect in the model to use as an error term. The procedure uses the mean square for the effect as the error mean square when calculating estimated standard errors (requested with the STDERR option) and probabilities (requested with the STDERR, PDIFF, or TDIFF option). Unless you specify STDERR, PDIFF or TDIFF, the E= option is ignored. By default, if you specify the STDERR, PDIFF, or TDIFF option and do not specify the E= option, the procedure uses the error mean square for calculating standard errors and probabilities.

**ETYPE=n**
specifies the type (1, 2, 3, or 4, corresponding to Type I, II, III, and IV tests, respectively) of the E= effect. If you specify the E= option but not the ETYPE= option, the highest type computed in the analysis is used. If you omit the E= option, the ETYPE= option has no effect.

**NOPRINT**
suppresses the normal display of results from the LSMEANS statement. This option is useful when an output data set is created with the OUT= option in the LSMEANS statement.

**OBSMARGINS**
**OM** specifies a potentially different weighting scheme for computing LS-means coefficients. The standard LS-means have equal coefficients across classification effects; however, the OM option changes these coefficients to be proportional to those found
in the input data set. For more information, see the section “Changing the Weighting Scheme” on page 1822.

The BYLEVEL option modifies the observed-margins LS-means. Instead of computing the margins across the entire data set, the procedure computes separate margins for each level of the LS-mean effect in question. The resulting LS-means are actually equal to raw means in this case. If you specify the BYLEVEL option, it disables the AT option.

\textbf{OUT=SAS-data-set} \\
creates an output data set that contains the values, standard errors, and, optionally, the covariances (see the \texttt{COV} option) of the LS-means. For more information, see the “Output Data Sets” section on page 1840.

\textbf{PDIFF=\texttt{\textless\textgreater difftype}} \\
requests that \textit{p}-values for differences of the LS-means be produced. The optional \texttt{difftype} specifies which differences to display. Possible values for \texttt{difftype} are \texttt{ALL}, \texttt{CONTROL}, \texttt{CONTROLL}, and \texttt{CONTROLU}. The \texttt{ALL} value requests all pairwise differences, and it is the default. The \texttt{CONTROL} value requests the differences with a control that, by default, is the first level of each of the specified LS-mean effects.

To specify which levels of the effects are the controls, list the quoted formatted values in parentheses after the keyword \texttt{CONTROL}. For example, if the effects \texttt{A}, \texttt{B}, and \texttt{C} are class variables, each having two levels, ‘1’ and ‘2’, the following LSMEANS statement specifies the ‘1’ ‘2’ level of \texttt{A*B} and the ‘2’ ‘1’ level of \texttt{B*C} as controls:

\begin{verbatim}
   lsmeans A*B B*C / pdiff=control('1' '2', '2' '1');
\end{verbatim}

For multiple effect situations such as this one, the ordering of the list is significant, and you should check the output to make sure that the controls are correct.

Two-tailed tests and confidence limits are associated with the \texttt{CONTROL} \texttt{difftype}. For one-tailed results, use either the \texttt{CONTROLL} or \texttt{CONTROLU} \texttt{difftype}.

- \texttt{PDIFF=CONTROLL} tests whether the noncontrol levels are less than the control; you declare a noncontrol level to be significantly less than the control if the associated upper confidence limit for the noncontrol level minus the control is less than zero, and you ignore the associated lower confidence limits (which are set to minus infinity).

- \texttt{PDIFF=CONTROLU} tests whether the noncontrol levels are greater than the control; you declare a noncontrol level to be significantly greater than the control if the associated lower confidence limit for the noncontrol level minus the control is greater than zero, and you ignore the associated upper confidence limits (which are set to infinity).

The default multiple comparisons adjustment for each \texttt{difftype} is shown in the following table.
If no `difftype` is specified, the default for the ADJUST= option is T (that is, no adjustment); for PDIFF=ALL, ADJUST=TUKEY is the default; in all other instances, the default value for the ADJUST= option is DUNNETT. If there is a conflict between the PDIFF= and ADJUST= options, the ADJUST= option takes precedence.

For example, in order to compute one-sided confidence limits for differences with a control, adjusted according to Dunnett’s procedure, the following statements are equivalent:

```
lsmeans Treatment / pdiff=controll cl;
lsmeans Treatment / pdiff=controll cl adjust=dunnett;
```

**SLICE = fixed-effect**

**SLICE = (fixed-effects)**

specifies effects within which to test for differences between interaction LS-mean effects. This can produce what are known as tests of simple effects (Winer 1971). For example, suppose that A*B is significant and you want to test for the effect of A within each level of B. The appropriate LSMEANS statement is

```
lsmeans A*B / slice=B;
```

This code tests for the simple main effects of A for B, which are calculated by extracting the appropriate rows from the coefficient matrix for the A*B LS-means and using them to form an F-test as performed by the CONTRAST statement.

**SINGULAR=number**

tunes the estimability checking. If \( |L - LH| > C \times number \) for any row, then \( L \) is declared nonestimable. \( H \) is the \((X'X)^{-1}X'X\) matrix, and \( C \) is \( |L| \) except for rows where \( L \) is zero, and then it is 1. The default value for the SINGULAR= option is \( 10^{-4} \). Values for the SINGULAR= option must be between 0 and 1.

**STDERR**

produces the standard error of the LS-means and the probability level for the hypothesis \( H_0: \text{LS-mean} = 0 \).

**TDIFF**

produces the \( t \) values for all hypotheses \( H_0: \text{LS-mean}(i) = \text{LS-mean}(j) \) and the corresponding probabilities.
MANOVA Statement

MANOVA < test-options > / detail-options > ;

If the MODEL statement includes more than one dependent variable, you can perform multivariate analysis of variance with the MANOVA statement. The test-options define which effects to test, while the detail-options specify how to execute the tests and what results to display.

When a MANOVA statement appears before the first RUN statement, PROC GLM enters a multivariate mode with respect to the handling of missing values; in addition to observations with missing independent variables, observations with any missing dependent variables are excluded from the analysis. If you want to use this mode of handling missing values and do not need any multivariate analyses, specify the MANOVA option in the PROC GLM statement.

If you use both the CONTRAST and MANOVA statements, the MANOVA statement must appear after the CONTRAST statement.

Test Options

The following options can be specified in the MANOVA statement as test-options in order to define which multivariate tests to perform.

H=effects | INTERCEPT | __ALL__

specifies effects in the preceding model to use as hypothesis matrices. For each H matrix (the SSCP matrix associated with an effect), the H= specification displays the characteristic roots and vectors of $E^{-1}H$ (where $E$ is the matrix associated with the error effect), Hotelling-Lawley trace, Pillai’s trace, Wilks’ criterion, and Roy’s maximum root criterion. By default, these statistics are tested with approximations based on the $F$ distribution. To test them with exact (but computationally intensive) calculations, use the MSTAT=EXACT option.

Use the keyword INTERCEPT to produce tests for the intercept. To produce tests for all effects listed in the MODEL statement, use the keyword __ALL__ in place of a list of effects. For background and further details, see the “Multivariate Analysis of Variance” section on page 1823.

E=effect

specifies the error effect. If you omit the E= specification, the GLM procedure uses the error SSCP (residual) matrix from the analysis.

M=equation, . . . , equation | (row-of-matrix, . . . , row-of-matrix)

specifies a transformation matrix for the dependent variables listed in the MODEL statement. The equations in the M= specification are of the form

$$c_1 \times \text{dependent-variable} \pm c_2 \times \text{dependent-variable}$$

$$\cdots \pm c_n \times \text{dependent-variable}$$

where the $c_i$ values are coefficients for the various dependent-variables. If the value of a given $c_i$ is 1, it can be omitted; in other words $1 \times Y$ is the same as $Y$. 
Equations should involve two or more dependent variables. For sample syntax, see the “Examples” section on page 1762.

Alternatively, you can input the transformation matrix directly by entering the elements of the matrix with commas separating the rows and parentheses surrounding the matrix. When this alternate form of input is used, the number of elements in each row must equal the number of dependent variables. Although these combinations actually represent the columns of the $M$ matrix, they are displayed by rows.

When you include an $M=$ specification, the analysis requested in the MANOVA statement is carried out for the variables defined by the equations in the specification, not the original dependent variables. If you omit the $M=$ option, the analysis is performed for the original dependent variables in the MODEL statement.

If an $M=$ specification is included without either the MNAMES= or PREFIX= option, the variables are labeled MAVAR1, MAVAR2, and so forth, by default. For further information, see the “Multivariate Analysis of Variance” section on page 1823.

**MNAMES=names**

provides names for the variables defined by the equations in the $M=$ specification. Names in the list correspond to the $M=$ equations or to the rows of the $M$ matrix (as it is entered).

**PREFIX=name**

is an alternative means of identifying the transformed variables defined by the $M=$ specification. For example, if you specify PREFIX=DIFF, the transformed variables are labeled DIFF1, DIFF2, and so forth.

### Detail Options

You can specify the following options in the MANOVA statement after a slash as detail-options.

**CANONICAL**

displays a canonical analysis of the $H$ and $E$ matrices (transformed by the $M$ matrix, if specified) instead of the default display of characteristic roots and vectors.

**ETYPE=n**

specifies the type (1, 2, 3, or 4, corresponding to Type I, II, III, and IV tests, respectively) of the $E$ matrix, the SSCP matrix associated with the $E=$ effect. You need this option if you use the $E=$ specification to specify an error effect other than residual error and you want to specify the type of sums of squares used for the effect. If you specify ETYPE=n, the corresponding test must have been performed in the MODEL statement, either by options SS$n$, En, or the default Type I and Type III tests. By default, the procedure uses an ETYPE= value corresponding to the highest type (largest $n$) used in the analysis.

**HTYPE=n**

specifies the type (1, 2, 3, or 4, corresponding to Type I, II, III, and IV tests, respectively) of the $H$ matrix. See the ETYPE= option for more details.
**MSTAT=FAPPROX**

**MSTAT=EXACT**

specifies the method of evaluating the multivariate test statistics. The default is MSTAT=FAPPROX, which specifies that the multivariate tests are evaluated using the usual approximations based on the $F$ distribution, as discussed in the “Multivariate Tests” section in Chapter 2, “Introduction to Regression Procedures.” Alternatively, you can specify MSTAT=EXACT to compute exact $p$-values for three of the four tests (Wilks’ Lambda, the Hotelling-Lawley Trace, and Roy’s Greatest Root) and an improved $F$-approximation for the fourth (Pillai’s Trace). While MSTAT=EXACT provides better control of the significance probability for the tests, especially for Roy’s Greatest Root, computations for the exact $p$-values can be appreciably more demanding, and are in fact infeasible for large problems (many dependent variables). Thus, although MSTAT=EXACT is more accurate for most data, it is not the default method. For more information on the results of MSTAT=EXACT, see the “Multivariate Analysis of Variance” section on page 1823.

**ORTH**

requests that the transformation matrix in the M= specification of the MANOVA statement be orthonormalized by rows before the analysis.

**PRINTE**

displays the error SSCP matrix $E$. If the $E$ matrix is the error SSCP (residual) matrix from the analysis, the partial correlations of the dependent variables given the independent variables are also produced.

For example, the statement

```
manova / prinote;
```

displays the error SSCP matrix and the partial correlation matrix computed from the error SSCP matrix.

**PRINTH**

displays the hypothesis SSCP matrix $H$ associated with each effect specified by the H= specification.

**SUMMARY**

produces analysis-of-variance tables for each dependent variable. When no $M$ matrix is specified, a table is displayed for each original dependent variable from the MODEL statement; with an $M$ matrix other than the identity, a table is displayed for each transformed variable defined by the $M$ matrix.
Examples

The following statements provide several examples of using a MANOVA statement.

```latex
proc glm;
  class A B;
  model Y1-Y5=A B(A) / nouni;
  manova h=A e=B(A) / printh printe htype=1 etype=1;
  manova h=B(A) / printe;
  manova h=A e=B(A) m=Y1-Y2,Y2-Y3,Y3-Y4,Y4-Y5
    prefix=diff;
  manova h=A e=B(A) m=(1 -1 0 0 0,
    0 1 -1 0 0,
    0 0 1 -1 0,
    0 0 0 1 -1) prefix=diff;
run;
```

Since this MODEL statement requests no options for type of sums of squares, the procedure uses Type I and Type III sums of squares. The first MANOVA statement specifies \( A \) as the hypothesis effect and \( B(A) \) as the error effect. As a result of the PRINTH option, the procedure displays the hypothesis SSCP matrix associated with the \( A \) effect; and, as a result of the PRINTE option, the procedure displays the error SSCP matrix associated with the \( B(A) \) effect. The option HTYPE=1 specifies a Type I \( H \) matrix, and the option ETYPE=1 specifies a Type I \( E \) matrix.

The second MANOVA statement specifies \( B(A) \) as the hypothesis effect. Since no error effect is specified, PROC GLM uses the error SSCP matrix from the analysis as the \( E \) matrix. The PRINTE option displays this \( E \) matrix. Since the \( E \) matrix is the error SSCP matrix from the analysis, the partial correlation matrix computed from this matrix is also produced.

The third MANOVA statement requests the same analysis as the first MANOVA statement, but the analysis is carried out for variables transformed to be successive differences between the original dependent variables. The option PREFIX=DIFF labels the transformed variables as DIFF1, DIFF2, DIFF3, and DIFF4.

Finally, the fourth MANOVA statement has the identical effect as the third, but it uses an alternative form of the M= specification. Instead of specifying a set of equations, the fourth MANOVA statement specifies rows of a matrix of coefficients for the five dependent variables.

As a second example of the use of the M= specification, consider the following:

```latex
proc glm;
  class group;
  model dose1-dose4=group / nouni;
  manova h = group
    m = -3*dose1 - dose2 + dose3 + 3*dose4,
    dose1 - dose2 - dose3 + dose4,
    -dose1 + 3*dose2 - 3*dose3 + dose4
    mnames = Linear Quadratic Cubic
    / printe;
run;
```
The \( M= \) specification gives a transformation of the dependent variables \( \text{dose1 through dose4} \) into orthogonal polynomial components, and the \( \text{MNAMES=} \) option labels the transformed variables \( \text{LINEAR, QUADRATIC, and CUBIC, respectively.} \) Since the \( \text{PRINTE} \) option is specified and the default residual matrix is used as an error term, the partial correlation matrix of the orthogonal polynomial components is also produced.

**MEANS Statement**

\[
\text{MEANS } \text{effects} < \text{l options} > ;
\]

Within each group corresponding to each effect specified in the MEANS statement, PROC GLM computes the arithmetic means and standard deviations of all continuous variables in the model (both dependent and independent). You may specify only classification effects in the MEANS statement—that is, effects that contain only classification variables.

Note that the arithmetic means are not adjusted for other effects in the model; for adjusted means, see the “\text{LSMEANS Statement}” section on page 1753. If you use a WEIGHT statement, PROC GLM computes weighted means; see the “\text{Weighted Means}” section on page 1820.

You may also specify options to perform multiple comparisons. However, the MEANS statement performs multiple comparisons only for main effect means; for multiple comparisons of interaction means, see the “\text{LSMEANS Statement}” section on page 1753.

You can use any number of MEANS statements, provided that they appear after the MODEL statement. For example, suppose \( A \) and \( B \) each have two levels. Then, if you use the following statements

```plaintext
proc glm;
  class A B;
  model Y=A B A*B;
  means A B / tukey;
  means A*B;
run;
```

the means, standard deviations, and Tukey’s multiple comparisons tests are displayed for each level of the main effects \( A \) and \( B \), and just the means and standard deviations are displayed for each of the four combinations of levels for \( A*B \). Since multiple comparisons tests apply only to main effects, the single MEANS statement

```plaintext
means A B A*B / tukey;
```

produces the same results.

PROC GLM does not compute means for interaction effects containing continuous variables. Thus, if you have the model
class A;
model Y=A X A*X;
then the effects X and A*X cannot be used in the MEANS statement. However, if you specify the effect A in the means statement

means A;
then PROC GLM, by default, displays within-A arithmetic means of both Y and X. Use the DEPONLY option to display means of only the dependent variables.

means A / deponly;
If you use a WEIGHT statement, PROC GLM computes weighted means and estimates their variance as inversely proportional to the corresponding sum of weights (see the “Weighted Means” section on page 1820). However, note that the statistical interpretation of multiple comparison tests for weighted means is not well understood. See the “Multiple Comparisons” section on page 1806 for formulas. The following table summarizes categories of options available in the MEANS statement.
### Table

</tbody>
</table>

These options are described in the following list.

**ALPHA=**

Specifies the level of significance for comparisons among the means. By default, \( p \) is equal to the value of the **ALPHA=** option in the PROC GLM statement or 0.05 if that option is not specified. You can specify any value greater than 0 and less than 1.

**BON**

Performs Bonferroni \( t \) tests of differences between means for all main effect means in the MEANS statement. See the **CLDIFF** and **LINES** options for a discussion of how the procedure displays results.

**CLDIFF**

Presents results of the BON, GABRIEL, SCHEFFE, SIDAK, SMM, GT2, T, LSD, and TUKEY options as confidence intervals for all pairwise differences between means, and the results of the DUNNETT, DUNNETTU, and DUNNETTL options
as confidence intervals for differences with the control. The CLDIFF option is the
default for unequal cell sizes unless the DUNCAN, REGWQ, SNK, or WALLER
option is specified.

CLM
presents results of the BON, GABRIEL, SCHEFFE, SIDAK, SMM, T, and LSD op-
tions as intervals for the mean of each level of the variables specified in the MEANS
statement. For all options except GABRIEL, the intervals are confidence intervals for
the true means. For the GABRIEL option, they are comparison intervals for compar-
ing means pairwise: in this case, if the intervals corresponding to two means overlap,
then the difference between them is insignificant according to Gabriel’s method.

DEPONLY
displays only means for the dependent variables. By default, PROC GLM produces
means for all continuous variables, including continuous independent variables.

DUNCAN
performs Duncan’s multiple range test on all main effect means given in the MEANS
statement. See the LINES option for a discussion of how the procedure displays
results.

DUNNETT < (formatted-control-values) >
performs Dunnett’s two-tailed t test, testing if any treatments are significantly differ-
ent from a single control for all main effects means in the MEANS statement.

To specify which level of the effect is the control, enclose the formatted value in
quotes in parentheses after the keyword. If more than one effect is specified in the
MEANS statement, you can use a list of control values within the parentheses. By
default, the first level of the effect is used as the control. For example,

```
means A / dunnett(‘CONTROL’);
```

where CONTROL is the formatted control value of A. As another example,

```
means A B C / dunnett(‘CNTLA’ ‘CNTLB’ ‘CNTLC’);
```

where CNTLA, CNTLB, and CNTLC are the formatted control values for A, B, and
C, respectively.

DUNNETTLL < (formatted-control-value) >
performs Dunnett’s one-tailed t test, testing if any treatment is significantly less than
the control. Control level information is specified as described for the DUNNETT
option.

DUNNETTTU < (formatted-control-value) >
performs Dunnett’s one-tailed t test, testing if any treatment is significantly greater
than the control. Control level information is specified as described for the
DUNNETT option.
E=effect
specifies the error mean square used in the multiple comparisons. By default, PROC GLM uses the overall residual or error mean square (MS). The effect specified with the E= option must be a term in the model; otherwise, the procedure uses the residual MS.

ETYPE=n
specifies the type of mean square for the error effect. When you specify E=effect, you may need to indicate which type (1, 2, 3, or 4) of MS is to be used. The n value must be one of the types specified in or implied by the MODEL statement. The default MS type is the highest type used in the analysis.

GABRIEL
performs Gabriel’s multiple-comparison procedure on all main effect means in the MEANS statement. See the CLDIFF and LINES options for discussions of how the procedure displays results.

GT2
see the SMM option.

HOVTEST
HOVTEST=BARTLETT
HOVTEST=BF
HOVTEST=LEVENE < ( TYPE= ABS | SQUARE )>
HOVTEST=OBRIEN < ( W=number )>
requests a homogeneity of variance test for the groups defined by the MEANS effect. You can optionally specify a particular test; if you do not specify a test, Levene’s test (Levene 1960) with TYPE=SQUARE is computed. Note that this option is ignored unless your MODEL statement specifies a simple one-way model.

The HOVTEST=BARTLETT option specifies Bartlett’s test (Bartlett 1937), a modification of the normal-theory likelihood ratio test.

The HOVTEST=BF option specifies Brown and Forsythe’s variation of Levene’s test (Brown and Forsythe 1974).

The HOVTEST=LEVENE option specifies Levene’s test (Levene 1960), which is widely considered to be the standard homogeneity of variance test. You can use the TYPE= option in parentheses to specify whether to use the absolute residuals (TYPE=ABS) or the squared residuals (TYPE=SQUARE) in Levene’s test. TYPE=SQUARE is the default.

The HOVTEST=OBRIEN option specifies O’Brien’s test (O’Brien 1979), which is basically a modification of HOVTEST=LEVENE(TYPE=SQUARE). You can use the W= option in parentheses to tune the variable to match the suspected kurtosis of the underlying distribution. By default, W=0.5, as suggested by O’Brien (1979; 1981).

See the “Homogeneity of Variance in One-Way Models” section on page 1818 for more details on these methods. Example 32.10 on page 1892 illustrates the use of the HOVTEST and WELCH options in the MEANS statement in testing for equal group variances and adjusting for unequal group variances in a one-way ANOVA.
**HTYPE=**\(n\)
specifies the MS type for the hypothesis MS. The HTYPE= option is needed only when the WALLER option is specified. The default HTYPE= value is the highest type used in the model.

**KRATIO=**\(value\)
specifies the Type 1/Type 2 error seriousness ratio for the Waller-Duncan test. Reasonable values for the KRATIO= option are 50, 100, 500, which roughly correspond for the two-level case to ALPHA levels of 0.1, 0.05, and 0.01, respectively. By default, the procedure uses the value of 100.

**LINES**
presents results of the BON, DUNCAN, GABRIEL, REGWQ, SCHEFFE, SIDAK, SMM, GT2, SNK, T, LSD, TUKEY, and WALLER options by listing the means in descending order and indicating nonsignificant subsets by line segments beside the corresponding means. The LINES option is appropriate for equal cell sizes, for which it is the default. The LINES option is also the default if the DUNCAN, REGWQ, SNK, or WALLER option is specified, or if there are only two cells of unequal size. The LINES option cannot be used in combination with the DUNNETT, DUNNETTL, or DUNNETTU option. In addition, the procedure has a restriction that no more than 24 overlapping groups of means can exist. If a mean belongs to more than 24 groups, the procedure issues an error message. You can either reduce the number of levels of the variable or use a multiple comparison test that allows the CLDIFF option rather than the LINES option.

**Note:** If the cell sizes are unequal, the harmonic mean of the cell sizes is used to compute the critical ranges. This approach is reasonable if the cell sizes are not too different, but it can lead to liberal tests if the cell sizes are highly disparate. In this case, you should not use the LINES option for displaying multiple comparisons results; use the TUKEY and CLDIFF options instead.

**LSD**
see the T option.

**NOSORT**
prevents the means from being sorted into descending order when the CLDIFF or CLM option is specified.

**REGWQ**
performs the Ryan-Einot-Gabriel-Welsch multiple range test on all main effect means in the MEANS statement. See the LINES option for a discussion of how the procedure displays results.

**SCHEFFE**
performs Scheffé’s multiple-comparison procedure on all main effect means in the MEANS statement. See the CLDIFF and LINES options for discussions of how the procedure displays results.
SIDAK
performs pairwise t tests on differences between means with levels adjusted according to Sidak’s inequality for all main effect means in the MEANS statement. See the CLDIFF and LINES options for discussions of how the procedure displays results.

SMM GT2
performs pairwise comparisons based on the studentized maximum modulus and Sidak’s uncorrelated-t inequality, yielding Hochberg’s GT2 method when sample sizes are unequal, for all main effect means in the MEANS statement. See the CLDIFF and LINES options for discussions of how the procedure displays results.

SNK
performs the Student-Newman-Keuls multiple range test on all main effect means in the MEANS statement. See the LINES option for discussions of how the procedure displays results.

T LSD
performs pairwise t tests, equivalent to Fisher’s least-significant-difference test in the case of equal cell sizes, for all main effect means in the MEANS statement. See the CLDIFF and LINES options for discussions of how the procedure displays results.

TUKEY
performs Tukey’s studentized range test (HSD) on all main effect means in the MEANS statement. (When the group sizes are different, this is the Tukey-Kramer test.) See the CLDIFF and LINES options for discussions of how the procedure displays results.

WALLER
performs the Waller-Duncan k-ratio t test on all main effect means in the MEANS statement. See the KRATIO= and HTYPE= options for information on controlling details of the test, and the LINES option for a discussion of how the procedure displays results.

WELCH
requests the variance-weighted one-way ANOVA of Welch (1951). This alternative to the usual analysis of variance for a one-way model is robust to the assumption of equal within-group variances. This option is ignored unless your MODEL statement specifies a simple one-way model.

Note that using the WELCH option merely produces one additional table consisting of Welch’s ANOVA. It does not affect all of the other tests displayed by the GLM procedure, which still require the assumption of equal variance for exact validity.

See the “Homogeneity of Variance in One-Way Models” section on page 1818 for more details on Welch’s ANOVA. Example 32.10 on page 1892 illustrates the use of the HOVTEST and WELCH options in the MEANS statement in testing for equal group variances and adjusting for unequal group variances in a one-way ANOVA.
MODEL Statement

MODEL  dependents=independents < / options > ;

The MODEL statement names the dependent variables and independent effects. The syntax of effects is described in the “Specification of Effects” section on page 1784. For any model effect involving classification variables (interactions as well as main effects), the number of levels can not exceed 32,767. If no independent effects are specified, only an intercept term is fit. You can specify only one MODEL statement (in contrast to the REG procedure, for example, which allows several MODEL statements in the same PROC REG run).

The following table summarizes options available in the MODEL statement.

<table>
<thead>
<tr>
<th>Task</th>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td>Produce tests for the intercept</td>
<td>INTERCEPT</td>
</tr>
<tr>
<td>Omit the intercept parameter from model</td>
<td>NOINT</td>
</tr>
<tr>
<td>Produce parameter estimates</td>
<td>SOLUTION</td>
</tr>
<tr>
<td>Produce tolerance analysis</td>
<td>TOLERANCE</td>
</tr>
<tr>
<td>Suppress univariate tests and output</td>
<td>NOUNI</td>
</tr>
<tr>
<td>Display estimable functions</td>
<td>E, E1, E2, E3, E4, ALIASING</td>
</tr>
<tr>
<td>Control hypothesis tests performed</td>
<td>SS1, SS2, SS3, SS4</td>
</tr>
<tr>
<td>Produce confidence intervals</td>
<td>ALPHA=</td>
</tr>
<tr>
<td></td>
<td>CLI, CLM, CLPARM</td>
</tr>
<tr>
<td>Display predicted and residual values</td>
<td>P</td>
</tr>
<tr>
<td>Display intermediate calculations</td>
<td>INVERSE, XPX</td>
</tr>
<tr>
<td>Tune sensitivity</td>
<td>SINGULAR=</td>
</tr>
<tr>
<td></td>
<td>ZETA=</td>
</tr>
</tbody>
</table>

These options are described in the following list.
ALIASING
specifies that the estimable functions should be displayed as an aliasing structure, for which each row says which linear combination of the parameters is estimated by each estimable function; also, adds a column of the same information to the table of parameter estimates, giving for each parameter the expected value of the estimate associated with that parameter. This option is most useful in fractional factorial experiments that can be analyzed without a CLASS statement.

ALPHA=\(p\)
specifies the level of significance \(p\) for \(100(1 - p)\)% confidence intervals. By default, \(p\) is equal to the value of the ALPHA= option in the PROC GLM statement, or 0.05 if that option is not specified. You may use values between 0 and 1.

CLI
produces confidence limits for individual predicted values for each observation. The CLI option is ignored if the CLM option is also specified.

CLM
produces confidence limits for a mean predicted value for each observation.

CLP ARM
produces confidence limits for the parameter estimates (if the SOLUTION option is also specified) and for the results of all ESTIMATE statements.

E
displays the general form of all estimable functions. This is useful for determining the order of parameters when writing CONTRAST and ESTIMATE statements.

E1
displays the Type I estimable functions for each effect in the model and computes the corresponding sums of squares.

E2
displays the Type II estimable functions for each effect in the model and computes the corresponding sums of squares.

E3
displays the Type III estimable functions for each effect in the model and computes the corresponding sums of squares.

E4
displays the Type IV estimable functions for each effect in the model and computes the corresponding sums of squares.

INTERCEPT
INT
produces the hypothesis tests associated with the intercept as an effect in the model. By default, the procedure includes the intercept in the model but does not display associated tests of hypotheses. Except for producing the uncorrected total sum of squares instead of the corrected total sum of squares, the INT option is ignored when you use an ABSORB statement.
**INVERSE**

displays the augmented inverse (or generalized inverse) $X'X$ matrix:

$$
\begin{bmatrix}
(X'X)^{-1} & (X'X)^{-1}X'Y \\
Y'(X'X)^{-1} & Y'Y - Y'X(X'X)^{-1}X'Y
\end{bmatrix}
$$

The upper left-hand corner is the generalized inverse of $X'X$, the upper right-hand corner is the parameter estimates, and the lower right-hand corner is the error sum of squares.

**NOINT**

omits the intercept parameter from the model.

**NOUNI**

suppresses the display of univariate statistics. You typically use the NOUNI option with a multivariate or repeated measures analysis of variance when you do not need the standard univariate results. The NOUNI option in a MODEL statement does not affect the univariate output produced by the REPEATED statement.

**P**

displays observed, predicted, and residual values for each observation that does not contain missing values for independent variables. The Durbin-Watson statistic is also displayed when the P option is specified. The PRESS statistic is also produced if either the CLM or CLI option is specified.

**SINGULAR=number**

tunes the sensitivity of the regression routine to linear dependencies in the design. If a diagonal pivot element is less than $C \times number$ as PROC GLM sweeps the $X'X$ matrix, the associated design column is declared to be linearly dependent with previous columns, and the associated parameter is zeroed.

The $C$ value adjusts the check to the relative scale of the variable. The $C$ value is equal to the corrected sum of squares for the variable, unless the corrected sum of squares is 0, in which case $C$ is 1. If you specify the NOINT option but not the ABSORB statement, PROC GLM uses the uncorrected sum of squares instead.

The default value of the SINGULAR= option, $10^{-7}$, may be too small, but this value is necessary in order to handle the high-degree polynomials used in the literature to compare regression routines.

**SOLUTION**

produces a solution to the normal equations (parameter estimates). PROC GLM displays a solution by default when your model involves no classification variables, so you need this option only if you want to see the solution for models with classification effects.

**SS1**

displays the sum of squares associated with Type I estimable functions for each effect. These are also displayed by default.
SS2  
   displays the sum of squares associated with Type II estimable functions for each effect.

SS3  
   displays the sum of squares associated with Type III estimable functions for each effect. These are also displayed by default.

SS4  
   displays the sum of squares associated with Type IV estimable functions for each effect.

TOLERANCE  
   displays the tolerances used in the SWEEP routine. The tolerances are of the form C/US or C/CSS, as described in the discussion of the SINGULAR= option. The tolerance value for the intercept is not divided by its uncorrected sum of squares.

XPX  
   displays the augmented $X'X$ crossproducts matrix:

   $\begin{bmatrix}
   X'X & X'Y \\
   Y'X & Y'Y
   \end{bmatrix}$

ZETA=value  
   tunes the sensitivity of the check for estimability for Type III and Type IV functions. Any element in the estimable function basis with an absolute value less than the ZETA= option is set to zero. The default value for the ZETA= option is $10^{-8}$.

   Although it is possible to generate data for which this absolute check can be defeated, the check suffices in most practical examples. Additional research needs to be performed to make this check relative rather than absolute.

### OUTPUT Statement

```
OUTPUT < OUTPUT=SAS-data-set > keyword=names < . . . keyword=names > < / option > ;
```

The OUTPUT statement creates a new SAS data set that saves diagnostic measures calculated after fitting the model. At least one specification of the form `keyword=names` is required.

All the variables in the original data set are included in the new data set, along with variables created in the OUTPUT statement. These new variables contain the values of a variety of diagnostic measures that are calculated for each observation in the data set. If you want to create a permanent SAS data set, you must specify a two-level name (refer to *SAS Language Reference: Concepts* for more information on permanent SAS data sets).

Details on the specifications in the OUTPUT statement follow.

`keyword=names`  
   specifies the statistics to include in the output data set and provides names to the new variables that contain the statistics. Specify a keyword for each desired statistic (see
the following list of keywords), an equal sign, and the variable or variables to contain the statistic.

In the output data set, the first variable listed after a keyword in the OUTPUT statement contains that statistic for the first dependent variable listed in the MODEL statement; the second variable contains the statistic for the second dependent variable in the MODEL statement, and so on. The list of variables following the equal sign can be shorter than the list of dependent variables in the MODEL statement. In this case, the procedure creates the new names in order of the dependent variables in the MODEL statement. See the “Examples” section on page 1775.

The keywords allowed and the statistics they represent are as follows:

- **COOKD**  
  Cook’s $D$ influence statistic

- **COVRATIO**  
  standard influence of observation on covariance of parameter estimates

- **DFFITS**  
  standard influence of observation on predicted value

- **H**  
  leverage, $h_i = x_i(X'X)^{-1}x_i'$

- **LCL**  
  lower bound of a $100(1 - p)\%$ confidence interval for an individual prediction. The $p$-level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the ALPHA= option in the PROC GLM statement. If neither of these options is set then $p = 0.05$ by default, resulting in the lower bound for a 95% confidence interval. The interval also depends on the variance of the error, as well as the variance of the parameter estimates. For the corresponding upper bound, see the **UCL** keyword.

- **LCLM**  
  lower bound of a $100(1 - p)\%$ confidence interval for the expected value (mean) of the predicted value. The $p$-level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the ALPHA= option in the PROC GLM statement. If neither of these options is set then $p = 0.05$ by default, resulting in the lower bound for a 95% confidence interval. For the corresponding upper bound, see the **UCLM** keyword.

- **PREDICTED | P**  
  predicted values

- **PRESS**  
  residual for the $i$th observation that results from dropping it and predicting it on the basis of all other observations. This is the residual divided by $(1 - h_i)$ where $h_i$ is the leverage, defined previously.

- **RESIDUAL | R**  
  residuals, calculated as $\text{ACTUAL} - \text{PREDICTED}$

- **RSTUDENT**  
  a studentized residual with the current observation deleted

- **STDI**  
  standard error of the individual predicted value

- **STDP**  
  standard error of the mean predicted value

- **STDR**  
  standard error of the residual

- **STUDENT**  
  studentized residuals, the residual divided by its standard error
UCL upper bound of a $100(1 - p)\%$ confidence interval for an individual prediction. The $p$-level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the ALPHA= option in the PROC GLM statement. If neither of these options is set then $p = 0.05$ by default, resulting in the upper bound for a 95% confidence interval. The interval also depends on the variance of the error, as well as the variance of the parameter estimates. For the corresponding lower bound, see the LCL keyword.

UCLM upper bound of a $100(1 - p)\%$ confidence interval for the expected value (mean) of the predicted value. The $p$-level is equal to the value of the ALPHA= option in the OUTPUT statement or, if this option is not specified, to the ALPHA= option in the PROC GLM statement. If neither of these options is set then $p = 0.05$ by default, resulting in the upper bound for a 95% confidence interval. For the corresponding lower bound, see the LCLM keyword.

**OUT=SAS-data-set**

Gives the name of the new data set. By default, the procedure uses the DATA convention to name the new data set.

The following option is available in the OUTPUT statement and is specified after a slash(/):

**ALPHA=p**

Specifies the level of significance $p$ for $100(1 - p)\%$ confidence intervals. By default, $p$ is equal to the value of the ALPHA= option in the PROC GLM statement or 0.05 if that option is not specified. You may use values between 0 and 1.

**Examples**

The following statements show the syntax for creating an output data set with a single dependent variable.

```sas
proc glm;
  class a b;
  model y=a b a*b;
  output out=new p=yhat r=resid stdr=eresid;
run;
```

These statements create an output data set named `new`. In addition to all the variables from the original data set, `new` contains the variable `yhat`, with values that are predicted values of the dependent variable $y$; the variable `resid`, with values that are the residual values of $y$; and the variable `eresid`, with values that are the standard errors of the residuals.

The following statements show a situation with five dependent variables.
proc glm;
by group;
class a;
model y1-y5=a x(a);
output out=pout predicted=py1-py5;
run;

Data set pout contains five new variables, py1 through py5. The values of py1 are the predicted values of y1; the values of py2 are the predicted values of y2; and so on.

For more information on the data set produced by the OUTPUT statement, see the section “Output Data Sets” on page 1840.

**RANDOM Statement**

```
RANDOM effects < / options > ;
```

When some model effects are random (that is, assumed to be sampled from a normal population of effects), you can specify these effects in the RANDOM statement in order to compute the expected values of mean squares for various model effects and contrasts and, optionally, to perform random effects analysis of variance tests. You can use as many RANDOM statements as you want, provided that they appear after the MODEL statement. If you use a CONTRAST statement with a RANDOM statement and you want to obtain the expected mean squares for the contrast hypothesis, you must enter the CONTRAST statement before the RANDOM statement.

**Note:** PROC GLM uses only the information pertaining to expected mean squares when you specify the TEST option in the RANDOM statement and, even then, only in the extra $F$ tests produced by the RANDOM statement. Other features in the GLM procedure—including the results of the LSMEANS and ESTIMATE statements—assume that all effects are fixed, so that all tests and estimability checks for these statements are based on a fixed effects model, even when you use a RANDOM statement. Therefore, you should use the MIXED procedure to compute tests involving these features that take the random effects into account; see the section “PROC GLM versus PROC MIXED for Random Effects Analysis” on page 1833 and Chapter 46, “The MIXED Procedure,” for more information.

When you use the RANDOM statement, by default the GLM procedure produces the Type III expected mean squares for model effects and for contrasts specified before the RANDOM statement in the program code. In order to obtain expected values for other types of mean squares, you need to specify which types of mean squares are of interest in the MODEL statement. See the section “Computing Type I, II, and IV Expected Mean Squares” on page 1835 for more information.

The list of effects in the RANDOM statement should contain one or more of the pure classification effects specified in the MODEL statement (that is, main effects, crossed effects, or nested effects involving only class variables). The coefficients corresponding to each effect specified are assumed to be normally and independently distributed with common variance. Levels in different effects are assumed to be independent.
You can specify the following options in the RANDOM statement after a slash:

**Q**

displays all quadratic forms in the fixed effects that appear in the expected mean squares. For some designs, large mixed-level factorials, for example, the Q option may generate a substantial amount of output.

**TEST**

performs hypothesis tests for each effect specified in the model, using appropriate error terms as determined by the expected mean squares.

**Caution:** PROC GLM does not automatically declare interactions to be random when the effects in the interaction are declared random. For example,

```
random a b / test;
```

does not produce the same expected mean squares or tests as

```
random a b a*b / test;
```

To ensure correct tests, you need to list all random interactions and random main effects in the RANDOM statement.

See the section “Random Effects Analysis” on page 1833 for more information on the calculation of expected mean squares and tests and on the similarities and differences between the GLM and MIXED procedures. See Chapter 3, “Introduction to Analysis-of-Variance Procedures,” and Chapter 46, “The MIXED Procedure,” for more information on random effects.

---

**REPEATED Statement**

```
REPEATED factor-specification < / options > ;
```

When values of the dependent variables in the MODEL statement represent repeated measurements on the same experimental unit, the REPEATED statement enables you to test hypotheses about the measurement factors (often called *within-subject factors*) as well as the interactions of within-subject factors with independent variables in the MODEL statement (often called *between-subject factors*). The REPEATED statement provides multivariate and univariate tests as well as hypothesis tests for a variety of single-degree-of-freedom contrasts. There is no limit to the number of within-subject factors that can be specified.

The REPEATED statement is typically used for handling repeated measures designs with one repeated response variable. Usually, the variables on the left-hand side of the equation in the MODEL statement represent one repeated response variable. This does not mean that only one factor can be listed in the REPEATED statement. For example, one repeated response variable (hemoglobin count) might be measured 12 times (implying variables Y1 to Y12 on the left-hand side of the equal sign in the MODEL statement), with the associated within-subject factors treatment and time
(implying two factors listed in the REPEATED statement). See the “Examples” section on page 1781 for an example of how PROC GLM handles this case. Designs with two or more repeated response variables can, however, be handled with the IDENTITY transformation; see page 1779 for more information, and Example 32.9 on page 1886 for an example of analyzing a doubly-multivariate repeated measures design.

When a REPEATED statement appears, the GLM procedure enters a multivariate mode of handling missing values. If any values for variables corresponding to each combination of the within-subject factors are missing, the observation is excluded from the analysis.

If you use a CONTRAST or TEST statement with a REPEATED statement, you must enter the CONTRAST or TEST statement before the REPEATED statement.

The simplest form of the REPEATED statement requires only a factor-name. With two repeated factors, you must specify the factor-name and number of levels (levels) for each factor. Optionally, you can specify the actual values for the levels (level-values), a transformation that defines single-degree-of freedom contrasts, and options for additional analyses and output. When you specify more than one within-subject factor, the factor-names (and associated level and transformation information) must be separated by a comma in the REPEATED statement. These terms are described in the following section, “Syntax Details.”

**Syntax Details**

You can specify the following terms in the REPEATED statement.

**factor-specification**

The factor-specification for the REPEATED statement can include any number of individual factor specifications, separated by commas, of the following form:

\[
\text{factor-name levels (level-values) > transformation}
\]

where

**factor-name** names a factor to be associated with the dependent variables. The name should not be the same as any variable name that already exists in the data set being analyzed and should conform to the usual conventions of SAS variable names.

When specifying more than one factor, list the dependent variables in the MODEL statement so that the within-subject factors defined in the REPEATED statement are nested; that is, the first factor defined in the REPEATED statement should be the one with values that change least frequently.

**levels** gives the number of levels associated with the factor being defined. When there is only one within-subject factor, the number of levels is equal to the number of dependent variables. In this case, levels is optional. When more than one within-subject factor is defined,
however, *levels* is required, and the product of the number of levels of all the factors must equal the number of dependent variables in the MODEL statement.

(*level-values*) gives values that correspond to levels of a repeated-measures factor. These values are used to label output and as spacings for constructing orthogonal polynomial contrasts if you specify a POLYNOMIAL transformation. The number of values specified must correspond to the number of levels for that factor in the REPEATED statement. Enclose the *level-values* in parentheses.

The following transformation keywords define single-degree-of-freedom contrasts for factors specified in the REPEATED statement. Since the number of contrasts generated is always one less than the number of levels of the factor, you have some control over which contrast is omitted from the analysis by which transformation you select. The only exception is the IDENTITY transformation; this transformation is not composed of contrasts and has the same degrees of freedom as the factor has levels. By default, the procedure uses the CONTRAST transformation.

**CONTRAST** < *(ordinal-reference-level)* > generates contrasts between levels of the factor and a reference level. By default, the procedure uses the last level as the reference level; you can optionally specify a reference level in parentheses after the keyword CONTRAST. The reference level corresponds to the ordinal value of the level rather than the level value specified. For example, to generate contrasts between the first level of a factor and the other levels, use

```
contrast(1)
```

**HELMERT** generates contrasts between each level of the factor and the mean of subsequent levels.

**IDENTITY** generates an identity transformation corresponding to the associated factor. This transformation is *not* composed of contrasts; it has *n* degrees of freedom for an *n*-level factor, instead of *n* − 1. This can be used for doubly-multivariate repeated measures.

**MEAN** < *(ordinal-reference-level)* > generates contrasts between levels of the factor and the mean of all other levels of the factor. Specifying a reference level eliminates the contrast between that level and the mean. Without a reference level, the contrast involving the last level is omitted. See the CONTRAST transformation for an example.

**POLYNOMIAL** generates orthogonal polynomial contrasts. Level values, if provided, are used as spacings in the construction of the polynomials; otherwise, equal spacing is assumed.

**PROFILE** generates contrasts between adjacent levels of the factor.

You can specify the following options in the REPEATED statement after a slash.
CANONICAL
performs a canonical analysis of the $H$ and $E$ matrices corresponding to the transformed variables specified in the REPEATED statement.

HTYPE=n
specifies the type of the $H$ matrix used in the multivariate tests and the type of sums of squares used in the univariate tests. See the HTYPE= option in the specifications for the MANOVA statement for further details.

MEAN
generates the overall arithmetic means of the within-subject variables.

MSTAT=FAPPROX
MSTAT=EXACT
specifies the method of evaluating the test statistics for the multivariate analysis. The default is MSTAT=FAPPROX, which specifies that the multivariate tests are evaluated using the usual approximations based on the $F$ distribution, as discussed in the “Multivariate Tests” section in Chapter 2, “Introduction to Regression Procedures.” Alternatively, you can specify MSTAT=EXACT to compute exact $p$-values for three of the four tests (Wilks’ Lambda, the Hotelling-Lawley Trace, and Roy’s Greatest Root) and an improved $F$-approximation for the fourth (Pillai’s Trace). While MSTAT=EXACT provides better control of the significance probability for the tests, especially for Roy’s Greatest Root, computations for the exact $p$-values can be appreciably more demanding, and are in fact infeasible for large problems (many dependent variables). Thus, although MSTAT=EXACT is more accurate for most data, it is not the default method. For more information on the results of MSTAT=EXACT, see the “Multivariate Analysis of Variance” section on page 1823.

NOM
displays only the results of the univariate analyses.

NOU
displays only the results of the multivariate analyses.

PRINTE
displays the $E$ matrix for each combination of within-subject factors, as well as partial correlation matrices for both the original dependent variables and the variables defined by the transformations specified in the REPEATED statement. In addition, the PRINTE option provides sphericity tests for each set of transformed variables. If the requested transformations are not orthogonal, the PRINTE option also provides a sphericity test for a set of orthogonal contrasts.

PRINTH
displays the $H$ (SSCP) matrix associated with each multivariate test.

PRINTM
displays the transformation matrices that define the contrasts in the analysis. PROC GLM always displays the $M$ matrix so that the transformed variables are defined by the rows, not the columns, of the displayed $M$ matrix. In other words, PROC GLM actually displays $M’$. 
PRINTRV

displays the characteristic roots and vectors for each multivariate test.

SUMMARY

produces analysis-of-variance tables for each contrast defined by the within-subject factors. Along with tests for the effects of the independent variables specified in the MODEL statement, a term labeled MEAN tests the hypothesis that the overall mean of the contrast is zero.

Examples

When specifying more than one factor, list the dependent variables in the MODEL statement so that the within-subject factors defined in the REPEATED statement are nested; that is, the first factor defined in the REPEATED statement should be the one with values that change least frequently. For example, assume that three treatments are administered at each of four times, for a total of twelve dependent variables on each experimental unit. If the variables are listed in the MODEL statement as Y1 through Y12, then the following REPEATED statement

```
proc glm;
   classes group;
   model Y1-Y12=group / nouni;
   repeated trt 3, time 4;
run;
```

implies the following structure:

<table>
<thead>
<tr>
<th>Dependent Variables</th>
<th>Y1</th>
<th>Y2</th>
<th>Y3</th>
<th>Y4</th>
<th>Y5</th>
<th>Y6</th>
<th>Y7</th>
<th>Y8</th>
<th>Y9</th>
<th>Y10</th>
<th>Y11</th>
<th>Y12</th>
</tr>
</thead>
<tbody>
<tr>
<td>Value of trt</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>2</td>
<td>3</td>
<td>3</td>
<td>3</td>
</tr>
<tr>
<td>Value of time</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>4</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>4</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>4</td>
</tr>
</tbody>
</table>

The REPEATED statement always produces a table like the preceding one. For more information, see the section “Repeated Measures Analysis of Variance” on page 1825.

TEST Statement

```
TEST < H=effects > E=effect < / options >;
```

Although an $F$ value is computed for all sums of squares in the analysis using the residual MS as an error term, you may request additional $F$ tests using other effects as error terms. You need a TEST statement when a nonstandard error structure (as in a split-plot design) exists. Note, however, that this may not be appropriate if the design is unbalanced, since in most unbalanced designs with nonstandard error structures, mean squares are not necessarily independent with equal expectations under the null hypothesis.
Caution: The GLM procedure does not check any of the assumptions underlying the $F$ statistic. When you specify a TEST statement, you assume sole responsibility for the validity of the $F$ statistic produced. To help validate a test, you can use the RANDOM statement and inspect the expected mean squares, or you can use the TEST option of the RANDOM statement.

You may use as many TEST statements as you want, provided that they appear after the MODEL statement.

You can specify the following terms in the TEST statement.

$H=\text{effects}$ specifies which effects in the preceding model are to be used as hypothesis (numerator) effects.

$E=\text{effect}$ specifies one, and only one, effect to use as the error (denominator) term. The $E=$ specification is required.

By default, the sum of squares type for all hypothesis sum of squares and error sum of squares is the highest type computed in the model. If the hypothesis type or error type is to be another type that was computed in the model, you should specify one or both of the following options after a slash.

$\text{ETYPE}=n$ specifies the type of sum of squares to use for the error term. The type must be a type computed in the model ($n=1, 2, 3, \text{ or } 4$).

$\text{HTYPE}=n$ specifies the type of sum of squares to use for the hypothesis. The type must be a type computed in the model ($n=1, 2, 3, \text{ or } 4$).

This example illustrates the TEST statement with a split-plot model:

```plaintext
proc glm;
  class a b c;
  model y=a b(a) c a*c b*c(a);
  test h=a e=b(a)/ htype=1 etype=1;
  test h=c a*c e=b*c(a) / htype=1 etype=1;
run;
```

**WEIGHT Statement**

**WEIGHT** variable;

When a WEIGHT statement is used, a weighted residual sum of squares

$$\sum_i w_i(y_i - \hat{y}_i)^2$$

is minimized, where $w_i$ is the value of the variable specified in the WEIGHT statement, $y_i$ is the observed value of the response variable, and $\hat{y}_i$ is the predicted value of the response variable.
If you specify the WEIGHT statement, it must appear before the first RUN statement or it is ignored.

An observation is used in the analysis only if the value of the WEIGHT statement variable is nonmissing and greater than zero.

The WEIGHT statement has no effect on degrees of freedom or number of observations, but it is used by the MEANS statement when calculating means and performing multiple comparison tests (as described in the “MEANS Statement” section beginning on page 1763). The normal equations used when a WEIGHT statement is present are

\[ X'WX\beta = X'WY \]

where \( W \) is a diagonal matrix consisting of the values of the variable specified in the WEIGHT statement.

If the weights for the observations are proportional to the reciprocals of the error variances, then the weighted least-squares estimates are best linear unbiased estimators (BLUE).

## Details

### Statistical Assumptions for Using PROC GLM

The basic statistical assumption underlying the least-squares approach to general linear modeling is that the observed values of each dependent variable can be written as the sum of two parts: a fixed component \( x'\beta \), which is a linear function of the independent coefficients, and a random noise, or error, component \( \epsilon \):

\[ y = x'\beta + \epsilon \]

The independent coefficients \( x \) are constructed from the model effects as described in the “Parameterization of PROC GLM Models” section on page 1787. Further, the errors for different observations are assumed to be uncorrelated with identical variances. Thus, this model can be written

\[ E(Y) = X\beta, \quad \text{Var}(Y) = \sigma^2 I \]

where \( Y \) is the vector of dependent variable values, \( X \) is the matrix of independent coefficients, \( I \) is the identity matrix, and \( \sigma^2 \) is the common variance for the errors. For multiple dependent variables, the model is similar except that the errors for different dependent variables within the same observation are not assumed to be uncorrelated. This yields a multivariate linear model of the form

\[ E(Y) = XB, \quad \text{Var}(\text{vec}(Y)) = \Sigma \otimes I \]
where \( Y \) and \( B \) are now matrices, with one column for each dependent variable, \( \text{vec}(Y) \) strings \( Y \) out by rows, and \( \otimes \) indicates the Kronecker matrix product.

Under the assumptions thus far discussed, the least-squares approach provides estimates of the linear parameters that are unbiased and have minimum variance among linear estimators. Under the further assumption that the errors have a normal (or Gaussian) distribution, the least-squares estimates are the maximum likelihood estimates and their distribution is known. All of the significance levels (“\( p \) values”) and confidence limits calculated by the GLM procedure require this assumption of normality in order to be exactly valid, although they are good approximations in many other cases.

### Specification of Effects

Each term in a model, called an effect, is a variable or combination of variables. Effects are specified with a special notation using variable names and operators. There are two kinds of variables: classification (or class) variables and continuous variables. There are two primary operators: crossing and nesting. A third operator, the bar operator, is used to simplify effect specification.

In an analysis-of-variance model, independent variables must be variables that identify classification levels. In the SAS System, these are called class variables and are declared in the CLASS statement. (They can also be called categorical, qualitative, discrete, or nominal variables.) Class variables can be either numeric or character. The values of a class variable are called levels. For example, the class variable Sex has the levels “male” and “female.”

In a model, an independent variable that is not declared in the CLASS statement is assumed to be continuous. Continuous variables, which must be numeric, are used for response variables and covariates. For example, the heights and weights of subjects are continuous variables.

### Types of Effects

There are seven different types of effects used in the GLM procedure. In the following list, assume that \( A, B, C, D, \) and \( E \) are class variables and that \( X_1, X_2, \) and \( Y \) are continuous variables:

- Regressor effects are specified by writing continuous variables by themselves: \( X_1 \ \text{X2} \).
- Polynomial effects are specified by joining two or more continuous variables with asterisks: \( X_1 \ast X_1 \ \text{X1} \ast X_2 \).
- Main effects are specified by writing class variables by themselves: \( A \ \text{B} \ \text{C} \).
- Crossed effects (interactions) are specified by joining class variables with asterisks: \( A \ast B \ \text{B} \ast C \ \text{A} \ast \text{B} \ast \text{C} \).
• Nested effects are specified by following a main effect or crossed effect with a class variable or list of class variables enclosed in parentheses. The main effect or crossed effect is nested within the effects listed in parentheses:

\[ B(A) \quad C(B*A) \quad D*E(C*B*A) . \]

In this example, \( B(A) \) is read “\( B \) nested within \( A \).”

• Continuous-by-class effects are written by joining continuous variables and class variables with asterisks: \( X1*A \).

• Continuous-nesting-class effects consist of continuous variables followed by a class variable interaction enclosed in parentheses: \( X1(A) \quad X1*X2(A*B) \).

One example of the general form of an effect involving several variables is

\[ X1*X2*A*B*C(D*E) \]

This example contains crossed continuous terms by crossed classification terms nested within more than one class variable. The continuous list comes first, followed by the crossed list, followed by the nesting list in parentheses. Note that asterisks can appear within the nested list but not immediately before the left parenthesis. For details on how the design matrix and parameters are defined with respect to the effects specified in this section, see the section “Parameterization of PROC GLM Models” on page 1787.

The MODEL statement and several other statements use these effects. Some examples of MODEL statements using various kinds of effects are shown in the following table; \( a, b, \) and \( c \) represent class variables, and \( y, y1, y2, x, \) and \( z \) represent continuous variables.

<table>
<thead>
<tr>
<th>Specification</th>
<th>Kind of Model</th>

<td>separate-slopes model</td>
</tr>
<tr>
<td>model y=a x x*a;</td>
<td>homogeneity-of-slopes model</td>
</tr>
</tbody>
</table>
The Bar Operator

You can shorten the specification of a large factorial model using the bar operator. For example, two ways of writing the model for a full three-way factorial model are

```r
proc glm;
  class A B C;
  model Y=A B C A*B A*C B*C A*B*C;
run;
```

When the bar (|) is used, the right- and left-hand sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 given in Searle (1971, p. 390).

- Multiple bars are evaluated left to right. For instance, \(A \mid B \mid C\) is evaluated as follows.
  \[
  A \mid B \mid C \rightarrow \{A \mid B\} \mid C \\
  \rightarrow \{A \ B \ A*B\} \mid C \\
  \rightarrow A \ B \ A*B \ C \ A*C \ B*C \ A*B*C
  \]

- Crossed and nested groups of variables are combined. For example, \(A(\ B) \mid C(D)\) generates \(A*C(B \ D)\), among other terms.

- Duplicate variables are removed. For example, \(A(C) \mid B(C)\) generates \(A*B(C\ C)\), among other terms, and the extra \(C\) is removed.

- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For instance, \(A(\ B) \mid B(\ D \ E)\) generates \(A*B(B \ D \ E)\), but this effect is eliminated immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an @ sign, at the end of the bar effect. For example, the specification \(A \mid B \mid C@2\) would result in only those effects that contain 2 or fewer variables: in this case, \(A \ B \ A*B \ C \ A*C\) and \(B*C\).

The following table gives more examples of using the bar and at operators.

<table>
<thead>
<tr>
<th>(A \mid C(B))</th>
<th>is equivalent to</th>
<th>(A \ C(B) \ A*C(B))</th>
</tr>
</thead>
<tbody>
<tr>
<td>(A(B) \mid C(B))</td>
<td>is equivalent to</td>
<td>(A(B) \ C(B) \ A*C(B))</td>
</tr>
<tr>
<td>(A(B) \mid B(D) \ E)</td>
<td>is equivalent to</td>
<td>(A(B) \ B(D) \ E)</td>
</tr>
<tr>
<td>(A \mid B(A) \mid C)</td>
<td>is equivalent to</td>
<td>(A \ B(A) \ C \ A<em>C \ B</em>C(A))</td>
</tr>
<tr>
<td>(A \mid B(A) \mid C@2)</td>
<td>is equivalent to</td>
<td>(A \ B(A) \ C \ A*C)</td>
</tr>
<tr>
<td>(A \mid B \mid C \mid D@2)</td>
<td>is equivalent to</td>
<td>(A \ B \ A<em>B \ C \ A</em>C \ B<em>C \ D \ A</em>D \ B<em>D \ C</em>D)</td>
</tr>
<tr>
<td>(A<em>B(C</em>D))</td>
<td>is equivalent to</td>
<td>(A*B(C \ D))</td>
</tr>
</tbody>
</table>
Using PROC GLM Interactively

You can use the GLM procedure interactively. After you specify a model with a MODEL statement and run PROC GLM with a RUN statement, you can execute a variety of statements without reinvoking PROC GLM.

The “Syntax” section (page 1742) describes which statements can be used interactively. These interactive statements can be executed singly or in groups by following the single statement or group of statements with a RUN statement. Note that the MODEL statement cannot be repeated; PROC GLM allows only one MODEL statement.

If you use PROC GLM interactively, you can end the GLM procedure with a DATA step, another PROC step, an ENDSAS statement, or a QUIT statement.

When you are using PROC GLM interactively, additional RUN statements do not end the procedure but tell PROC GLM to execute additional statements.

When you specify a WHERE statement with PROC GLM, it should appear before the first RUN statement. The WHERE statement enables you to select only certain observations for analysis without using a subsetting DATA step. For example, the statement
\[
\text{WHERE group ne 5 ;}
\]
omits observations with GROUP = 5 from the analysis. Refer to SAS Language Reference: Dictionary for details on this statement.

When you specify a BY statement with PROC GLM, interactive processing is not possible; that is, once the first RUN statement is encountered, processing proceeds for each BY group in the data set, and no further statements are accepted by the procedure.

Interactivity is also disabled when there are different patterns of missing values among the dependent variables. For details, see the “Missing Values” section on page 1836.

Parameterization of PROC GLM Models

The GLM procedure constructs a linear model according to the specifications in the MODEL statement. Each effect generates one or more columns in a design matrix $X$. This section shows precisely how $X$ is built.

**Intercept**

All models include a column of 1s by default to estimate an intercept parameter $\mu$. You can use the NOINT option to suppress the intercept.

**Regression Effects**

Regression effects (covariates) have the values of the variables copied into the design matrix directly. Polynomial terms are multiplied out and then installed in $X$. 
Main Effects

If a class variable has \( m \) levels, PROC GLM generates \( m \) columns in the design matrix for its main effect. Each column is an indicator variable for one of the levels of the class variable. The default order of the columns is the sort order of the values of their levels; this order can be controlled with the ORDER= option in the PROC GLM statement, as shown in the following table.

<table>
<thead>
<tr>
<th>Data</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A B</td>
<td>A1 A2 B1 B2 B3</td>
</tr>
<tr>
<td>1 1</td>
<td>1 1 0 0 0 0 0 0</td>
</tr>
<tr>
<td>1 2</td>
<td>1 1 1 1 0 0 1 0</td>
</tr>
<tr>
<td>1 3</td>
<td>1 1 1 1 0 0 0 1</td>
</tr>
<tr>
<td>2 1</td>
<td>1 0 1 0 1 0 0 0</td>
</tr>
<tr>
<td>2 2</td>
<td>1 0 1 0 0 0 0 1</td>
</tr>
<tr>
<td>2 3</td>
<td>1 0 1 0 0 0 0 1</td>
</tr>
</tbody>
</table>

There are more columns for these effects than there are degrees of freedom for them; in other words, PROC GLM is using an over-parameterized model.

Crossed Effects

First, PROC GLM reorders the terms to correspond to the order of the variables in the CLASS statement; thus, \( B*A \) becomes \( A*B \) if \( A \) precedes \( B \) in the CLASS statement. Then, PROC GLM generates columns for all combinations of levels that occur in the data. The order of the columns is such that the rightmost variables in the cross index faster than the leftmost variables. No columns are generated corresponding to combinations of levels that do not occur in the data.

<table>
<thead>
<tr>
<th>Data</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 1</td>
<td>1 1 0 1 0 0 1 0 0 0 0 0</td>
</tr>
<tr>
<td>1 2</td>
<td>1 1 0 0 1 0 0 1 0 0 0 0</td>
</tr>
<tr>
<td>1 3</td>
<td>1 1 0 0 0 1 0 0 1 0 0 0</td>
</tr>
<tr>
<td>2 1</td>
<td>1 0 1 1 0 0 0 0 1 0 0 0</td>
</tr>
<tr>
<td>2 2</td>
<td>1 0 1 0 1 0 0 0 0 1 0 0</td>
</tr>
<tr>
<td>2 3</td>
<td>1 0 1 0 0 1 0 0 0 0 0 1</td>
</tr>
</tbody>
</table>

In this matrix, main-effects columns are not linearly independent of crossed-effect columns; in fact, the column space for the crossed effects contains the space of the main effect.
**Nested Effects**

Nested effects are generated in the same manner as crossed effects. Hence, the design columns generated by the following statements are the same (but the ordering of the columns is different):

```plaintext
model y=a b(a);  (B nested within A)
model y=a a*b;   (omitted main effect for B)
```

The nesting operator in PROC GLM is more a notational convenience than an operation distinct from crossing. Nested effects are characterized by the property that the nested variables never appear as main effects. The order of the variables within nesting parentheses is made to correspond to the order of these variables in the CLASS statement. The order of the columns is such that variables outside the parentheses index faster than those inside the parentheses, and the rightmost nested variables index faster than the leftmost variables.

</tr>
</tbody>
</table>

**Continuous-Nesting-Class Effects**

When a continuous variable nests with a class variable, the design columns are constructed by multiplying the continuous values into the design columns for the class effect.

<table>
<thead>
<tr>
<th>Data</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>X</td>
<td>A</td>
</tr>
<tr>
<td>A</td>
<td>μ</td>
</tr>
<tr>

</tr>
<tr>
<td>28</td>
<td>2</td>
</tr>
<tr>
<td>19</td>
<td>2</td>
</tr>
<tr>
<td>23</td>
<td>2</td>
</tr>
</tbody>
</table>

This model estimates a separate slope for $X$ within each level of $A$.  

Continuous-by-Class Effects

Continuous-by-class effects generate the same design columns as continuous-nesting-class effects. The two models differ by the presence of the continuous variable as a regressor by itself, in addition to being a contributor to $X^A$.

![Data Design Matrix](image)

Continuous-by-class effects are used to test the homogeneity of slopes. If the continuous-by-class effect is nonsignificant, the effect can be removed so that the response with respect to $X$ is the same for all levels of the class variables.

General Effects

An example that combines all the effects is

$$X_1^*X_2^*A^*B^*C(D \ E)$$

The continuous list comes first, followed by the crossed list, followed by the nested list in parentheses.

The sequencing of parameters is important to learn if you use the CONTRAST or ESTIMATE statement to compute or test some linear function of the parameter estimates.

Effects may be retitled by PROC GLM to correspond to ordering rules. For example, $B^*A(E \ D)$ may be retitled $A^*B(D \ E)$ to satisfy the following:

- Class variables that occur outside parentheses (crossed effects) are sorted in the order in which they appear in the CLASS statement.
- Variables within parentheses (nested effects) are sorted in the order in which they appear in a CLASS statement.

The sequencing of the parameters generated by an effect can be described by which variables have their levels indexed faster:

- Variables in the crossed part index faster than variables in the nested list.
Within a crossed or nested list, variables to the right index faster than variables to the left.

For example, suppose a model includes four effects—A, B, C, and D—each having two levels, 1 and 2. If the CLASS statement is

```plaintext
class A B C D;
```

then the order of the parameters for the effect B*A(C D), which is retitled A*B(C D), is as follows.

\[
\begin{align*}
A_1B_1C_1D_1 \\
A_1B_2C_1D_1 \\
A_2B_1C_1D_1 \\
A_1B_1C_1D_2 \\
A_1B_2C_1D_2 \\
A_2B_1C_1D_2 \\
A_2B_2C_1D_2 \\
A_1B_1C_2D_1 \\
A_1B_2C_2D_1 \\
A_2B_1C_2D_1 \\
A_2B_2C_2D_1 \\
A_1B_1C_2D_2 \\
A_1B_2C_2D_2 \\
A_2B_1C_2D_2 \\
A_2B_2C_2D_2
\end{align*}
\]

Note that first the crossed effects B and A are sorted in the order in which they appear in the CLASS statement so that A precedes B in the parameter list. Then, for each combination of the nested effects in turn, combinations of A and B appear. The B effect changes fastest because it is rightmost in the (renamed) cross list. Then A changes next fastest. The D effect changes next fastest, and C is the slowest since it is leftmost in the nested list.

When numeric class variables are used, their levels are sorted by their character format, which may not correspond to their numeric sort sequence. Therefore, it is advisable to include a format for numeric class variables or to use the ORDER=INTERNAL option in the PROC GLM statement to ensure that levels are sorted by their internal values.

**Degrees of Freedom**

For models with classification (categorical) effects, there are more design columns constructed than there are degrees of freedom for the effect. Thus, there are linear dependencies among the columns. In this event, the parameters are not jointly estimable; there is an infinite number of least-squares solutions. The GLM procedure uses a generalized (g2) inverse to obtain values for the estimates; see the
“Computational Method” section on page 1840 for more details. The solution values are not produced unless the SOLUTION option is specified in the MODEL statement. The solution has the characteristic that estimates are zero whenever the design column for that parameter is a linear combination of previous columns. (Strictly termed, the solution values should not be called estimates, since the parameters may not be formally estimable.) With this full parameterization, hypothesis tests are constructed to test linear functions of the parameters that are estimable.

Other procedures (such as the CATMOD procedure) reparameterize models to full rank using certain restrictions on the parameters. PROC GLM does not reparameterize, making the hypotheses that are commonly tested more understandable. See Goodnight (1978a) for additional reasons for not reparameterizing.

PROC GLM does not actually construct the entire design matrix $X$; rather, a row $x_i$ of $X$ is constructed for each observation in the data set and used to accumulate the crossproduct matrix $X'X = \sum_i x_i'x_i$.

### Hypothesis Testing in PROC GLM

See Chapter 11, “The Four Types of Estimable Functions,” for a complete discussion of the four standard types of hypothesis tests.

#### Example

To illustrate the four types of tests and the principles upon which they are based, consider a two-way design with interaction based on the following data:

<table>
<thead>
<tr>
<th></th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>23.5</td>
<td>28.7</td>
</tr>
<tr>
<td>2</td>
<td>23.7</td>
<td></td>
</tr>
<tr>
<td>3</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>8.9</td>
<td>5.6</td>
</tr>
<tr>
<td>2</td>
<td>5.6</td>
<td>8.9</td>
</tr>
<tr>
<td>3</td>
<td>10.3</td>
<td>13.6</td>
</tr>
<tr>
<td>3</td>
<td>12.5</td>
<td>14.6</td>
</tr>
</tbody>
</table>

Invoke PROC GLM and specify all the estimable functions options to examine what the GLM procedure can test. The following statements are followed by the summary ANOVA table. See Figure 32.8.

```plaintext
data example;
  input a b y @@;
datalines;
1 1 23.5 1 1 23.7 1 2 28.7 2 1 8.9 2 2 5.6
2 2 8.9 3 1 10.3 3 1 12.5 3 2 13.6 3 2 14.6
;
proc glm;
```
class a b;
model y=a b a*b / e e1 e2 e3 e4;
run;

The GLM Procedure

Figure 32.8. Summary ANOVA Table from PROC GLM

The following sections show the general form of estimable functions and discuss the
four standard tests, their properties, and abbreviated output for the two-way crossed
example.

Estimability

Figure 32.9 is the general form of estimable functions for the example. In order to be
testable, a hypothesis must be able to fit within the framework displayed here.

a∗b 3 2 L1−L2−L3−L5+L7+L9

Figure 32.9. General Form of Estimable Functions
If a hypothesis is estimable, the \( L \)s in the preceding scheme can be set to values that match the hypothesis. All the standard tests in PROC GLM can be shown in the preceding format, with some of the \( L \)s zeroed and some set to functions of other \( L \)s.

The following sections show how many of the hypotheses can be tested by comparing the model sum-of-squares regression from one model to a submodel. The notation used is

\[
SS(B \text{ effects}|A \text{ effects}) = SS(B \text{ effects}, A \text{ effects}) - SS(A \text{ effects})
\]

where \( SS(A \text{ effects}) \) denotes the regression model sum of squares for the model consisting of \( A \text{ effects} \). This notation is equivalent to the reduction notation defined by Searle (1971) and summarized in Chapter 11, “The Four Types of Estimable Functions.”

**Type I Tests**

Type I sums of squares (SS), also called *sequential sums of squares*, are the incremental improvement in error sums of squares as each effect is added to the model. They can be computed by fitting the model in steps and recording the difference in error sum of squares at each step.

<table>
<thead>
<tr>
<th>Source</th>
<th>Type I SS</th>
</tr>
</thead>
<tbody>
<tr>
<td>( A )</td>
<td>( SS(A</td>
</tr>
<tr>
<td>( B )</td>
<td>( SS(B</td>
</tr>
<tr>
<td>( A*B )</td>
<td>( SS(A*B</td>
</tr>
</tbody>
</table>

Type I sums of squares are displayed by default because they are easy to obtain and can be used in various hand calculations to produce sum of squares values for a series of different models. Nelder (1994) and others have argued that Type I and II sums are essentially the only appropriate ones for testing ANOVA effects; however, refer also to the discussion of Nelder’s article, especially Rodriguez et al. (1995) and Searle (1995).

The Type I hypotheses have these properties:

- Type I sum of squares for all effects add up to the model sum of squares. None of the other sum of squares types have this property, except in special cases.
- Type I hypotheses can be derived from rows of the Forward-Dolittle transformation of \( X'X \) (a transformation that reduces \( X'X \) to an upper triangular matrix by row operations).
- Type I sum of squares are statistically independent of each other under the usual assumption that the true residual errors are independent and identically normally distributed (see page 1783).
- Type I hypotheses depend on the order in which effects are specified in the MODEL statement.
• Type I hypotheses are uncontaminated by parameters corresponding to effects that precede the effect being tested; however, the hypotheses usually involve parameters for effects following the tested effect in the model. For example, in the model

\[ Y = A \times B; \]

the Type I hypothesis for \( B \) does not involve \( A \) parameters, but the Type I hypothesis for \( A \) does involve \( B \) parameters.

• Type I hypotheses are functions of the cell counts for unbalanced data; the hypotheses are not usually the same hypotheses that are tested if the data are balanced.

• Type I sums of squares are useful for polynomial models where you want to know the contribution of a term as though it had been made orthogonal to preceding effects. Thus, in polynomial models, Type I sums of squares correspond to tests of the orthogonal polynomial effects.

The Type I estimable functions and associated tests for the example are shown in Figure 32.10. (This combines tables from several pages of output.)
#### Type II Tests

The Type II tests can also be calculated by comparing the error sums of squares (SS) for subset models. The Type II SS are the reduction in error SS due to adding the term after all other terms have been added to the model except terms that contain the effect being tested. An effect is contained in another effect if it can be derived by deleting variables from the latter effect. For example, $A$ and $B$ are both contained in $A*B$. For this model

$$
\begin{align*}
\text{Source} & & \text{Type II SS} \\
A & & \text{SS}(A \mid \mu, B) \\
B & & \text{SS}(B \mid \mu, A) \\
A*B & & \text{SS}(A*B \mid \mu, A, B)
\end{align*}
$$

Type II SS have these properties:

- Type II SS do not necessarily sum to the model SS.
- The hypothesis for an effect does not involve parameters of other effects except for containing effects (which it must involve to be estimable).
- Type II SS are invariant to the ordering of effects in the model.
- For unbalanced designs, Type II hypotheses for effects that are contained in other effects are not usually the same hypotheses that are tested if the data are balanced. The hypotheses are generally functions of the cell counts.

The Type II estimable functions and associated tests for the example are shown in Figure 32.11. (Again, this combines tables from several pages of output.)

### Type III and Type IV Tests

Type III and Type IV sums of squares (SS), sometimes referred to as *partial sums of squares*, are considered by many to be the most desirable; see Searle (1987, Section 4.6). These SS cannot, in general, be computed by comparing model SS from several models using PROC GLM’s parameterization. However, they can sometimes be computed by reduction for methods that reparameterize to full rank, when such a reparameterization effectively imposes Type III linear constraints on the parameters. In PROC GLM, they are computed by constructing a hypothesis matrix \( L \) and then computing the SS associated with the hypothesis \( L\beta = 0 \). As long as there are no missing cells in the design, Type III and Type IV SS are the same.

These are properties of Type III and Type IV SS:

- The hypothesis for an effect does not involve parameters of other effects except for containing effects (which it must involve to be estimable).
- The hypotheses to be tested are invariant to the ordering of effects in the model.
- The hypotheses are the same hypotheses that are tested if there are no missing cells. They are not functions of cell counts.
- The SS do not generally add up to the model SS and, in some cases, can exceed the model SS.

The SS are constructed from the general form of estimable functions. Type III and Type IV tests are different only if the design has missing cells. In this case, the Type III tests have an orthogonality property, while the Type IV tests have a balancing property. These properties are discussed in Chapter 11, “The Four Types of Estimable Functions.” For this example, since the data contains observations for all pairs of levels of A and B, Type IV tests are identical to the Type III tests that are shown in Figure 32.12. (This combines tables from several pages of output.)

**Figure 32.12.** Type III Estimable Functions and Associated Tests
Absorption is a computational technique used to reduce computing resource needs in certain cases. The classic use of absorption occurs when a blocking factor with a large number of levels is a term in the model.

For example, the statements

```plaintext
proc glm;
    absorb herd;
    class a b;
    model y=a b a*b;
run;
```

are equivalent to

```plaintext
proc glm;
    class herd a b;
    model y=herd a b a*b;
run;
```

The exception to the previous statements is that the Type II, Type III, or Type IV SS for HERD are not computed when HERD is absorbed.

The algorithm for absorbing variables is similar to the one used by the NESTED procedure for computing a nested analysis of variance. As each new row of \([X|Y]\) (corresponding to the nonabsorbed independent effects and the dependent variables) is constructed, it is adjusted for the absorbed effects in a Type I fashion. The efficiency of the absorption technique is due to the fact that this adjustment can be done in one pass of the data and without solving any linear equations, assuming that the data have been sorted by the absorbed variables.

Several effects can be absorbed at one time. For example, these statements

```plaintext
proc glm;
    absorb herd cow;
    class a b;
    model y=a b a*b;
run;
```

are equivalent to

```plaintext
proc glm;
    class herd cow a b;
    model y=herd cow(herd) a b a*b;
run;
```
When you use absorption, the size of the $X^T X$ matrix is a function only of the effects in the MODEL statement. The effects being absorbed do not contribute to the size of the $X^T X$ matrix.

For the preceding example, $a$ and $b$ can be absorbed:

```sas
proc glm;
  absorb a b;
  class herd cow;
  model y=herd cow(herd);
run;
```

Although the sources of variation in the results are listed as

```
a  b(a)  herd  cow(herd)
```

all types of estimable functions for `herd` and `cow(herd)` are free of $a$, $b$, and $a*b$ parameters.

To illustrate the savings in computing using the ABSORB statement, PROC GLM is run on generated data with 1147 degrees of freedom in the model with the following statements:

```sas
data a;
  do herd=1 to 40;
    do cow=1 to 30;
      do treatment=1 to 3;
        do rep=1 to 2;
          y = herd/5 + cow/10 + treatment + rannor(1);
          output;
        end;
      end;
    end;
  end;
proc glm;
  class herd cow treatment;
  model y=herd cow(herd) treatment;
run;
```

This analysis would have required over 6 megabytes of memory for the $X^T X$ matrix had PROC GLM solved it directly. However, in the following statements, the GLM procedure needs only a $4 \times 4$ matrix for the intercept and treatment because the other effects are absorbed.

```sas
proc glm;
  absorb herd cow;
  class treatment;
  model y = treatment;
run;
```
These statements produce the results shown in Figure 32.13.

Figure 32.13. Absorption of Effects

Specification of ESTIMATE Expressions

Consider the model

\[ E(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3. \]

The corresponding MODEL statement for PROC GLM is

```
model y=x1 x2 x3;
```
To estimate the difference between the parameters for \( x_1 \) and \( x_2 \),

\[
\beta_1 - \beta_2 = \begin{pmatrix} 0 & 1 & -1 & 0 \end{pmatrix} \beta,
\]

where \( \beta = (\beta_0 \ \beta_1 \ \beta_2 \ \beta_3)' \),

you can use the following ESTIMATE statement:

\[
\text{estimate 'B1-B2' } x_1 \ 1 \ x_2 \ -1;
\]

To predict \( y \) at \( x_1 = 1, x_2 = 0 \), and \( x_3 = -2 \), you can estimate

\[
\beta_0 + \beta_1 - 2\beta_3 = \begin{pmatrix} 1 & 1 & 0 \end{pmatrix} \beta
\]

with the following ESTIMATE statement:

\[
\text{estimate 'B0+B1-2B3' intercept 1 x1 1 x3 -2;}
\]

Now consider models involving class variables such as

\[
\text{model } y = A \ B \ A*B;
\]

with the associated parameters:

\[
( \mu \ \alpha_1 \ \alpha_2 \ \alpha_3 \ \beta_1 \ \beta_2 \ \gamma_{11} \ \gamma_{12} \ \gamma_{21} \ \gamma_{22} \ \gamma_{31} \ \gamma_{32} )
\]

The LS-mean for the first level of \( A \) is \( L\beta \), where

\[
L = \begin{pmatrix} 1 & 1 & 0 & 0 & 0.5 & 0.5 & 0.5 & 0.5 & 0 & 0 & 0 & 0 \end{pmatrix}
\]

You can estimate this with the following ESTIMATE statement:

\[
\text{estimate 'LS-mean(A1)' intercept 1 A 1 B 0.5 0.5 A*B 0.5 0.5;}
\]

Note in this statement that only one element of \( L \) is specified following the \( A \) effect, even though \( A \) has three levels. Whenever the list of constants following an effect name is shorter than the effect’s number of levels, zeros are used as the remaining constants. (If the list of constants is longer than the number of levels for the effect, the extra constants are ignored, and a warning message is displayed.)

To estimate the \( A \) linear effect in the preceding model, assuming equally spaced levels for \( A \), you can use the following \( L \):

\[
L = \begin{pmatrix} 0 & -1 & 0 & 1 & 0 & 0 & -0.5 & -0.5 & 0 & 0 & 0.5 & 0.5 \end{pmatrix}
\]
The ESTIMATE statement for this $L$ is written as

$$\text{estimate 'A Linear' A -1 0 1;}$$

If you do not specify the elements of $L$ for an effect that contains a specified effect, then the elements of the specified effect are equally distributed over the corresponding levels of the higher-order effect. In addition, if you specify the intercept in an ESTIMATE or CONTRAST statement, it is distributed over all classification effects that are not contained by any other specified effect. The distribution of lower-order coefficients to higher-order effect coefficients follows the same general rules as in the LSMEANS statement, and it is similar to that used to construct Type IV tests. In the previous example, the $-1$ associated with $\alpha_1$ is divided by the number $n_{1j}$ of $\gamma_{1j}$ parameters; then each $\gamma_{1j}$ coefficient is set to $-1/n_{1j}$. The $1$ associated with $\alpha_3$ is distributed among the $\gamma_{3j}$ parameters in a similar fashion. In the event that an unspecified effect contains several specified effects, only that specified effect with the most factors in common with the unspecified effect is used for distribution of coefficients to the higher-order effect.

Numerous syntactical expressions for the ESTIMATE statement were considered, including many that involved specifying the effect and level information associated with each coefficient. For models involving higher-level effects, the requirement of specifying level information can lead to very bulky specifications. Consequently, the simpler form of the ESTIMATE statement described earlier was implemented. The syntax of this ESTIMATE statement puts a burden on you to know a priori the order of the parameter list associated with each effect. You can use the ORDER= option in the PROC GLM statement to ensure that the levels of the classification effects are sorted appropriately.

Note: If you use the ESTIMATE statement with unspecified effects, use the E option to make sure that the actual $L$ constructed by the preceding rules is the one you intended.

**A Check for Estimability**

Each $L$ is checked for estimability using the relationship: $L = LH$ where $H = (X'X)^{-1}X'X$. The $L$ vector is declared nonestimable, if for any $i$

$$\text{ABS}(L_i - (LH)_i) > \begin{cases} 
\epsilon & \text{if } L_i = 0 \\
\epsilon \times \text{ABS}(L_i) & \text{otherwise}
\end{cases}$$

where $\epsilon = 10^{-4}$ by default; you can change this with the SINGULAR= option. Continued fractions (like $1/3$) should be specified to at least six decimal places, or the DIVISOR parameter should be used.
Comparing Groups

An important task in analyzing data with classification effects is to estimate the typical response for each level of a given effect; often, you also want to compare these estimates to determine which levels are equivalent in terms of the response. You can perform this task in two ways with the GLM procedure: with direct, arithmetic group means; and with so-called least-squares means (LS-means).

Means Versus LS-Means

Computing and comparing arithmetic means—either simple or weighted within-group averages of the input data—is a familiar and well-studied statistical process. This is the right approach to summarizing and comparing groups for one-way and balanced designs. However, in unbalanced designs with more than one effect, the arithmetic mean for a group may not accurately reflect the “typical” response for that group, since it does not take other effects into account.

For example, consider the following analysis of an unbalanced two-way design:

```plaintext
data twoway;
  input Treatment Block y @@;
datalines;
  1 1 17 1 1 28 1 1 19 1 1 21 1 1 19
  1 2 43 1 2 30 1 2 39 1 2 44 1 2 44
  1 3 16
  2 1 21 2 1 21 2 1 24 2 1 25
  2 2 39 2 2 45 2 2 42 2 2 47
  2 3 19 2 3 22 2 3 16
  3 1 22 3 1 30 3 1 33 3 1 31
  3 2 46
  3 3 26 3 3 31 3 3 26 3 3 33 3 3 29 3 3 25
;

title1 "Unbalanced Two-way Design";

Figure 32.16. Treatment LS-means for Unbalanced Two-Way Design

No matter how you look at it, this data exhibits a strong effect due to the blocks (F-test p < 0.0001) and no significant interaction between treatments and blocks (F-test p > 0.7). But the lack of balance affects how the treatment effect is interpreted: in a main-effects-only model, there are no significant differences between the treatment means themselves (Type I F-test p > 0.7), but there are highly significant differences between the treatment means corrected for the block effects (Type III F-test p < 0.01).

LS-means are, in effect, within-group means appropriately adjusted for the other ef-
fects in the model. More precisely, they estimate the marginal means for a balanced population (as opposed to the unbalanced design). For this reason, they are also called estimated population marginal means by Searle et al. (1980). In the same way that the Type I $F$-test assesses differences between the arithmetic treatment means (when the treatment effect comes first in the model), the Type III $F$-test assesses differences between the LS-means. Accordingly, for the unbalanced two-way design, the discrepancy between the Type I and Type III tests is reflected in the arithmetic treatment means and treatment LS-means, as shown in Figure 32.15 and Figure 32.16. See the section “Construction of Least-Squares Means” on page 1820 for more on LS-means.

Note that, while the arithmetic means are always uncorrelated (under the usual assumptions for analysis of variance; see page 1783), the LS-means may not be. This fact complicates the problem of multiple comparisons for LS-means; see the following section.

**Multiple Comparisons**

When comparing more than two means, an ANOVA $F$-test tells you whether the means are significantly different from each other, but it does not tell you which means differ from which other means. Multiple comparison procedures (MCPs), also called mean separation tests, give you more detailed information about the differences among the means. The goal in multiple comparisons is to compare the average effects of three or more “treatments” (for example, drugs, groups of subjects) to decide which treatments are better, which ones are worse, and by how much, while controlling the probability of making an incorrect decision. A variety of multiple comparison methods are available with the MEANS and LSMEANS statement in the GLM procedure.

The following classification is due to Hsu (1996). Multiple comparison procedures can be categorized in two ways: by the comparisons they make and by the strength of inference they provide. With respect to which comparisons are made, the GLM procedure offers two types:

- comparisons between all pairs of means
- comparisons between a control and all other means

The strength of inference says what can be inferred about the structure of the means when a test is significant; it is related to what type of error rate the MCP controls. MCPs available in the GLM procedure provide one of the following types of inference, in order from weakest to strongest.

- Individual: differences between means, unadjusted for multiplicity
- Inhomogeneity: means are different
- Inequalities: which means are different
- Intervals: simultaneous confidence intervals for mean differences

Methods that control only individual error rates are not true MCPs at all. Methods that yield the strongest level of inference, simultaneous confidence intervals, are usually
preferred, since they enable you not only to say which means are different but also to put confidence bounds on how much they differ, making it easier to assess the practical significance of a difference. They are also less likely to lead nonstatisticians to the invalid conclusion that nonsignificantly different sample means imply equal population means. Interval MCPs are available for both arithmetic means and LS-means via the MEANS and LSMEANS statements, respectively.*

Table 32.3 and Table 32.4 display MCPs available in PROC GLM for all pairwise comparisons and comparisons with a control, respectively, along with associated strength of inference and the syntax (when applicable) for both the MEANS and the LSMEANS statements.

**Note:** One-sided Dunnett’s tests are also available from the MEANS statement with the DUNNETTL and DUNNETTU options and from the LSMEANS statement with PDIFF=CONTROLU and PDIFF=CONTROLU.

Details of these multiple comparison methods are given in the following sections.

**Pairwise Comparisons**

All the methods discussed in this section depend on the standardized pairwise differences $t_{ij} = (\bar{y}_i - \bar{y}_j)/\hat{\sigma}_{ij}$, where

*The Duncan-Waller method does not fit into the preceding scheme, since it is based on the Bayes risk rather than any particular error rate.*
• i and j are the indices of two groups
• \( \bar{y}_i \) and \( \bar{y}_j \) are the means or LS-means for groups i and j
• \( \hat{\sigma}_{ij} \) is the square-root of the estimated variance of \( \bar{y}_i - \bar{y}_j \). For simple arithmetic means, \( \hat{\sigma}_{ij}^2 = s^2(1/n_i + 1/n_j) \), where \( n_i \) and \( n_j \) are the sizes of groups i and j, respectively, and \( s^2 \) is the mean square for error, with \( \nu \) degrees of freedom. For weighted arithmetic means, \( \hat{\sigma}_{ij}^2 = s^2(1/w_i + 1/w_j) \), where \( w_i \) and \( w_j \) are the sums of the weights in groups i and j, respectively. Finally, for LS-means defined by the linear combinations \( l'_i b \) and \( l'_j b \) of the parameter estimates, \( \hat{\sigma}_{ij}^2 = s^2 l'_i (X'X)^{-1} l'_j \).

Furthermore, all of the methods are discussed in terms of significance tests of the form

\[
|t_{ij}| \geq c(\alpha)
\]

where \( c(\alpha) \) is some constant depending on the significance level. Such tests can be inverted to form confidence intervals of the form

\[
(\bar{y}_i - \bar{y}_j) - \hat{\sigma}_{ij}c(\alpha) \leq \mu_i - \mu_j \leq (\bar{y}_i - \bar{y}_j) + \hat{\sigma}_{ij}c(\alpha)
\]

The simplest approach to multiple comparisons is to do a t test on every pair of means (the T option in the MEANS statement, ADJUST=T in the LSMEANS statement). For the ith and jth means, you can reject the null hypothesis that the population means are equal if

\[
|t_{ij}| \geq t(\alpha; \nu)
\]

where \( \alpha \) is the significance level, \( \nu \) is the number of error degrees of freedom, and \( t(\alpha; \nu) \) is the two-tailed critical value from a Student’s t distribution. If the cell sizes are all equal to, say, \( n \), the preceding formula can be rearranged to give

\[
|\bar{y}_i - \bar{y}_j| \geq t(\alpha; \nu)s\sqrt{\frac{2}{n}}
\]

the value of the right-hand side being Fisher’s least significant difference (LSD).

There is a problem with repeated t tests, however. Suppose there are ten means and each t test is performed at the 0.05 level. There are 10(10-1)/2=45 pairs of means to compare, each with a 0.05 probability of a type 1 error (a false rejection of the null hypothesis). The chance of making at least one type 1 error is much higher than 0.05. It is difficult to calculate the exact probability, but you can derive a pessimistic approximation by assuming that the comparisons are independent, giving an upper bound to the probability of making at least one type 1 error (the experimentwise error rate) of

\[
1 - (1 - 0.05)^{45} = 0.90
\]
The actual probability is somewhat less than 0.90, but as the number of means increases, the chance of making at least one type 1 error approaches 1.

If you decide to control the individual type 1 error rates for each comparison, you are controlling the individual or comparisonwise error rate. On the other hand, if you want to control the overall type 1 error rate for all the comparisons, you are controlling the experimentwise error rate. It is up to you to decide whether to control the comparisonwise error rate or the experimentwise error rate, but there are many situations in which the experimentwise error rate should be held to a small value. Statistical methods for comparing three or more means while controlling the probability of making at least one type 1 error are called multiple comparisons procedures.

It has been suggested that the experimentwise error rate can be held to the $\alpha$ level by performing the overall ANOVA $F$-test at the $\alpha$ level and making further comparisons only if the $F$-test is significant, as in Fisher’s protected LSD. This assertion is false if there are more than three means (Einot and Gabriel 1975). Consider again the situation with ten means. Suppose that one population mean differs from the others by such a sufficiently large amount that the power (probability of correctly rejecting the null hypothesis) of the $F$-test is near 1 but that all the other population means are equal to each other. There will be $9(9 - 1)/2 = 36$ $t$ tests of true null hypotheses, with an upper limit of 0.84 on the probability of at least one type 1 error. Thus, you must distinguish between the experimentwise error rate under the complete null hypothesis, in which all population means are equal, and the experimentwise error rate under a partial null hypothesis, in which some means are equal but others differ. The following abbreviations are used in the discussion:

- **CER** comparisonwise error rate
- **EERC** experimentwise error rate under the complete null hypothesis
- **MEER** maximum experimentwise error rate under any complete or partial null hypothesis

These error rates are associated with the different strengths of inference discussed on page 1806: individual tests control the CER; tests for inhomogeneity of means control the EERC; tests that yield confidence inequalities or confidence intervals control the MEER. A preliminary $F$-test controls the EERC but not the MEER.

You can control the MEER at the $\alpha$ level by setting the CER to a sufficiently small value. The Bonferroni inequality (Miller 1981) has been widely used for this purpose. If

$$CER = \frac{\alpha}{c}$$

where $c$ is the total number of comparisons, then the MEER is less than $\alpha$. Bonferroni $t$ tests (the BON option in the MEANS statement, ADJUST=BON in the LSMEANS statement) with MEER < $\alpha$ declare two means to be significantly different if

$$|t_{ij}| \geq t(\epsilon; \nu)$$
where
\[ \epsilon = \frac{2\alpha}{k(k - 1)} \]
for comparison of \( k \) means.

Sidak (1967) has provided a tighter bound, showing that
\[ \text{CER} = 1 - (1 - \alpha)^{1/c} \]
also ensures that \( \text{MEER} \leq \alpha \) for any set of \( c \) comparisons. A Sidak \( t \) test (Games 1977), provided by the SIDAK option, is thus given by
\[ |t_{ij}| \geq t(\epsilon; \nu) \]
where
\[ \epsilon = 1 - (1 - \alpha)^{2/k} \]
for comparison of \( k \) means.

You can use the Bonferroni additive inequality and the Sidak multiplicative inequality to control the MEER for any set of contrasts or other hypothesis tests, not just pairwise comparisons. The Bonferroni inequality can provide simultaneous inferences in any statistical application requiring tests of more than one hypothesis. Other methods discussed in this section for pairwise comparisons can also be adapted for general contrasts (Miller 1981).

Scheffé (1953; 1959) proposes another method to control the MEER for any set of contrasts or other linear hypotheses in the analysis of linear models, including pairwise comparisons, obtained with the SCHEFFE option. Two means are declared significantly different if
\[ |t_{ij}| \geq \sqrt{(k - 1)F(\alpha; k - 1, \nu)} \]
where \( F(\alpha; k - 1, \nu) \) is the \( \alpha \)-level critical value of an \( F \) distribution with \( k - 1 \) numerator degrees of freedom and \( \nu \) denominator degrees of freedom.

Scheffé’s test is compatible with the overall ANOVA \( F \)-test in that Scheffé’s method never declares a contrast significant if the overall \( F \)-test is nonsignificant. Most other multiple comparison methods can find significant contrasts when the overall \( F \)-test is nonsignificant and, therefore, suffer a loss of power when used with a preliminary \( F \)-test.

Scheffé’s method may be more powerful than the Bonferroni or Sidak methods if the number of comparisons is large relative to the number of means. For pairwise comparisons, Sidak \( t \) tests are generally more powerful.
Tukey (1952; 1953) proposes a test designed specifically for pairwise comparisons based on the studentized range, sometimes called the “honestly significant difference test,” that controls the MEER when the sample sizes are equal. Tukey (1953) and Kramer (1956) independently propose a modification for unequal cell sizes. The Tukey or Tukey-Kramer method is provided by the TUKEY option in the MEANS statement and the ADJUST=TUKEY option in the LSMEANS statement. This method has fared extremely well in Monte Carlo studies (Dunnett 1980). In addition, Hayter (1984) gives a proof that the Tukey-Kramer procedure controls the MEER for means comparisons, and Hayter (1989) describes the extent to which the Tukey-Kramer procedure has been proven to control the MEER for LS-means comparisons. The Tukey-Kramer method is more powerful than the Bonferroni, Sidak, or Scheffé methods for pairwise comparisons. Two means are considered significantly different by the Tukey-Kramer criterion if

\[ |t_{ij}| \geq q(\alpha; k, \nu) \]

where \( q(\alpha; k, \nu) \) is the \( \alpha \)-level critical value of a studentized range distribution of \( k \) independent normal random variables with \( \nu \) degrees of freedom.

Hochberg (1974) devised a method (the GT2 or SMM option) similar to Tukey’s, but it uses the studentized maximum modulus instead of the studentized range and employs Sidak (1967) uncorrelated \( t \) inequality. It is proven to hold the MEER at a level not exceeding \( \alpha \) with unequal sample sizes. It is generally less powerful than the Tukey-Kramer method and always less powerful than Tukey’s test for equal cell sizes. Two means are declared significantly different if

\[ |t_{ij}| \geq m(\alpha; c, \nu) \]

where \( m(\alpha; c, \nu) \) is the \( \alpha \)-level critical value of the studentized maximum modulus distribution of \( c \) independent normal random variables with \( \nu \) degrees of freedom and \( c = k(k - 1)/2 \).

Gabriel (1978) proposes another method (the GABRIEL option) based on the studentized maximum modulus. This method is applicable only to arithmetic means. It rejects if

\[ \frac{|ar{y}_i - \bar{y}_j|}{s \left( \frac{1}{\sqrt{2n_i}} + \frac{1}{\sqrt{2n_j}} \right)} \geq m(\alpha; k, \nu) \]

For equal cell sizes, Gabriel’s test is equivalent to Hochberg’s GT2 method. For unequal cell sizes, Gabriel’s method is more powerful than GT2 but may become liberal with highly disparate cell sizes (refer also to Dunnett (1980)). Gabriel’s test is the only method for unequal sample sizes that lends itself to a graphical representation as intervals around the means. Assuming \( \bar{y}_i > \bar{y}_j \), you can rewrite the preceding inequality as

\[ \bar{y}_i - m(\alpha; k, \nu) \frac{s}{\sqrt{2n_i}} \geq \bar{y}_j + m(\alpha; k, \nu) \frac{s}{\sqrt{2n_j}} \]
Comparing All Treatments to a Control

One special case of means comparison is that in which the only comparisons that need to be tested are between a set of new treatments and a single control. In this case, you can achieve better power by using a method that is restricted to test only comparisons to the single control mean. Dunnett (1955) proposes a test for this situation that declares a mean significantly different from the control if

$$|t_{i0}| \geq d(\alpha; k, \nu, \rho_1, \ldots, \rho_{k-1})$$

where \(\bar{y}_0\) is the control mean and \(d(\alpha; k, \nu, \rho_1, \ldots, \rho_{k-1})\) is the critical value of the “many-to-one \(t\) statistic” (Miller 1981; Krishnaiah and Armitage 1966) for \(k\) means to be compared to a control, with \(\nu\) error degrees of freedom and correlations \(\rho_1, \ldots, \rho_{k-1}, \rho_i = n_i/(n_0 + n_i)\). The correlation terms arise because each of the treatment means is being compared to the same control. Dunnett’s test holds the MEER to a level not exceeding the stated \(\alpha\).

Approximate and Simulation-based Methods

Both Tukey’s and Dunnett’s tests are based on the same general quantile calculation:

$$q^t(\alpha, \nu, R) = \{q \geq P(\max(|t_1|, \ldots, |t_n|) > q) = \alpha\}$$

where the \(t_i\) have a joint multivariate \(t\) distribution with \(\nu\) degrees of freedom and correlation matrix \(R\). In general, evaluating \(q^t(\alpha, \nu, R)\) requires repeated numerical calculation of an \((n + 1)\)-fold integral. This is usually intractable, but the problem reduces to a feasible 2-fold integral when \(R\) has a certain symmetry in the case of Tukey’s test, and a factor analytic structure (cf. Hsu 1992) in the case of Dunnett’s test. The \(R\) matrix has the required symmetry for exact computation of Tukey’s test if the \(t_i\)s are studentized differences between

- \(k(k - 1)/2\) pairs of \(k\) uncorrelated means with equal variances—that is, equal sample sizes
- \(k(k - 1)/2\) pairs of \(k\) LS-means from a variance-balanced design (for example, a balanced incomplete block design)

Refer to Hsu (1992; 1996) for more information. The \(R\) matrix has the factor analytic structure for exact computation of Dunnett’s test if the \(t_i\)s are studentized differences between

- \(k-1\) means and a control mean, all uncorrelated. (Dunnett’s one-sided methods depend on a similar probability calculation, without the absolute values.) Note that it is not required that the variances of the means (that is, the sample sizes) be equal.
- $k-1$ LS-means and a control LS-mean from either a variance-balanced design, or a design in which the other factors are orthogonal to the treatment factor (for example, a randomized block design with proportional cell frequencies).

However, other important situations that do not result in a correlation matrix $R$ that has the structure for exact computation include:

- all pairwise differences with unequal sample sizes
- differences between LS-means in many unbalanced designs

In these situations, exact calculation of $q^t(\alpha, \nu, R)$ is intractable in general. Most of the preceding methods can be viewed as using various approximations for $q^t(\alpha, \nu, R)$. When the sample sizes are unequal, the Tukey-Kramer test is equivalent to another approximation. For comparisons with a control when the correlation $R$ does not have a factor analytic structure, Hsu (1992) suggests approximating $R$ with a matrix $R^*$ that does have such a structure and correspondingly approximating $q^t(\alpha, \nu, R)$ with $q^t(\alpha, \nu, R^*)$. When you request Dunnett’s test for LS-means (the PDIFF=CONTROL and ADJUST=DUNNETT options), the GLM procedure automatically uses Hsu’s approximation when appropriate.

Finally, Edwards and Berry (1987) suggest calculating $q^t(\alpha, \nu, R)$ by simulation. Multivariate $t$ vectors are sampled from a distribution with the appropriate $\nu$ and $R$ parameters, and Edwards and Berry (1987) suggest estimating $q^t(\alpha, \nu, R)$ by $\hat{q}$, the $\alpha$ percentile of the observed values of $\max(|t_1|, \ldots, |t_n|)$. Sufficient samples are generated for the true $P(\max(|t_1|, \ldots, |t_n|) > \hat{q})$ to be within a certain accuracy radius $\gamma$ of $\alpha$ with accuracy confidence $100(1 - \epsilon)$. You can approximate $q^t(\alpha, \nu, R)$ by simulation for comparisons between LS-means by specifying ADJUST=SIM (with either PDIFF=ALL or PDIFF=CONTROL). By default, $\gamma = 0.005$ and $\epsilon = 0.01$, so that the tail area of $\hat{q}$ is within 0.005 of $\alpha$ with 99% confidence. You can use the ACC= and EPS= options with ADJUST=SIM to reset $\gamma$ and $\epsilon$, or you can use the NSAMP= option to set the sample size directly. You can also control the random number sequence with the SEED= option.

Hsu and Nelson (1998) suggest a more accurate simulation method for estimating $q^t(\alpha, \nu, R)$, using a control variate adjustment technique. The same independent, standardized normal variates that are used to generate multivariate $t$ vectors from a distribution with the appropriate $\nu$ and $R$ parameters are also used to generate multivariate $t$ vectors from a distribution for which the exact value of $q^t(\alpha, \nu, R)$ is known. $\max(|t_1|, \ldots, |t_n|)$ for the second sample is used as a control variate for adjusting the quantile estimate based on the first sample; refer to Hsu and Nelson (1998) for more details. The control variate adjustment has the drawback that it takes somewhat longer than the crude technique of Edwards and Berry (1987), but it typically yields an estimate that is many times more accurate. In most cases, if you are using ADJUST=SIM, then you should specify ADJUST=SIM(CVADJUST). You can also specify ADJUST=SIM(CVADJUST REPORT) to display a summary of the simulation that includes, among other things, the actual accuracy radius $\gamma$, which should be substantially smaller than the target accuracy radius (0.005 by default).
Multiple-Stage Tests

You can use all of the methods discussed so far to obtain simultaneous confidence intervals (Miller 1981). By sacrificing the facility for simultaneous estimation, you can obtain simultaneous tests with greater power using multiple-stage tests (MSTs). MSTs come in both step-up and step-down varieties (Welsch 1977). The step-down methods, which have been more widely used, are available in SAS/STAT software.

Step-down MSTs first test the homogeneity of all of the means at a level $\gamma_k$. If the test results in a rejection, then each subset of $k - 1$ means is tested at level $\gamma_{k-1}$; otherwise, the procedure stops. In general, if the hypothesis of homogeneity of a set of $p$ means is rejected at the $\gamma_p$ level, then each subset of $p - 1$ means is tested at the $\gamma_{p-1}$ level; otherwise, the set of $p$ means is considered not to differ significantly and none of its subsets are tested. The many varieties of MSTs that have been proposed differ in the levels $\gamma_p$ and the statistics on which the subset tests are based. Clearly, the EERC of a step-down MST is not greater than $\gamma_k$, and the CER is not greater than $\gamma_2$, but the MEER is a complicated function of $\gamma_p, p = 2, \ldots, k$.

With unequal cell sizes, PROC GLM uses the harmonic mean of the cell sizes as the common sample size. However, since the resulting operating characteristics can be undesirable, MSTs are recommended only for the balanced case. When the sample sizes are equal and if the range statistic is used, you can arrange the means in ascending or descending order and test only contiguous subsets. But if you specify the $F$ statistic, this shortcut cannot be taken. For this reason, only range-based MSTs are implemented. It is common practice to report the results of an MST by writing the means in such an order and drawing lines parallel to the list of means spanning the homogeneous subsets. This form of presentation is also convenient for pairwise comparisons with equal cell sizes.

The best known MSTs are the Duncan (the DUNCAN option) and Student-Newman-Keuls (the SNK option) methods (Miller 1981). Both use the studentized range statistic and, hence, are called multiple range tests. Duncan’s method is often called the “new” multiple range test despite the fact that it is one of the oldest MSTs in current use.

The Duncan and SNK methods differ in the $\gamma_p$ values used. For Duncan’s method, they are

$$\gamma_p = 1 - (1 - \alpha)^{p-1}$$

whereas the SNK method uses

$$\gamma_p = \alpha$$

Duncan’s method controls the CER at the $\alpha$ level. Its operating characteristics appear similar to those of Fisher’s unprotected LSD or repeated $t$ tests at level $\alpha$ (Petrinovich and Hardyck 1969). Since repeated $t$ tests are easier to compute, easier to explain, and applicable to unequal sample sizes, Duncan’s method is not recommended. Several published studies (for example, Carmer and Swanson (1973)) have
claimed that Duncan’s method is superior to Tukey’s because of greater power without considering that the greater power of Duncan’s method is due to its higher type 1 error rate (Einot and Gabriel 1975).

The SNK method holds the EERC to the $\alpha$ level but does not control the MEER (Einot and Gabriel 1975). Consider ten population means that occur in five pairs such that means within a pair are equal, but there are large differences between pairs. If you make the usual sampling assumptions and also assume that the sample sizes are very large, all subset homogeneity hypotheses for three or more means are rejected. The SNK method then comes down to five independent tests, one for each pair, each at the $\alpha$ level. Letting $\alpha$ be 0.05, the probability of at least one false rejection is

$$1 - (1 - 0.05)^5 = 0.23$$

As the number of means increases, the MEER approaches 1. Therefore, the SNK method cannot be recommended.

A variety of MSTs that control the MEER have been proposed, but these methods are not as well known as those of Duncan and SNK. An approach developed by Ryan (1959; 1960), Einot and Gabriel (1975), and Welsch (1977) sets

$$\gamma_p = \begin{cases} 1 - (1 - \alpha)^{p/k} & \text{for } p < k - 1 \\ \alpha & \text{for } p \geq k - 1 \end{cases}$$

You can use range statistics, leading to what is called the REGWQ method after the authors’ initials. If you assume that the sample means have been arranged in descending order from $\bar{y}_1$ through $\bar{y}_k$, the homogeneity of means $\bar{y}_i, \ldots, \bar{y}_j, i < j$, is rejected by REGWQ if

$$\bar{y}_i - \bar{y}_j \geq q(\gamma_p; p, \nu) \frac{s}{\sqrt{n}}$$

where $p = j - i + 1$ and the summations are over $u = i, \ldots, j$ (Einot and Gabriel 1975). To ensure that the MEER is controlled, the current implementation checks whether $q(\gamma_p; p, \nu)$ is monotonically increasing in $p$. If not, then a set of critical values that are increasing in $p$ is substituted instead.

REGWQ appears to be the most powerful step-down MST in the current literature (for example, Ramsey 1978). Use of a preliminary $F$-test decreases the power of all the other multiple comparison methods discussed previously except for Scheffé’s test.

**Bayesian Approach**

Waller and Duncan (1969) and Duncan (1975) take an approach to multiple comparisons that differs from all the methods previously discussed in minimizing the Bayes risk under additive loss rather than controlling type 1 error rates. For each
pair of population means \( \mu_i \) and \( \mu_j \), null (\( H_{ij}^0 \)) and alternative (\( H_{ij}^a \)) hypotheses are defined:

\[
\begin{align*}
H_{ij}^0 &: \quad \mu_i - \mu_j \leq 0 \\
H_{ij}^a &: \quad \mu_i - \mu_j > 0
\end{align*}
\]

For any \( i, j \) pair, let \( d_0 \) indicate a decision in favor of \( H_{ij}^0 \) and \( d_a \) indicate a decision in favor of \( H_{ij}^a \), and let \( \delta = \mu_i - \mu_j \). The loss function for the decision on the \( i, j \) pair is

\[
L(d | \delta) = \begin{cases} 
0 & \text{if } \delta \leq 0 \\
\delta & \text{if } \delta > 0
\end{cases}
\]

where \( k \) represents a constant that you specify rather than the number of means. The loss for the joint decision involving all pairs of means is the sum of the losses for each individual decision. The population means are assumed to have a normal prior distribution with unknown variance, the logarithm of the variance of the means having a uniform prior distribution. For the \( i, j \) pair, the null hypothesis is rejected if

\[
\bar{y}_i - \bar{y}_j \geq t_B s \sqrt{\frac{2}{n}}
\]

where \( t_B \) is the Bayesian \( t \) value (Waller and Kemp 1976) depending on \( k \), the \( F \) statistic for the one-way ANOVA, and the degrees of freedom for \( F \). The value of \( t_B \) is a decreasing function of \( F \), so the Waller-Duncan test (specified by the WALLER option) becomes more liberal as \( F \) increases.

**Recommendations**

In summary, if you are interested in several individual comparisons and are not concerned about the effects of multiple inferences, you can use repeated \( t \) tests or Fisher’s unprotected LSD. If you are interested in all pairwise comparisons or all comparisons with a control, you should use Tukey’s or Dunnett’s test, respectively, in order to make the strongest possible inferences. If you have weaker inferential requirements and, in particular, if you don’t want confidence intervals for the mean differences, you should use the REGWQ method. Finally, if you agree with the Bayesian approach and Waller and Duncan’s assumptions, you should use the Waller-Duncan test.

**Interpretation of Multiple Comparisons**

When you interpret multiple comparisons, remember that failure to reject the hypothesis that two or more means are equal should not lead you to conclude that the population means are, in fact, equal. Failure to reject the null hypothesis implies only that the difference between population means, if any, is not large enough to be detected with the given sample size. A related point is that nonsignificance is nontransitive:
that is, given three sample means, the largest and smallest may be significantly different from each other, while neither is significantly different from the middle one. Nontransitive results of this type occur frequently in multiple comparisons.

Multiple comparisons can also lead to counter-intuitive results when the cell sizes are unequal. Consider four cells labeled A, B, C, and D, with sample means in the order A>B>C>D. If A and D each have two observations, and B and C each have 10,000 observations, then the difference between B and C may be significant, while the difference between A and D is not.

**Simple Effects**

Suppose you use the following statements to fit a full factorial model to a two-way design:

```plaintext
data twoway;
  input A B Y @@;
datalines;
  1 1 10.6 1 1 11.0 1 1 10.6 1 1 11.3
  1 2 -0.2 1 2 1.3 1 2 -0.2 1 2 0.2

**Figure 32.17.** Two-way Design with Significant Interaction
The interaction $A\times B$ is significant, indicating that the effect of $A$ depends on the level of $B$. In some cases, you may be interested in looking at the differences between predicted values across $A$ for different levels of $B$. Winer (1971) calls this the simple effects of $A$. You can compute simple effects with the LSMEAN statement by specifying the SLICE= option. In this case, since the GLM procedure is interactive, you can compute the simple effects of $A$ by submitting the following statements after the preceding statements.

```plaintext
lsmeans A*B / slice=B;
run;
```

The results are shown Figure 32.18. Note that $A$ has a significant effect for $B=1$ but not for $B=2$ and $B=3$.

\section*{Homogeneity of Variance in One-Way Models}

One of the usual assumptions for the GLM procedure is that the underlying errors are all uncorrelated with homogeneous variances (see page 1783). You can test this assumption in PROC GLM by using the HOVTEST option in the MEANS statement, requesting a homogeneity of variance test. This section discusses the computational details behind these tests. Note that the GLM procedure allows homogeneity of variance testing for simple one-way models only. Homogeneity of variance testing for more complex models is a subject of current research.
Bartlett (1937) proposes a test for equal variances that is a modification of the normal-theory likelihood ratio test (the HOVTEST=BARTLETT option). While Bartlett’s test has accurate Type I error rates and optimal power when the underlying distribution of the data is normal, it can be very inaccurate if that distribution is even slightly nonnormal (Box 1953). Therefore, Bartlett’s test is not recommended for routine use.

An approach that leads to tests that are much more robust to the underlying distribution is to transform the original values of the dependent variable to derive a dispersion variable and then to perform analysis of variance on this variable. The significance level for the test of homogeneity of variance is the p-value for the ANOVA F-test on the dispersion variable. All of the homogeneity of variance tests available in PROC GLM except Bartlett’s use this approach.

Levene’s test (Levene 1960) is widely considered to be the standard homogeneity of variance test (the HOVTEST=LEVENE option). Levene’s test is of the dispersion-variable-ANOVA form discussed previously, where the dispersion variable is either

\[
\begin{align*}
    z_{ij}^2 &= (y_{ij} - \bar{y}_i)^2 \quad \text{TYPE=SQUARE, the default)} \\
    z_{ij} &= |y_{ij} - \bar{y}_i| \quad \text{TYPE=ABS}
\end{align*}
\]

O’Brien (1979) proposes a test (HOVTEST=OBRIEN) that is basically a modification of Levene’s \( z_{ij}^2 \), using the dispersion variable

\[
z_{ij}^W = \frac{(W + n_i - 2)n_i(y_{ij} - \bar{y}_i)^2 - W(n_i - 1)\sigma_i^2}{(n_i - 1)(n_i - 2)}
\]

where \( n_i \) is the size of the \( i^{th} \) group and \( \sigma_i^2 \) is its sample variance. You can use the W= option in parentheses to tune O’Brien’s \( z_{ij}^W \) dispersion variable to match the suspected kurtosis of the underlying distribution. The choice of the value of the W= option is rarely critical. By default, \( W=0.5 \), as suggested by O’Brien (1979; 1981).

Finally, Brown and Forsythe (1974) suggest using the absolute deviations from the group medians:

\[
z_{ij}^{BF} = |y_{ij} - m_i|
\]

where \( m_i \) is the median of the \( i^{th} \) group. You can use the HOVTEST=BF option to specify this test.

Simulation results (Conover et al. 1981; Olejnik and Algina 1987) show that, while all of these ANOVA-based tests are reasonably robust to the underlying distribution, the Brown-Forsythe test seems best at providing power to detect variance differences while protecting the Type I error probability. However, since the within-group medians are required for the Brown-Forsythe test, it can be resource intensive if there are very many groups or if some groups are very large.

If one of these tests rejects the assumption of homogeneity of variance, you should use Welch’s ANOVA instead of the usual ANOVA to test for differences between
group means. However, this conclusion holds only if you use one of the robust homogeneity of variance tests (that is, not for HOVTEST=BARTLETT); even then, any homogeneity of variance test has too little power to be relied upon always to detect when Welch’s ANOVA is appropriate. Unless the group variances are extremely different or the number of groups is large, the usual ANOVA test is relatively robust when the groups are all about the same size. As Box (1953) notes, “To make the preliminary test on variances is rather like putting to sea in a rowing boat to find out whether conditions are sufficiently calm for an ocean liner to leave port!”

Example 32.10 on page 1892 illustrates the use of the HOVTEST and WELCH options in the MEANS statement in testing for equal group variances and adjusting for unequal group variances in a one-way ANOVA.

Weighted Means

In previous releases, if you specified a WEIGHT statement and one or more of the multiple comparisons options, PROC GLM estimated the variance of the difference between weighted group means for group \(i\) and \(j\) as

\[
MSE \times \left( \frac{1}{n_i} + \frac{1}{n_j} \right)
\]

where MSE is the (weighted) mean square for error and \(n_i\) is the size of group \(i\). This variance is involved in all of the multiple comparison methods. Beginning with Release 6.12, the variance of the difference between weighted group means for group \(i\) and \(j\) is computed as

\[
MSE \times \left( \frac{1}{w_i} + \frac{1}{w_j} \right)
\]

where \(w_i\) is the sum of the weights for the observations in group \(i\).

Construction of Least-Squares Means

To construct a least-squares mean (LS-mean) for a given level of a given effect, construct a row vector \(L\) according to the following rules and use it in an ESTIMATE statement to compute the value of the LS-mean:

1. Set all \(L_i\) corresponding to covariates (continuous variables) to their mean value.

2. Consider effects contained by the given effect. Set the \(L_i\) corresponding to levels associated with the given level equal to 1. Set all other \(L_i\) in these effects equal to 0. (See Chapter 11, “The Four Types of Estimable Functions,” for a definition of containing.)

3. Consider the given effect. Set the \(L_i\) corresponding to the given level equal to 1. Set the \(L_i\) corresponding to other levels equal to 0.

4. Consider the effects that contain the given effect. If these effects are not nested within the given effect, then set the \(L_i\) corresponding to the given level to \(1/k\), where \(k\) is the number of such columns. If these effects are nested within the given effect, then set the \(L_i\) corresponding to the given level to \(1/(k_1k_2)\), where
$k_1$ is the number of nested levels within this combination of nested effects, and $k_2$ is the number of such combinations. For $L_i$ corresponding to other levels, use 0.

5. Consider the other effects not yet considered. If there are no nested factors, then set all $L_i$ corresponding to this effect to $1/j$, where $j$ is the number of levels in the effect. If there are nested factors, then set all $L_i$ corresponding to this effect to $1/(j_1 j_2)$, where $j_1$ is the number of nested levels within a given combination of nested effects and $j_2$ is the number of such combinations.

The consequence of these rules is that the sum of the Xs within any classification effect is 1. This set of Xs forms a linear combination of the parameters that is checked for estimability before it is evaluated.

For example, consider the following model:

```plaintext
proc glm;
  class A B C;
  model Y=A B A*B C Z;
  lsmeans A B A*B C;
run;
```

Assume A has 3 levels, B has 2 levels, and C has 2 levels, and assume that every combination of levels of A and B exists in the data. Assume also that Z is a continuous variable with an average of 12.5. Then the least-squares means are computed by the following linear combinations of the parameter estimates:

<table>
<thead>
<tr>
<th></th>

Comparing Groups ♦ 1821
Setting Covariate Values

By default, all covariate effects are set equal to their mean values for computation of standard LS-means. The AT option in the LSMEANS statement enables you to set the covariates to whatever values you consider interesting.

If there is an effect containing two or more covariates, the AT option sets the effect equal to the product of the individual means rather than the mean of the product (as with standard LS-means calculations). The AT MEANS option leaves covariates equal to their mean values (as with standard LS-means) and incorporates this adjustment to crossproducts of covariates.

As an example, the following is a model with a classification variable A and two continuous variables, x1 and x2:

```plaintext
class A;
model y = A x1 x2 x1*x2;
```

The coefficients for the continuous effects with various AT specifications are shown in the following table.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>x1</th>
<th>x2</th>
<th>x1*x2</th>
</tr>
</thead>
<tbody>
<tr>
<td>lsmeans A;</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>lsmeans A / at means;</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>lsmeans A / at x1=1.2;</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>lsmeans A / at (x1 x2)=(1.2 0.3);</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

For the first two LSMEANS statements, the A LS-mean coefficient for x1 is \( \bar{x}_1 \) (the mean of x1) and for x2 is \( \bar{x}_2 \) (the mean of x2). However, for the first LSMEANS statement, the coefficient for x1*x2 is \( \bar{x}_1 \cdot \bar{x}_2 \), but for the second LSMEANS statement the coefficient is \( \bar{x}_1 \cdot \bar{x}_2 \). The third LSMEANS statement sets the coefficient for x1 equal to 1.2 and leaves that for x2 at \( \bar{x}_2 \), and the final LSMEANS statement sets these values to 1.2 and 0.3, respectively.

If you specify a WEIGHT variable, then weighted means are used for the covariate values. Also, observations with missing dependent variables are included in computing the covariate means, unless these observations form a missing cell. You can use the E option in conjunction with the AT option to check that the modified LS-means coefficients are the ones you desire.

The AT option is disabled if you specify the BYLEVEL option, in which case the coefficients for the covariates are set equal to their means within each level of the LS-mean effect in question.

Changing the Weighting Scheme

The standard LS-means have equal coefficients across classification effects; however, the OM option in the LSMEANS statement changes these coefficients to be proportional to those found in the input data set. This adjustment is reasonable when you
want your inferences to apply to a population that is not necessarily balanced but has
the margins observed in the original data set.

In computing the observed margins, PROC GLM uses all observations for which
there are no missing independent variables, including those for which there are miss-
ing dependent variables. Also, if there is a WEIGHT variable, PROC GLM uses
weighted margins to construct the LS-means coefficients. If the analysis data set is
balanced or if you specify a simple one-way model, the LS-means will be unchanged
by the OM option.

The BYLEVEL option modifies the observed-margins LS-means. Instead of com-
puting the margins across the entire data set, PROC GLM computes separate margins
for each level of the LS-mean effect in question. The resulting LS-means are actually
equal to raw means in this case. The BYLEVEL option disables the AT option if it is
specified.

Note that the MIXED procedure implements a more versatile form of the OM option,
offering you to specifying an alternative data set over which to compute observed
margins. If you use the BYLEVEL option, too, then this data set is effectively the
“population” over which the population marginal means are computed. See Chapter

You may want to use the E option in conjunction with either the OM or BYLEVEL
option to check that the modified LS-means coefficients are the ones you desire. It is
possible that the modified LS-means are not estimable when the standard ones are, or
vice versa.

**Multivariate Analysis of Variance**

If you fit several dependent variables to the same effects, you may want to make
tests jointly involving parameters of several dependent variables. Suppose you have
\( p \) dependent variables, \( k \) parameters for each dependent variable, and \( n \) observations.
The models can be collected into one equation:

\[
Y = X\beta + \epsilon
\]

where \( Y \) is \( n \times p \), \( X \) is \( n \times k \), \( \beta \) is \( k \times p \), and \( \epsilon \) is \( n \times p \). Each of the \( p \) models can
be estimated and tested separately. However, you may also want to consider the joint
distribution and test the \( p \) models simultaneously.

For multivariate tests, you need to make some assumptions about the errors. With \( p \)
dependent variables, there are \( n \times p \) errors that are independent across observations
but not across dependent variables. Assume

\[
\text{vec}(\epsilon) \sim N(0, I_n \otimes \Sigma)
\]

where vec(\( \epsilon \)) strings \( \epsilon \) out by rows, \( \otimes \) denotes Kronecker product multiplication, and
\( \Sigma \) is \( p \times p \). \( \Sigma \) can be estimated by

\[
S = \frac{e'e}{n - r} = \frac{(Y - X\hat{b})'(Y - X\hat{b})}{n - r}
\]
where \( b = (X'X)^{-1}X'Y \), \( r \) is the rank of the \( X \) matrix, and \( e \) is the matrix of residuals.

If \( S \) is scaled to unit diagonals, the values in \( S \) are called \textit{partial correlations of the Ys adjusting for the Xs}. This matrix can be displayed by PROC GLM if PRINTE is specified as a MANOVA option.

The multivariate general linear hypothesis is written

\[
L\beta M = 0
\]

You can form hypotheses for linear combinations across columns, as well as across rows of \( \beta \).

The MANOVA statement of the GLM procedure tests special cases where \( L \) corresponds to Type I, Type II, Type III, or Type IV tests, and \( M \) is the \( p \times p \) identity matrix. These tests are joint tests that the given type of hypothesis holds for all dependent variables in the model, and they are often sufficient to test all hypotheses of interest.

Finally, when these special cases are not appropriate, you can specify your own \( L \) and \( M \) matrices by using the CONTRAST statement before the MANOVA statement and the \( M= \) specification in the MANOVA statement, respectively. Another alternative is to use a REPEATED statement, which automatically generates a variety of \( M \) matrices useful in repeated measures analysis of variance. See the “REPEATED Statement” section on page 1777 and the “Repeated Measures Analysis of Variance” section on page 1825 for more information.

One useful way to think of a MANOVA analysis with an \( M \) matrix other than the identity is as an analysis of a set of transformed variables defined by the columns of the \( M \) matrix. You should note, however, that PROC GLM always displays the \( M \) matrix in such a way that the transformed variables are defined by the rows, not the columns, of the displayed \( M \) matrix.

All multivariate tests carried out by the GLM procedure first construct the matrices \( H \) and \( E \) corresponding to the numerator and denominator, respectively, of a univariate \( F \)-test.

\[
H = M'(Lb)'/(L(X'X)^{-1}L')^{-1}(Lb)M
\]
\[
E = M'(Y'Y - b'(X'X)b)M
\]

The diagonal elements of \( H \) and \( E \) correspond to the hypothesis and error SS for univariate tests. When the \( M \) matrix is the identity matrix (the default), these tests are for the original dependent variables on the left-hand side of the MODEL statement. When an \( M \) matrix other than the identity is specified, the tests are for transformed variables defined by the columns of the \( M \) matrix. These tests can be studied by requesting the SUMMARY option, which produces univariate analyses for each original or transformed variable.
Four multivariate test statistics, all functions of the eigenvalues of $E^{-1}H$ (or $(E + H)^{-1}H$), are constructed:

- Wilks’ lambda = $\frac{\text{det}(E)}{\text{det}(H + E)}$
- Pillai’s trace = $\text{trace}(H(H + E)^{-1})$
- Hotelling-Lawley trace = $\text{trace}(E^{-1}H)$
- Roy’s maximum root = $\lambda$, largest eigenvalue of $E^{-1}H$

By default, all four are reported with $p$-values based on $F$ approximations, as discussed in the “Multivariate Tests” section in Chapter 2, “Introduction to Regression Procedures.” Alternatively, if you specify MSTAT=EXACT on the associated MANOVA or REPEATED statement, $p$-values for three of the four tests are computed exactly (Wilks’ Lambda, the Hotelling-Lawley Trace, and Roy’s Greatest Root), and the $p$-values for the fourth (Pillai’s trace) are based on an $F$-approximation that is more accurate than the default. See the “Multivariate Tests” section in Chapter 2, “Introduction to Regression Procedures,” for more details on the exact calculations.

### Repeated Measures Analysis of Variance

When several measurements are taken on the same experimental unit (person, plant, machine, and so on), the measurements tend to be correlated with each other. When the measurements represent qualitatively different things, such as weight, length, and width, this correlation is best taken into account by use of multivariate methods, such as multivariate analysis of variance. When the measurements can be thought of as responses to levels of an experimental factor of interest, such as time, treatment, or dose, the correlation can be taken into account by performing a repeated measures analysis of variance.

PROC GLM provides both univariate and multivariate tests for repeated measures for one response. For an overall reference on univariate repeated measures, refer to Winer (1971). The multivariate approach is covered in Cole and Grizzle (1966). For a discussion of the relative merits of the two approaches, see LaTour and Miniard (1983).

Another approach to analysis of repeated measures is via general mixed models. This approach can handle balanced as well as unbalanced or missing within-subject data, and it offers more options for modeling the within-subject covariance. The main drawback of the mixed models approach is that it generally requires iteration and, thus, may be less computationally efficient. For further details on this approach, see Chapter 46, “The MIXED Procedure,” and Wolfinger and Chang (1995).

### Organization of Data for Repeated Measures Analysis

In order to deal efficiently with the correlation of repeated measures, the GLM procedure uses the multivariate method of specifying the model, even if only a univariate analysis is desired. In some cases, data may already be entered in the univariate mode, with each repeated measure listed as a separate observation along with a variable that
represents the experimental unit (subject) on which measurement is taken. Consider the following data set \texttt{old}:

<table>
<thead>
<tr>
<th>SUBJ</th>
<th>GROUP</th>
<th>TIME</th>
<th>Y</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>1</td>
<td>15</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>2</td>
<td>19</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
<td>3</td>
<td>25</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>1</td>
<td>21</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>2</td>
<td>18</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>3</td>
<td>17</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>1</td>
<td>14</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>2</td>
<td>12</td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>3</td>
<td>16</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>1</td>
<td>11</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>2</td>
<td>20</td>
</tr>
<tr>
<td>.</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>10</td>
<td>3</td>
<td>1</td>
<td>14</td>
</tr>
<tr>
<td>10</td>
<td>3</td>
<td>2</td>
<td>18</td>
</tr>
<tr>
<td>10</td>
<td>3</td>
<td>3</td>
<td>16</td>
</tr>
</tbody>
</table>

There are three observations for each subject, corresponding to measurements taken at times 1, 2, and 3. These data could be analyzed using the following statements:

```plaintext
proc glm data=old;
   class group subj time;
   model y=group subj(group) time group*time;
   test h=group e=subj(group);
run;
```

However, this analysis assumes subjects’ measurements are uncorrelated across time. A repeated measures analysis does not make this assumption. It uses a data set \texttt{new}:

<table>
<thead>
<tr>
<th>GROUP</th>
<th>Y1</th>
<th>Y2</th>
<th>Y3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>15</td>
<td>19</td>
<td>25</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
<td>18</td>
<td>17</td>
</tr>
<tr>
<td>2</td>
<td>14</td>
<td>12</td>
<td>16</td>
</tr>
<tr>
<td>2</td>
<td>11</td>
<td>20</td>
<td>21</td>
</tr>
<tr>
<td>.</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>14</td>
<td>18</td>
<td>16</td>
</tr>
</tbody>
</table>

In the data set \texttt{new}, the three measurements for a subject are all in one observation. For example, the measurements for subject 1 for times 1, 2, and 3 are 15, 19, and 25. For these data, the statements for a repeated measures analysis (assuming default options) are
Repeated Measures Analysis of Variance

```sas
proc glm data=new;
class group;
model y1-y3=group / nouni;
repeated time;
run;
```

To convert the univariate form of repeated measures data to the multivariate form, you can use a program like the following:

```sas
proc sort data=old;
   by group subj;
run;

data new(keep=y1-y3 group);
   array yy(3) y1-y3;
   do time=1 to 3;
      set old;
      by group subj;
      yy(time)=y;
      if last.subj then return;
   end;
run;
```

Alternatively, you could use PROC TRANSPOSE to achieve the same results with a program like this one:

```sas
proc sort data=old;
   by group subj;
run;

proc transpose out=new(rename=(_1=y1 _2=y2 _3=y3));
   by group subj;
   id time;
run;
```

Refer to the discussions in *SAS Language Reference: Concepts* for more information on rearrangement of data sets.

**Hypothesis Testing in Repeated Measures Analysis**

In repeated measures analysis of variance, the effects of interest are

- between-subject effects (such as GROUP in the previous example)
- within-subject effects (such as TIME in the previous example)
- interactions between the two types of effects (such as GROUP*TIME in the previous example)
Repeated measures analyses are distinguished from MANOVA because of interest in testing hypotheses about the within-subject effects and the within-subject-by-between-subject interactions.

For tests that involve only between-subjects effects, both the multivariate and univariate approaches give rise to the same tests. These tests are provided for all effects in the MODEL statement, as well as for any CONTRASTs specified. The ANOVA table for these tests is labeled “Tests of Hypotheses for Between Subjects Effects” on the PROC GLM results. These tests are constructed by first adding together the dependent variables in the model. Then an analysis of variance is performed on the sum divided by the square root of the number of dependent variables. For example, the statements

```
model y1-y3=group;
repeated time;
```

give a one-way analysis of variance using \((Y1 + Y2 + Y3)/\sqrt{3}\) as the dependent variable for performing tests of hypothesis on the between-subject effect GROUP. Tests for between-subject effects are equivalent to tests of the hypothesis \(L\beta M = 0\), where \(M\) is simply a vector of 1s.

For within-subject effects and for within-subject-by-between-subject interaction effects, the univariate and multivariate approaches yield different tests. These tests are provided for the within-subject effects and for the interactions between these effects and the other effects in the MODEL statement, as well as for any CONTRASTs specified. The univariate tests are displayed in a table labeled “Univariate Tests of Hypotheses for Within Subject Effects.” Results for multivariate tests are displayed in a table labeled “Repeated Measures Analysis of Variance.”

The multivariate tests provided for within-subject effects and interactions involving these effects are Wilks’ Lambda, Pillai’s Trace, Hotelling-Lawley Trace, and Roy’s maximum root. For further details on these four statistics, see the “Multivariate Tests” section in Chapter 2, “Introduction to Regression Procedures.” As an example, the statements

```
model y1-y3=group;
repeated time;
```

produce multivariate tests for the within-subject effect TIME and the interaction TIME*GROUP.

The multivariate tests for within-subject effects are produced by testing the hypothesis \(L\beta M = 0\), where the \(L\) matrix is the usual matrix corresponding to Type I, Type II, Type III, or Type IV hypotheses tests, and the \(M\) matrix is one of several matrices depending on the transformation that you specify in the REPEATED statement. The only assumption required for valid tests is that the dependent variables in the model have a multivariate normal distribution with a common covariance matrix across the between-subject effects.
The univariate tests for within-subject effects and interactions involving these effects require some assumptions for the probabilities provided by the ordinary $F$-tests to be correct. Specifically, these tests require certain patterns of covariance matrices, known as Type H covariances (Huynh and Feldt 1970). Data with these patterns in the covariance matrices are said to satisfy the Huynh-Feldt condition. You can test this assumption (and the Huynh-Feldt condition) by applying a sphericity test (Anderson 1958) to any set of variables defined by an orthogonal contrast transformation. Such a set of variables is known as a set of orthogonal components. When you use the PRINTTE option in the REPEATED statement, this sphericity test is applied both to the transformed variables defined by the REPEATED statement and to a set of orthogonal components if the specified transformation is not orthogonal. It is the test applied to the orthogonal components that is important in determining whether your data have Type H covariance structure. When there are only two levels of the within-subject effect, there is only one transformed variable, and a sphericity test is not needed. The sphericity test is labeled “Test for Sphericity” on the output.

If your data satisfy the preceding assumptions, use the usual $F$-tests to test univariate hypotheses for the within-subject effects and associated interactions.

If your data do not satisfy the assumption of Type H covariance, an adjustment to numerator and denominator degrees of freedom can be used. Two such adjustments, based on a degrees of freedom adjustment factor known as $\epsilon$ (epsilon) (Box 1954), are provided in PROC GLM. Both adjustments estimate $\epsilon$ and then multiply the numerator and denominator degrees of freedom by this estimate before determining significance levels for the $F$-tests. Significance levels associated with the adjusted tests are labeled “Adj Pr > F” on the output. The first adjustment, initially proposed for use in data analysis by Greenhouse and Geisser (1959), is labeled “Greenhouse-Geisser Epsilon” and represents the maximum-likelihood estimate of Box’s $\epsilon$ factor. Significance levels associated with adjusted $F$-tests are labeled “G-G” on the output. Huynh and Feldt (1976) have shown that the G-G estimate tends to be biased downward (that is, too conservative), especially for small samples, and they have proposed an alternative estimator that is constructed using unbiased estimators of the numerator and denominator of Box’s $\epsilon$. Huynh and Feldt’s estimator is labeled “Huynh-Feldt Epsilon” on the PROC GLM output, and the significance levels associated with adjusted $F$-tests are labeled “H-F.” Although $\epsilon$ must be in the range of 0 to 1, the H-F estimator can be outside this range. When the H-F estimator is greater than 1, a value of 1 is used in all calculations for probabilities, and the H-F probabilities are not adjusted. In summary, if your data do not meet the assumptions, use adjusted $F$-tests. However, when you strongly suspect that your data may not have Type H covariance, all these univariate tests should be interpreted cautiously. In such cases, you should consider using the multivariate tests instead.

The univariate sums of squares for hypotheses involving within-subject effects can be easily calculated from the $H$ and $E$ matrices corresponding to the multivariate tests described in the “Multivariate Analysis of Variance” section on page 1823. If the $M$ matrix is orthogonal, the univariate sums of squares is calculated as the trace (sum of diagonal elements) of the appropriate $H$ matrix; if it is not orthogonal, PROC GLM calculates the trace of the $H$ matrix that results from an orthogonal $M$ matrix transformation. The appropriate error term for the univariate $F$-tests is constructed.
in a similar way from the error SSCP matrix and is labeled Error(factorname), where factorname indicates the M matrix that is used in the transformation.

When the design specifies more than one repeated measures factor, PROC GLM computes the M matrix for a given effect as the direct (Kronecker) product of the M matrices defined by the REPEATED statement if the factor is involved in the effect or as a vector of 1s if the factor is not involved. The test for the main effect of a repeated-measures factor is constructed using an L matrix that corresponds to a test that the mean of the observation is zero. Thus, the main effect test for repeated measures is a test that the means of the variables defined by the M matrix are all equal to zero, while interactions involving repeated-measures effects are tests that the between-subjects factors involved in the interaction have no effect on the means of the transformed variables defined by the M matrix. In addition, you can specify other L matrices to test hypotheses of interest by using the CONTRAST statement, since hypotheses defined by CONTRAST statements are also tested in the REPEATED analysis. To see which combinations of the original variables the transformed variables represent, you can specify the PRINTM option in the REPEATED statement. This option displays the transpose of M, which is labeled as M in the PROC GLM results. The tests produced are the same for any choice of transformation (M) matrix specified in the REPEATED statement; however, depending on the nature of the repeated measurements being studied, a particular choice of transformation matrix, coupled with the CANONICAL or SUMMARY option, can provide additional insight into the data being studied.

Transformations Used in Repeated Measures Analysis of Variance

As mentioned in the specifications of the REPEATED statement, several different M matrices can be generated automatically, based on the transformation that you specify in the REPEATED statement. Remember that both the univariate and multivariate tests that PROC GLM performs are unaffected by the choice of transformation; the choice of transformation is important only when you are trying to study the nature of a repeated measures effect, particularly with the CANONICAL and SUMMARY options. If one of these matrices does not meet your needs for a particular analysis, you may want to use the M= option in the MANOVA statement to perform the tests of interest.

The following sections describe the transformations available in the REPEATED statement, provide an example of the M matrix that is produced, and give guidelines for the use of the transformation. As in the PROC GLM output, the displayed matrix is labeled M. This is the M’ matrix.

CONTRAST Transformation

This is the default transformation used by the REPEATED statement. It is useful when one level of the repeated measures effect can be thought of as a control level against which the others are compared. For example, if five drugs are administered to each of several animals and the first drug is a control or placebo, the statements

```plaintext
proc glm;
   model d1-d5= / nouni;
```
Repeated Measures Analysis of Variance

repeated drug 5 contrast(1) / summary printm;
run;

produce the following M matrix:

\[
M = \begin{bmatrix}
-1 & 1 & 0 & 0 & 0 \\
-1 & 0 & 1 & 0 & 0 \\
-1 & 0 & 0 & 1 & 0 \\
-1 & 0 & 0 & 0 & 1
\end{bmatrix}
\]

When you examine the analysis of variance tables produced by the SUMMARY option, you can tell which of the drugs differed significantly from the placebo.

POLYNOMIAL Transformation

This transformation is useful when the levels of the repeated measure represent quantitative values of a treatment, such as dose or time. If the levels are unequally spaced, level values can be specified in parentheses after the number of levels in the REPEATED statement. For example, if five levels of a drug corresponding to 1, 2, 5, 10 and 20 milligrams are administered to different treatment groups, represented by the variable group, the statements

```plaintext
proc glm;
   class group;
   model r1-r5=group / nouni;
   repeated dose 5 (1 2 5 10 20) polynomial / summary printm;
run;
```

produce the following M matrix.

\[
M = \begin{bmatrix}
-0.4250 & -0.3606 & -0.1674 & 0.1545 & 0.7984 \\
0.4349 & 0.2073 & -0.3252 & -0.7116 & 0.3946 \\
-0.4331 & 0.1366 & 0.7253 & -0.5108 & 0.0821 \\
0.4926 & -0.7800 & 0.3743 & -0.0936 & 0.0066
\end{bmatrix}
\]

The SUMMARY option in this example provides univariate ANOVAs for the variables defined by the rows of this M matrix. In this case, they represent the linear, quadratic, cubic, and quartic trends for dose and are labeled dose_1, dose_2, dose_3, and dose_4, respectively.

HELMERT Transformation

Since the Helmert transformation compares a level of a repeated measure to the mean of subsequent levels, it is useful when interest lies in the point at which responses cease to change. For example, if four levels of a repeated measures factor represent responses to treatments administered over time to males and females, the statements
Chapter 32. The GLM Procedure

```plaintext
proc glm;
  class sex;
  model resp1-resp4=sex / nouni;
  repeated trtmnt 4 helmert / canon printm;
run;
```

produce the following M matrix:

$$
M = \begin{bmatrix}
1 & -0.33333 & -0.33333 & -0.33333 \\
0 & 1 & -0.50000 & -0.50000 \\
0 & 0 & 1 & -1
\end{bmatrix}
$$

**MEAN Transformation**

This transformation can be useful in the same types of situations in which the CONTRAST transformation is useful. If you substitute the following statement for the REPEATED statement shown in the “CONTRAST Transformation” section,

```plaintext
repeated drug 5 mean / printm;
```

the following M matrix is produced:

$$
M = \begin{bmatrix}
1 & -0.25 & -0.25 & -0.25 & -0.25 \\
-0.25 & 1 & -0.25 & -0.25 & -0.25 \\
-0.25 & -0.25 & 1 & -0.25 & -0.25 \\
-0.25 & -0.25 & -0.25 & 1 & -0.25
\end{bmatrix}
$$

As with the CONTRAST transformation, if you want to omit a level other than the last, you can specify it in parentheses after the keyword MEAN in the REPEATED statement.

**PROFILE Transformation**

When a repeated measure represents a series of factors administered over time, but a polynomial response is unreasonable, a profile transformation may prove useful. As an example, consider a training program in which four different methods are employed to teach students at several different schools. The repeated measure is the score on tests administered after each of the methods is completed. The statements

```plaintext
proc glm;
  class school;
  model t1-t4=school / nouni;
  repeated method 4 profile / summary nom printm;
run;
```
produce the following $M$ matrix:

$$M = \begin{bmatrix}
1 & -1 & 0 & 0 \\
0 & 1 & -1 & 0 \\
0 & 0 & 1 & -1
\end{bmatrix}$$

To determine the point at which an improvement in test scores takes place, you can examine the analyses of variance for the transformed variables representing the differences between adjacent tests. These analyses are requested by the SUMMARY option in the REPEATED statement, and the variables are labeled METHOD.1, METHOD.2, and METHOD.3.

**Random Effects Analysis**

When some model effects are random (that is, assumed to be sampled from a normal population of effects), you can specify these effects in the RANDOM statement in order to compute the expected values of mean squares for various model effects and contrasts and, optionally, to perform random effects analysis of variance tests.

**PROC GLM versus PROC MIXED for Random Effects Analysis**

Other SAS procedures that can be used to analyze models with random effects include the MIXED and VARCOMP procedures. Note that, for these procedures, the random effects specification is an integral part of the model, affecting how both random and fixed effects are fit; for PROC GLM, the random effects are treated in a post hoc fashion after the complete fixed effect model is fit. This distinction affects other features in the GLM procedure, such as the results of the LSMEANS and ESTIMATE statements. These features assume that all effects are fixed, so that all tests and estimability checks for these statements are based on a fixed effects model, even when you use a RANDOM statement. Standard errors for estimates and LS-means based on the fixed effects model may be significantly smaller than those based on a true random effects model; in fact, some functions that are estimable under a true random effects model may not even be estimable under the fixed effects model. Therefore, you should use the MIXED procedure to compute tests involving these features that take the random effects into account; see Chapter 46, “The MIXED Procedure,” for more information.

Note that, for balanced data, the test statistics computed when you specify the TEST option on the RANDOM statement have an exact $F$ distribution only when the design is balanced; for unbalanced designs, the $p$ values for the $F$-tests are approximate. For balanced data, the values obtained by PROC GLM and PROC MIXED agree; for unbalanced data, they usually do not.

**Computation of Expected Mean Squares for Random Effects**

The RANDOM statement in PROC GLM declares one or more effects in the model to be random rather than fixed. By default, PROC GLM displays the coefficients of the expected mean squares for all terms in the model. In addition, when you specify the TEST option in the RANDOM statement, the procedure determines what tests are appropriate and provides $F$ ratios and probabilities for these tests.
The expected mean squares are computed as follows. Consider the model

\[ Y = X_0\beta_0 + X_1\beta_1 + \cdots + X_k\beta_k + \epsilon \]

where \( \beta_0 \) represents the fixed effects and \( \beta_1, \beta_2, \cdots, \epsilon \) represent the random effects. Random effects are assumed to be normally and independently distributed. For any \( L \) in the row space of \( X = (X_0 \mid X_1 \mid X_2 \mid \cdots \mid X_k) \), the expected value of the sum of squares for \( L\beta \) is

\[
E(\text{SS}_L) = \beta_0' C_0' C_0 \beta_0 + \text{SSQ}(C_1) \sigma_1^2 + \text{SSQ}(C_2) \sigma_2^2 + \cdots + \text{SSQ}(C_k) \sigma_k^2 + \text{rank}(L) \sigma^2
\]

where \( C \) is of the same dimensions as \( L \) and is partitioned as the \( X \) matrix. In other words,

\[
C = (C_0 \mid C_1 \mid \cdots \mid C_k)
\]

Furthermore, \( C = ML \), where \( M \) is the inverse of the lower triangular Cholesky decomposition matrix of \( L(X'X)^{-1}L' \). \( \text{SSQ}(A) \) is defined as \( \text{tr}(A'A) \).

For the model in the following MODEL statement

```
model Y=A B(A) C A*C;
random B(A);
```

with \( B(A) \) declared as random, the expected mean square of each effect is displayed as

\[
\text{Var(Error)} + \text{constant} \times \text{Var(B(A))} + Q(A, C, A \ast C)
\]

If any fixed effects appear in the expected mean square of an effect, the letter Q followed by the list of fixed effects in the expected value is displayed. The actual numeric values of the quadratic form (Q matrix) can be displayed using the Q option.

To determine appropriate means squares for testing the effects in the model, the TEST option in the RANDOM statement performs the following.

1. First, it forms a matrix of coefficients of the expected mean squares of those effects that were declared to be random.
2. Next, for each effect in the model, it determines the combination of these expected mean squares that produce an expectation that includes all the terms in the expected mean square of the effect of interest except the one corresponding to the effect of interest. For example, if the expected mean square of an effect \( A\ast B \) is

\[
\text{Var(Error)} + 3 \times \text{Var(A)} + \text{Var(A \ast B)}
\]
PROC GLM determines the combination of other expected mean squares in the model that has expectation

\[ \text{Var(Error)} + 3 \times \text{Var(A)} \]

3. If the preceding criterion is met by the expected mean square of a single effect in the model (as is often the case in balanced designs), the \( F \) test is formed directly. In this case, the mean square of the effect of interest is used as the numerator, the mean square of the single effect with an expected mean square that satisfies the criterion is used as the denominator, and the degrees of freedom for the test are simply the usual model degrees of freedom.

4. When more than one mean square must be combined to achieve the appropriate expectation, an approximation is employed to determine the appropriate degrees of freedom (Satterthwaite 1946). When effects other than the effect of interest are listed after the Q in the output, tests of hypotheses involving the effect of interest are not valid unless all other fixed effects involved in it are assumed to be zero. When tests such as these are performed by using the TEST option in the RANDOM statement, a note is displayed reminding you that further assumptions are necessary for the validity of these tests. Remember that although the tests are not valid unless these assumptions are made, this does not provide a basis for these assumptions to be true. The particulars of a given experiment must be examined to determine whether the assumption is reasonable.

Refer to Goodnight and Speed (1978), Milliken and Johnson (1984, Chapters 22 and 23), and Hocking (1985) for further theoretical discussion.

**Sum-to-Zero Assumptions**

The formulation and parameterization of the expected mean squares for random effects in mixed models is an ongoing item of controversy in the statistical literature. Confusion arises over whether or not to assume that terms involving fixed effects sum to zero. Cornfield and Tukey (1956), Winer (1971), and others assume that they do sum to zero; Searle (1971), Hocking (1973), and others (including PROC GLM) do not.

Different assumptions about these sum-to-zero constraints can lead to different expected mean squares for certain terms, and hence to different \( F \) and \( p \) values.

For arguments in favor of not assuming that terms involving fixed effects sum to zero, see Section 9.7 of Searle (1971) and Sections 1 and 4 of McLean et al. (1991). Other references are Hartley and Searle (1969) and Searle et al. (1992).

**Computing Type I, II, and IV Expected Mean Squares**

When you use the RANDOM statement, by default the GLM procedure produces the Type III expected mean squares for model effects and for contrasts specified before the RANDOM statement. In order to obtain expected values for other types of mean squares, you need to specify which types of mean squares are of interest in
the MODEL statement. For example, in order to obtain the Type IV expected mean squares for effects in the RANDOM and CONTRAST statements, specify the SS4 option in the MODEL statement. If you want both Type III and Type IV expected mean squares, specify both the SS3 and SS4 options in the MODEL statement. Since the estimable function basis is not automatically calculated for Type I and Type II SS, the E1 (for Type I) or E2 (for Type II) option must be specified in the MODEL statement in order for the RANDOM statement to produce the expected mean squares for the Type I or Type II sums of squares. Note that it is important to list the fixed effects first in the MODEL statement when requesting the Type I expected mean squares.

For example, suppose you have a two-way design with factors A and B in which the main effect for B and the interaction are random. In order to compute the Type III expected mean squares (in addition to the fixed-effect analysis), you can use the following statements:

```plaintext
proc glm;
  class A B;
  model Y = A B A*B;
  random B A*B;
run;
```

If you use the SS4 option in the MODEL statement,

```plaintext
proc glm;
  class A B;
  model Y = A B A*B / ss4;
  random B A*B;
run;
```

then only the Type IV expected mean squares are computed (as well as the Type IV fixed-effect tests). For the Type I expected mean squares, you can use the following statements:

```plaintext
proc glm;
  class A B;
  model Y = A B A*B / e1;
  random B A*B;
run;
```

For each of these cases, in order to perform random effect analysis of variance tests for each effect specified in the model, you need to specify the TEST option in the RANDOM statement, as follows:

```plaintext
proc glm;
  class A B;
  model Y = A B A*B;
  random B A*B / test;
run;
```

The GLM procedure automatically determines the appropriate error term for each test, based on the expected mean squares.
Missing Values

For an analysis involving one dependent variable, PROC GLM uses an observation if values are nonmissing for that dependent variable and all the class variables.

For an analysis involving multiple dependent variables without the MANOVA or REPEATED statement, or without the MANOVA option in the PROC GLM statement, a missing value in one dependent variable does not eliminate the observation from the analysis of other nonmissing dependent variables. On the other hand, for an analysis with the MANOVA or REPEATED statement, or with the MANOVA option in the PROC GLM statement, PROC GLM uses an observation if values are nonmissing for all dependent variables and all the variables used in independent effects.

During processing, the GLM procedure groups the dependent variables by their pattern of missing values across observations so that sums and crossproducts can be collected in the most efficient manner.

If your data have different patterns of missing values among the dependent variables, interactivity is disabled. This can occur when some of the variables in your data set have missing values and

- you do not use the MANOVA option in the PROC GLM statement
- you do not use a MANOVA or REPEATED statement before the first RUN statement

Note that the REG procedure handles missing values differently in this case; see Chapter 61, “The REG Procedure,” for more information.

Computational Resources

Memory

For large problems, most of the memory resources are required for holding the $X'X$ matrix of the sums and crossproducts. The section “Parameterization of PROC GLM Models” on page 1787 describes how columns of the $X$ matrix are allocated for various types of effects. For each level that occurs in the data for a combination of class variables in a given effect, a row and column for $X'X$ is needed.

The following example illustrates the calculation. Suppose $A$ has 20 levels, $B$ has 4 levels, and $C$ has 3 levels. Then consider the model

```plaintext
proc glm;
  class A B C;
  model Y1 Y2 Y3=A B A*B C A*C B*C A*B*C X1 X2;
run;
```

The $X'X$ matrix (bordered by $X'Y$ and $Y'Y$) can have as many as 425 rows and columns:
for the intercept term
20 for A
4 for B
80 for A*B
3 for C
60 for A*C
12 for B*C
240 for A*B*C
2 for X1 and X2 (continuous variables)
3 for Y1, Y2, and Y3 (dependent variables)

The matrix has 425 rows and columns only if all combinations of levels occur for each effect in the model. For \( m \) rows and columns, \( 8m^2 \) bytes are needed for crossproducts. In this case, \( 8 \cdot 425^2 = 1,445,000 \) bytes, or about \( 1,445,000/1024 = 1411K \).

The required memory grows as the square of the number of columns of \( X \); most of the memory is for the \( A*B*C \) interaction. Without \( A*B*C \), you have 185 columns and need 268K for \( X'X \). Without either \( A*B*C \) or \( A*B \), you need 86K. If A is recoded to have ten levels, then the full model has only 220 columns and requires 378K.

The second time that a large amount of memory is needed is when Type III, Type IV, or contrast sums of squares are being calculated. This memory requirement is a function of the number of degrees of freedom of the model being analyzed and the maximum degrees of freedom for any single source. Let Rank equal the sum of the model degrees of freedom, MaxDF be the maximum number of degrees of freedom for any single source, and \( N_y \) be the number of dependent variables in the model. Then the memory requirement in bytes is

\[
\left( 8 \times \left( \frac{\text{Rank} \times (\text{Rank} + 1)}{2} \right) \right) + (N_y \times \text{Rank}) + \left( \frac{\text{MaxDF} \times (\text{MaxDF} + 1)}{2} \right) + (N_y \times \text{MaxDF})
\]

Unfortunately, these quantities are not available when the \( X'X \) matrix is being constructed, so PROC GLM may occasionally request additional memory even after you have increased the memory allocation available to the program.

If you have a large model that exceeds the memory capacity of your computer, these are your options:

- Eliminate terms, especially high-level interactions.
- Reduce the number of levels for variables with many levels.
- Use the ABSORB statement for parts of the model that are large.
• Use the REPEATED statement for repeated measures variables.
• Use PROC ANOVA or PROC REG rather than PROC GLM, if your design allows.

A related limitation is that for any model effect involving classification variables (interactions as well as main effects), the number of levels can not exceed 32,767. This is because GLM internally indexes effect levels using signed short (16-bit) integers, for which the maximum value is $2^{15} - 1 = 32,767$.

**CPU Time**

Typically, if the GLM procedure requires a lot of CPU time, it will be for one of several reasons. Suppose that the input data has $n$ rows (observations) and the model has $E$ effects which together produce a design matrix $X$ with $m$ columns. Then if $m$ or $n$ is relatively large, the procedure may spend a lot of time in any of the following areas:

- collecting the sums of squares and crossproducts
- solving the normal equations
- computing the Type III tests

The time required for collecting sums and crossproducts is difficult to calculate because it is a complicated function of the model. The worst case occurs if all columns are continuous variables, involving $nm^2/2$ multiplications and additions. If the columns are levels of a classification, then only $m$ sums may be needed, but a significant amount of time may be spent in look-up operations. Solving the normal equations requires time for approximately $m^3/2$ multiplications and additions, and the number of operations required to compute the Type III tests is also proportional to both $E$ and $m^3$.

Suppose that you know that Type IV sums of squares are appropriate for the model you are analyzing (for example, if your design has no missing cells). You can specify the SS4 option in your MODEL statement, which saves CPU time by requesting the Type IV sums of squares instead of the more computationally burdensome Type III sums of squares. This proves especially useful if you have a factor in your model that has many levels and is involved in several interactions.

If the operating system enables SAS to run parallel computational threads on multiple CPUs, then both the solution of the normal equations and the computation of Type III tests can take advantage of this to reduce the computational time for large models. In solving the normal equations, the fundamental row sweep operations (Goodnight 1979) are performed in parallel. In computing the Type III tests, both the orthogonalization for the estimable functions and the sums of squares calculation have been parallelized.

The reduction in computational time due to parallel processing depends on the size of the model, the number of processors, and the parallel architecture of the operating system. If the model is large enough that the overwhelming proportion of CPU time
for the procedure is accounted for in solving the normal equations and/or computing the Type III tests, then you can expect a reduction in computational time approximately inversely proportional to the number of CPUs. However, as you increase the number of processors, the efficiency of this scaling can be reduced by several effects. One mitigating factor is a purely mathematical one known as “Amdahl’s Law”, which is related to the fact that only part of the processing time for the procedure can be parallelized. Even taking Amdahl’s Law into account, the parallelization efficiency can be reduced by cache effects related to how fast the multiple processors can access memory. See Cohen (2002) for a discussion of these issues. For additional information on parallel processing in SAS, refer to the chapter on “Support for Parallel Processing” in SAS Language Reference: Concepts.

### Computational Method

Let \( X \) represent the \( n \times p \) design matrix and \( Y \) the \( n \times 1 \) vector of dependent variables. (See the section “Parameterization of PROC GLM Models” on page 1787 for information on how \( X \) is formed from your model specification.)

The normal equations \( X'X\beta = X'Y \) are solved using a modified sweep routine that produces a generalized (g2) inverse \((X'X)^{-}\) and a solution \( b = (X'X)^{-}X'y \) (Pringle and Raynor 1971).

For each effect in the model, a matrix \( L \) is computed such that the rows of \( L \) are estimable. Tests of the hypothesis \( L\beta = 0 \) are then made by first computing

\[
SS(L\beta = 0) = (Lb)'(L(X'X)^{-}L')^{-1}(Lb)
\]

and then computing the associated \( F \) value using the mean squared error.

### Output Data Sets

**OUT= Data Set Created by the OUTPUT Statement**

The OUTPUT statement produces an output data set that contains the following:

- all original data from the SAS data set input to PROC GLM
- the new variables corresponding to the diagnostic measures specified with statistics keywords in the OUTPUT statement (PREDICTED=, RESIDUAL=, and so on).

With multiple dependent variables, a name can be specified for any of the diagnostic measures for each of the dependent variables in the order in which they occur in the MODEL statement.

For example, suppose that the input data set \( A \) contains the variables \( y1, y2, y3, x1, \) and \( x2 \). Then you can use the following statements:
proc glm data=A;
  model y1 y2 y3=x1;
  output out=out p=y1hat y2hat y3hat
       r=y1resid lclm=y1lcl uclm=y1ucl;
run;

The output data set out contains y1, y2, y3, x1, x2, y1hat, y2hat, y3hat, y1resid, y1lcl, and y1ucl. The variable x2 is output even though it is not used by PROC GLM. Although predicted values are generated for all three dependent variables, residuals are output for only the first dependent variable.

When any independent variable in the analysis (including all class variables) is missing for an observation, then all new variables that correspond to diagnostic measures are missing for the observation in the output data set.

When a dependent variable in the analysis is missing for an observation, then some new variables that correspond to diagnostic measures are missing for the observation in the output data set, and some are still available. Specifically, in this case, the new variables that correspond to COOKD, COVRATIO, DFFITS, PRESS, R, RSTUDENT, STDR, and STUDENT are missing in the output data set. The variables corresponding to H, LCL, LCLM, P, STDI, STDP, UCL, and UCLM are not missing.

**OUT= Data Set Created by the LSMEANS Statement**

The OUT= option in the LSMEANS statement produces an output data set that contains

- the unformatted values of each classification variable specified in any effect in the LSMEANS statement
- a new variable, LSMEAN, which contains the LS-mean for the specified levels of the classification variables
- a new variable, STDERR, which contains the standard error of the LS-mean

The variances and covariances among the LS-means are also output when the COV option is specified along with the OUT= option. In this case, only one effect can be specified in the LSMEANS statement, and the following variables are included in the output data set:

- new variables, COV1, COV2, ..., COVn, where n is the number of levels of the effect specified in the LSMEANS statement. These variables contain the covariances of each LS-mean with each other LS-mean.
- a new variable, NUMBER, which provides an index for each observation to identify the covariances that correspond to that observation. The covariances for the observation with NUMBER equal to n can be found in the variable COVn.
OUTSTAT= Data Set

The OUTSTAT= option in the PROC GLM statement produces an output data set that contains

- the BY variables, if any
- _TYPE_, a new character variable. _TYPE_ may take the values ‘SS1’, ‘SS2’, ‘SS3’, ‘SS4’, or ‘CONTRAST’, corresponding to the various types of sums of squares generated, or the values ‘CANCORR’, ‘STRUCTUR’, or ‘SCORE’, if a canonical analysis is performed through the MANOVA statement and no M= matrix is specified.
- _SOURCE_, a new character variable. For each observation in the data set, _SOURCE_ contains the name of the model effect or contrast label from which the corresponding statistics are generated.
- _NAME_, a new character variable. For each observation in the data set, _NAME_ contains the name of one of the dependent variables in the model or, in the case of canonical statistics, the name of one of the canonical variables (CAN1, CAN2, and so forth).
- four new numeric variables: SS, DF, F, and PROB, containing sums of squares, degrees of freedom, F values, and probabilities, respectively, for each model or contrast sum of squares generated in the analysis. For observations resulting from canonical analyses, these variables have missing values.
- if there is more than one dependent variable, then variables with the same names as the dependent variables represent
  - for _TYPE_=SS1, SS2, SS3, SS4, or CONTRAST, the crossproducts of the hypothesis matrices
  - for _TYPE_=CANCORR, canonical correlations for each variable
  - for _TYPE_=STRUCTUR, coefficients of the total structure matrix
  - for _TYPE_=SCORE, raw canonical score coefficients

The output data set can be used to perform special hypothesis tests (for example, with the IML procedure in SAS/IML software), to reformat output, to produce canonical variates (through the SCORE procedure), or to rotate structure matrices (through the FACTOR procedure).

Displayed Output

The GLM procedure produces the following output by default:

- The overall analysis-of-variance table breaks down the Total Sum of Squares for the dependent variable into the portion attributed to the Model and the portion attributed to Error.
- The Mean Square term is the Sum of Squares divided by the degrees of freedom (DF).
• The Mean Square for Error is an estimate of $\sigma^2$, the variance of the true errors.

• The $F$ Value is the ratio produced by dividing the Mean Square for the Model by the Mean Square for Error. It tests how well the model as a whole (adjusted for the mean) accounts for the dependent variable’s behavior. An $F$-test is a joint test to determine that all parameters except the intercept are zero.

• A small significance probability, Pr > F, indicates that some linear function of the parameters is significantly different from zero.

• R-Square, $R^2$, measures how much variation in the dependent variable can be accounted for by the model. $R^2$, which can range from 0 to 1, is the ratio of the sum of squares for the model divided by the sum of squares for the corrected total. In general, the larger the value of $R^2$, the better the model’s fit.

• Coef Var, the coefficient of variation, which describes the amount of variation in the population, is 100 times the standard deviation estimate of the dependent variable. Root MSE (Mean Square for Error), divided by the Mean. The coefficient of variation is often a preferred measure because it is unitless.

• Root MSE estimates the standard deviation of the dependent variable (or equivalently, the error term) and equals the square root of the Mean Square for Error.

• Mean is the sample mean of the dependent variable.

These tests are used primarily in analysis-of-variance applications:

• The Type I SS (sum of squares) measures incremental sums of squares for the model as each variable is added.

• The Type III SS is the sum of squares for a balanced test of each effect, adjusted for every other effect.

These items are used primarily in regression applications:

• The Estimates for the model Parameters (the intercept and the coefficients)

• t Value is the Student’s $t$ value for testing the null hypothesis that the parameter (if it is estimable) equals zero.

• The significance level, Pr > |t|, is the probability of getting a larger value of $t$ if the parameter is truly equal to zero. A very small value for this probability leads to the conclusion that the independent variable contributes significantly to the model.

• The Standard Error is the square root of the estimated variance of the estimate of the true value of the parameter.

Other portions of output are discussed in the following examples.
### ODS Table Names

PROC GLM assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**ODS Graphics (Experimental)**

This section describes the use of ODS for creating statistical graphs with the GLM procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release. To request these graphs you must specify the ODS GRAPHICS statement with an appropriate model, as discussed in the following. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

When the ODS GRAPHICS are in effect, then for particular models the GLM procedure will produce default graphics.

- If you specify an analysis of covariance model, with one classification variable and one continuous variable, the GLM procedure will produce an analysis of covariance plot of the response values versus the covariate values, with lines representing the fitted relationship within each classification level. For an example of the analysis of covariance plot, see Example 32.4 on page 1860.
- If you specify a one-way analysis of variance model, with just one independent classification variable, the GLM procedure will produce a grouped box plot of the response values versus the classification levels. For an example of the box plot, see the “One-Way Layout with Means Comparisons” section on page 424.
Example 32.1. Balanced Randomized Complete Blocks

ODS Graph Names

PROC GLM assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 32.6.

To request these graphs you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

Examples

Example 32.1. Balanced Data from Randomized Complete Block with Means Comparisons and Contrasts

The following example, reported by Stenstrom (1940), analyzes an experiment to investigate how snapdragons grow in various soils. To eliminate the effect of local fertility variations, the experiment is run in blocks, with each soil type sampled in each block. Since these data are balanced, the Type I and Type III SS are the same and are equal to the traditional ANOVA SS.

First, the standard analysis is shown followed by an analysis that uses the SOLUTION option and includes MEANS and CONTRAST statements. The ORDER=DATA option in the second PROC GLM statement is used so that the ordering of coefficients in the CONTRAST statement can correspond to the ordering in the input data. The SOLUTION option requests a display of the parameter estimates, which are only produced by default if there are no CLASS variables. A MEANS statement is used to request a table of the means with two multiple comparison procedures requested. In experiments with focused treatment questions, CONTRAST statements are preferable to general means comparison methods. The following statements produce Output 32.1.1 through Output 32.1.6:

```plaintext

| Type Wabash              | 4.86666667 | B 1.04729432 | 4.65  | 0.0006 |
| Type Webster             | 0.00000000 | B . . . .    | . .   | . .   |

NOTE: The X’X matrix has been found to be singular, and a generalized inverse was used to solve the normal equations. Terms whose estimates are followed by the letter ‘B’ are not uniquely estimable.

Output 32.1.4 shows the tests for contrasts that you specified as well as the estimated parameters. The contrast label, degrees of freedom, sum of squares, Mean Square, F Value, and Pr > F are shown for each contrast requested. In this example, the contrast results show that at the 5% significance level,

- the stem length of plants grown in compost soil is significantly different from the average stem length of plants grown in other soils
- the stem length of plants grown in river soils is significantly different from the average stem length of those grown in nonriver soils
- the average stem length of plants grown in glacial soils (Clarion and Webster) is significantly different from the average stem length of those grown in drift soils (Knox and O’Neill)
- stem lengths for Clarion and Webster are not significantly different
- stem lengths for Knox and O’Neill are not significantly different
In addition to the estimates for the parameters of the model, the results of $t$ tests about the parameters are also displayed. The ‘B’ following the parameter estimates indicates that the estimates are biased and do not represent a unique solution to the normal equations.

**Output 32.1.5. Waller-Duncan tests**

*Balanced Data from Randomized Complete Block*

**The GLM Procedure**

**Waller-Duncan K-ratio $t$ Test for StemLength**

NOTE: This test minimizes the Bayes risk under additive loss and certain other assumptions.

The final two pages of output (Output 32.1.5 and Output 32.1.6) present results of the Waller-Duncan and REGWQ multiple comparison procedures. For each test, notes and information pertinent to the test are given on the output. The Type means are arranged from highest to lowest. Means with the same letter are not significantly different. For this example, while some pairs of means are significantly different, there are no clear equivalence classes among the different soils.
Example 32.2. Regression with Mileage Data

A car is tested for gas mileage at various speeds to determine at what speed the car achieves the greatest gas mileage. A quadratic model is fit to the experimental data. The following statements produce Output 32.2.1 through Output 32.2.5:

```sas
title 'Gasoline Mileage Experiment';
data mileage;
    input mph mpg @@;
datalines;
20 15.4
30 20.2
40 25.7
50 26.2 50 26.6 50 27.4
55 
60 24.8
;
proc glm;
    model mpg=mph mph*mph / p clm;
    output out=pp p=mpgpred r=resid;
    axis1 minor=none major=(number=5); axis2 minor=none major=(number=8);
    symbol1 c=black i=none v=plus;
    symbol2 c=black i=spline v=none;
    proc gplot data=pp;
        plot mpg*mph=1 mpgpred*mph=2 / overlay haxis=axis1 vaxis=axis2;
    run;
```

| Parameter   | Estimate | Standard Error | t Value | Pr > |t| |
|-------------|----------|----------------|---------|------|-----|
| Intercept   | -5.985245902 | 3.18522249 | -1.88   | 0.1334 |
| mph         | 1.305245902  | 0.17259876  | 7.56    | 0.0016 |
| mph*mph     | -0.013098361  | 0.00216852  | -6.04   | 0.0038 |

The overall $F$ statistic is significant. The tests of mph and mph*mph in the Type I sums of squares show that both the linear and quadratic terms in the regression model are significant. The model fits well, with an $R^2$ of 0.97. The table of parameter estimates indicates that the estimated regression equation is

$$
mpg = -5.9852 + 1.3052 \times \text{mph} - 0.0131 \times \text{mph}^2
$$
The P and CLM options in the MODEL statement produce the table shown in Output 32.2.3. For each observation, the observed, predicted, and residual values are shown. In addition, the 95% confidence limits for a mean predicted value are shown for each observation. Note that the observation with a missing value for mph is not used in the analysis, but predicted and confidence limit values are shown.

</tbody>
</table>

The final portion of output gives some additional information on the residuals. The Press statistic gives the sum of squares of predicted residual errors, as described in Chapter 2, “Introduction to Regression Procedures.” The First Order Autocorrelation and the Durbin-Watson D statistic, which measures first-order autocorrelation, are also given.
Output 32.2.5 shows the actual and predicted values for the data. The quadratic relationship between mpg and mph is evident.

Example 32.3. Unbalanced ANOVA for Two-Way Design with Interaction

This example uses data from Kutner (1974, p. 98) to illustrate a two-way analysis of variance. The original data source is Afifi and Azen (1972, p. 166). These statements produce Output 32.3.1 and Output 32.3.2.
Example 32.3. Unbalanced ANOVA for Two-Way Design with Interaction

```sas
/*---------------------------------------------------------*/
/* Note: Kutner's 24 for drug 2, disease 1 changed to 34. */

</tbody>
</table>

Note the differences between the four types of sums of squares. The Type I sum of squares for drug essentially tests for differences between the expected values of the arithmetic mean response for different drugs, unadjusted for the effect of disease. By contrast, the Type II sum of squares for drug measure the differences between arithmetic means for each drug after adjusting for disease. The Type III sum of squares measures the differences between predicted drug means over a balanced drug×disease population—that is, between the LS-means for drug. Finally, the Type IV sum of squares is the same as the Type III sum of squares in this case, since there is data for every drug-by-disease combination.
No matter which sum of squares you prefer to use, this analysis shows a significant
difference among the four drugs, while the disease effect and the drug-by-disease
interaction are not significant. As the previous discussion indicates, Type III sums
of squares correspond to differences between LS-means, so you can follow up the
Type III tests with a multiple comparisons analysis of the drug LS-means. Since the
GLM procedure is interactive, you can accomplish this by submitting the following statements after the previous ones that performed the ANOVA.

\[
\text{lsmeans drug / pdiff=all adjust=tukey;}
\]
\[
\text{run;}
\]

Both the LS-means themselves and a matrix of adjusted \( p \)-values for pairwise differ-
ences between them are displayed; see Output 32.3.3.

The multiple comparisons analysis shows that drugs 1 and 2 have very similar effects,
and that drugs 3 and 4 are also insignificantly different from each other. Evidently,
the main contribution to the significant drug effect is the difference between the 1/2
pair and the 3/4 pair.
Example 32.4. Analysis of Covariance

Analysis of covariance combines some of the features of both regression and analysis of variance. Typically, a continuous variable (the covariate) is introduced into the model of an analysis-of-variance experiment.

Data in the following example are selected from a larger experiment on the use of drugs in the treatment of leprosy (Snedecor and Cochran 1967, p. 422).

Variables in the study are

- Drug - two antibiotics (A and D) and a control (F)
- PreTreatment - a pre-treatment score of leprosy bacilli
- PostTreatment - a post-treatment score of leprosy bacilli

Ten patients are selected for each treatment (Drug), and six sites on each patient are measured for leprosy bacilli.

The covariate (a pretreatment score) is included in the model for increased precision in determining the effect of drug treatments on the posttreatment count of bacilli.

The following code creates the data set, performs a parallel-slopes analysis of covariance with PROC GLM, and computes Drug LS-means. These statements produce Output 32.4.1.

```plaintext
data drugtest;
  input Drug $ PreTreatment PostTreatment @@;
datalines;
A 11 6 A 8 0 A 5 2 A 14 8 A 19 11
A 6 4 A 10 13 A 6 1 A 11 8 A 3 0
D 6 0 D 6 2 D 7 3 D 8 1 D 18 18
D 8 4 D 19 14 D 8 9 D 5 1 D 15 9
F 16 13 F 13 10 F 11 18 F 9 5 F 21 23
F 16 12 F 12 5 F 12 16 F 7 1 F 12 20 ;

proc glm;
  class Drug;
  model PostTreatment = Drug PreTreatment / solution;
  lsmeans Drug / stderr pdiff cov out=adjmeans;
run;

proc print data=adjmeans;
run;

R-Square Coeff Var Root MSE PostTreatment Mean
0.676261 50.70604 4.00578 7.900000

This model assumes that the slopes relating posttreatment scores to pretreatment scores are parallel for all drugs. You can check this assumption by including the class-by-covariate interaction, Drug*PreTreatment, in the model and examining the ANOVA test for the significance of this effect. This extra test is omitted in this example, but it is insignificant, justifying the equal-slopes assumption.

In Output 32.4.2, the Type I SS for Drug (293.6) gives the between-drug sums of squares that are obtained for the analysis-of-variance model PostTreatment=Drug. This measures the difference between arithmetic means of posttreatment scores for different drugs, disregarding the covariate. The Type III SS for Drug (68.5537) gives the Drug sum of squares adjusted for the covariate. This measures the differences between Drug LS-means, controlling for the covariate. The Type I test is highly significant ($p = 0.001$), but the Type III test is not. This indicates that, while there is a statistically significant difference between the arithmetic drug means, this difference is reduced to below the level of background noise when you take the pretreatment scores into account. From the table of parameter estimates, you can derive the least-squares predictive formula model for estimating posttreatment score based on
pretreatment score and drug.

\[
\text{post} = \begin{cases} 
(-0.435 + -3.446) + 0.987 \cdot \text{pre}, & \text{if Drug=A} \\
(-0.435 + -3.337) + 0.987 \cdot \text{pre}, & \text{if Drug=D} \\
-0.435 + 0.987 \cdot \text{pre}, & \text{if Drug=F} 
\end{cases}
\]

| Drug D      | -3.337166948 | 1.85386642 | -1.80  | 0.0835|
| Drug F      | 0.000000000 | .          | .      | .     |
| PreTreatment| 0.987183811 | 0.16449757 | 6.00   | <.0001|

NOTE: The X'X matrix has been found to be singular, and a generalized inverse was used to solve the normal equations. Terms whose estimates are followed by the letter 'B' are not uniquely estimable.

Output 32.4.3 displays the LS-means, which are, in a sense, the means adjusted for the covariate. The STDERR option in the LSMEANS statement causes the standard error of the LS-means and the probability of getting a larger \( t \) value under the hypothesis \( H_0: \text{LS-mean} = 0 \) to be included in this table as well. Specifying the PDIFF option causes all probability values for the hypothesis \( H_0: \text{LS-mean}(i) = \text{LS-mean}(j) \) to be displayed, where the indexes \( i \) and \( j \) are numbered treatment levels.
Output 32.4.3. LS-means

The GLM Procedure
Least Squares Means

```
Drug  Post Treatment  Standard  Pr > |t|  LSMEAN
      LSMEAN  Error     Number

A  6.7149635  1.2884943  <.0001  1
D  6.8239348  1.2724690  <.0001  2
F 10.1611017  1.3159234  <.0001  3

Least Squares Means for effect Drug
Pr > |t| for H0: LSMean(i)=LSMean(j)
Dependent Variable: PostTreatment

i/j  1   2   3
1  0.9521 0.0793
2  0.9521 0.0835
3  0.0793 0.0835
```

NOTE: To ensure overall protection level, only probabilities associated with pre-planned comparisons should be used.

The OUT= and COV options in the LSMEANS statement create a data set of the estimates, their standard errors, and the variances and covariances of the LS-means, which is displayed in Output 32.4.4.

Output 32.4.4. LS-means Output Data Set

```
Obs   _NAME_   Drug  LSMEAN  STDERR  NUMBER  COV1     COV2     COV3
1    PostTreatment  A  6.7150  1.28849  1  1.66022  0.02844  -0.08403
2    PostTreatment  D  6.8239  1.27247  2  0.02844  1.61918  -0.04299
3    PostTreatment  F 10.1611  1.31592  3  -0.08403 -0.04299  1.73165
```

The experimental graphics features of PROC GLM enable you to visualize the fitted analysis of covariance model.

```plaintext
ods html;
ods graphics on;

proc glm;
    class Drug;
    model PostTreatment = Drug PreTreatment;
run;

ods graphics off;
ods html close;
```
When you specify the experimental ODS GRAPHICS statement and fit an analysis of covariance model, the GLM procedure output includes an analysis of covariance plot, as in Output 32.4.5. For general information about ODS graphics see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the GLM procedure, see the section “ODS Graphics” on page 1846.

**Output 32.4.5.** Analysis of Covariance Plot (Experimental)

The plot makes it clear that the control (drug F) has higher post-treatment scores across the range of pre-treatment scores, while the fitted models for the two antibiotics (drugs A and D) nearly coincide.

**Example 32.5. Three-Way Analysis of Variance with Contrasts**

This example uses data from Cochran and Cox (1957, p. 176) to illustrate the analysis of a three-way factorial design with replication, including the use of the CONTRAST statement with interactions, the OUTSTAT= data set, and the SLICE= option in the LSMEANS statement.

The object of the study is to determine the effects of electric current on denervated muscle. The variables are
Rep  
the replicate number, 1 or 2

Time  
the length of time the current is applied to the muscle, ranging from 1 to 4

Current  
the level of electric current applied, ranging from 1 to 4

Number  
the number of treatments per day, ranging from 1 to 3

MuscleWeight  
the weight of the denervated muscle

The following code produces Output 32.5.1 through Output 32.5.4.

data muscles;
  do Rep=1 to 2;
    do Time=1 to 4;
      do Current=1 to 4;
        do Number=1 to 3;
          input MuscleWeight @@;
          output;
        end;
      end;
    end;
  end;
datalines;
72 74 69 61 65 62 65 70 85 76 61
67 52 62 60 55 59 64 65 67 72 60
57 66 72 72 43 43 63 66 72 56 75 92
57 56 78 60 63 58 61 79 68 73 86 71
46 74 58 60 64 52 71 64 71 53 65 66
44 58 54 57 55 51 62 64 71 56 58 69
46 55 64 56 55 57 64 66 62 59 58 88
;

proc glm outstat=summary;
  class Rep Current Time Number;
  model MuscleWeight = Rep Current|Time|Number;
  contrast ’Time in Current 3’
    Time 1 0 0 -1 Current*Time 0 0 0 0 0 0 0 0 1 0 0 -1,
    Time 0 1 0 -1 Current*Time 0 0 0 0 0 0 0 0 1 0 -1,
    Time 0 0 1 -1 Current*Time 0 0 0 0 0 0 0 0 0 1 -1;
  contrast ’Current 1 versus 2’ Current 1 -1;
  lsmeans Current*Time / slice=Current;
run;

proc print data=summary;
run;

The first CONTRAST statement examines the effects of Time within level 3 of Current. This is also called the simple effect of Time within Current*Time. Note that, since there are three degrees of freedom, it is necessary to specify three rows in the CONTRAST statement, separated by commas. Since the parameterization that PROC GLM uses is determined in part by the ordering of the variables in the CLASS
statement, Current is specified before Time so that the Time parameters are nested within the Current*Time parameters; thus, the Current*Time contrast coefficients in each row are simply the Time coefficients of that row within the appropriate level of Current.

The second CONTRAST statement isolates a single degree of freedom effect corresponding to the difference between the first two levels of Current. You can use such a contrast in a large experiment where certain preplanned comparisons are important, but you want to take advantage of the additional error degrees of freedom available when all levels of the factors are considered.

The LSMEANS statement with the SLICE= option is an alternative way to test for the simple effect of Time within Current*Time. In addition to listing the LS-means for each current strength and length of time, it gives a table of $F$-tests for differences between the LS-means across Time within each Current level. In some cases, this can be a way to disentangle a complex interaction.

**Output 32.5.1.** Overall Analysis

R-Square Coeff Var Root MSE MuscleWeight Mean

0.643805 13.05105 8.250712 63.21875

The output, shown in **Output 32.5.2** and **Output 32.5.3**, indicates that the main effects
for Rep, Current, and Number are significant (with $p$-values of 0.0045, <0.0001, and 0.0461, respectively), but Time is not significant, indicating that, in general, it doesn’t matter how long the current is applied. None of the interaction terms are significant, nor are the contrasts significant. Notice that the row in the sliced ANOVA table corresponding to level 3 of current matches the “Time in Current 3” contrast.

### Example 32.6. Multivariate Analysis of Variance

The following example employs multivariate analysis of variance (MANOVA) to measure differences in the chemical characteristics of ancient pottery found at four kiln sites in Great Britain. The data are from Tubb et al. (1980), as reported in Hand et al. (1994).

For each of 26 samples of pottery, the percentages of oxides of five metals are measured. The following statements create the data set and invoke the GLM procedure to perform a one-way MANOVA. Additionally, it is of interest to know whether the pottery from one site in Wales (Llanederyn) differs from the samples from other sites; a CONTRAST statement is used to test this hypothesis.

```sas
data pottery;
title1 "Romano-British Pottery";
  input Site $12. Al Fe Mg Ca Na;
datalines;
Llanederyn 14.4 7.00 4.30 0.15 0.51

AshleyRails 14.8 2.74 0.67 0.03 0.05
Ashley Rails 19.1 1.64 0.60 0.10 0.03
```

After the summary information, displayed in Output 32.6.1, PROC GLM produces the univariate analyses for each of the dependent variables, as shown in Output 32.6.2 to Output 32.6.6. These analyses show that sites are significantly different for all oxides individually. You can suppress these univariate analyses by specifying the NOUNI option in the MODEL statement.

The PRINTE option in the MANOVA statement displays the elements of the error matrix, also called the Error Sums of Squares and Crossproducts matrix. See Output 32.6.7. The diagonal elements of this matrix are the error sums of squares from the corresponding univariate analyses.

The PRINTE option also displays the partial correlation matrix associated with the E matrix. In this example, none of the oxides are very strongly correlated; the strongest correlation \( r = 0.488 \) is between magnesium oxide and calcium oxide.

The PRINTH option produces the SSCP matrix for the hypotheses being tested (Site and the contrast); see Output 32.6.8 and Output 32.6.9. Since the Type III SS are the highest level SS produced by PROC GLM by default, and since the HTYPE= option is not specified, the SSCP matrix for Site gives the Type III H matrix. The diagonal elements of this matrix are the model sums of squares from the corresponding univariate analyses.

Four multivariate tests are computed, all based on the characteristic roots and vectors of $E^{-1}H$. These roots and vectors are displayed along with the tests. All four tests can be transformed to variates that have $F$ distributions under the null hypothesis. Note that the four tests all give the same results for the contrast, since it has only one degree of freedom. In this case, the multivariate analysis matches the univariate results: there is an overall difference between the chemical composition of samples from different sites, and the samples from Llanederyn are different from the average of the other sites.

Example 32.7. Repeated Measures Analysis of Variance

This example uses data from Cole and Grizzle (1966) to illustrate a commonly occurring repeated measures ANOVA design. Sixteen dogs are randomly assigned to four groups. (One animal is removed from the analysis due to a missing value for one dependent variable.) Dogs in each group receive either morphine or trimethaphan (variable Drug) and have either depleted or intact histamine levels (variable Depleted) before receiving the drugs. The dependent variable is the blood concentration of histamine at 0, 1, 3, and 5 minutes after injection of the drug. Logarithms are applied to these concentrations to minimize correlation between the mean and the variance of the data.

The following SAS statements perform both univariate and multivariate repeated measures analyses and produce Output 32.7.1 through Output 32.7.7:
data dogs;
  input Drug $12. Depleted $ Histamine0 Histamine1 Histamine3 Histamine5;
  LogHistamine0=log(Histamine0);
  LogHistamine1=log(Histamine1);
  LogHistamine3=log(Histamine3);
  LogHistamine5=log(Histamine5);
datalines;
  Morphine N .04 .20 .10 .08
  Morphine N .02 .06 .02 .02
  Morphine N .07 1.40 .48 .24
  Morphine N .17 .57 .35 .24
  Morphine Y .10 .09 .13 .14
  Morphine Y .12 .11 .10
  Morphine Y .07 .07 .06 .07
  Morphine Y .05 .07 .06 .07

;
proc glm;
  class Drug Depleted;
  model LogHistamine0--LogHistamine5 =
    Drug Depleted Drug*Depleted / nouni;
  repeated Time 4 (0 1 3 5) polynomial / summary printe;
run;

The NOUNI option in the MODEL statement suppresses the individual ANOVA tables for the original dependent variables. These analyses are usually of no interest in a repeated measures analysis. The POLYNOMIAL option in the REPEATED statement indicates that the transformation used to implement the repeated measures analysis is an orthogonal polynomial transformation, and the SUMMARY option requests that the univariate analyses for the orthogonal polynomial contrast variables be displayed. The parenthetical numbers (0 1 3 5) determine the spacing of the orthogonal polynomials used in the analysis. The output is displayed in Output 32.7.1 through Output 32.7.7.
Output 32.7.1. Summary Information on Groups

The GLM Procedure

<td></td>
</tr>
<tr>
<td>Level of Time</td>
<td>0</td>
<td>1</td>
<td>3</td>
<td>5</td>
</tr>
</tbody>
</table>

The multivariate analyses for within-subject effects and related interactions are displayed in Output 32.7.3. For the example, the first table displayed shows that the TIME effect is significant. In addition, the Time*Drug*Depleted interaction is significant, as shown in the fourth table. This means that the effect of Time on the blood concentration of histamine is different for the four Drug*Depleted combinations studied.

Output 32.7.4 displays tests of hypotheses for between-subject (between-dog) effects. This section tests the hypotheses that the different Drugs, Depleteds, and their interactions have no effects on the dependent variables, while ignoring the within-dog effects. From this analysis, there is a significant between-dog effect for Depleted (p-value=0.0229). The interaction and the main effect for Drug are not significant (p-values=0.1734 and 0.1281, respectively).
Output 32.7.4. Tests of Between-Subject Effects

Output 32.7.5. Sphericity Test

Output 32.7.6. Univariate Tests of Within-Subject Effects

Output 32.7.7 is produced by the SUMMARY option in the REPEATED statement. If the POLYNOMIAL option is not used, a similar table is displayed using the default CONTRAST transformation. The linear, quadratic, and cubic trends for Time,
labeled as ‘Time_1’, ‘Time_2’, and ‘Time_3’, are displayed, and in each case, the Source labeled ‘Mean’ gives a test for the respective trend.

**Example 32.8.** Mixed Model Analysis of Variance Using the RANDOM Statement

Milliken and Johnson (1984) present an example of an unbalanced mixed model. Three machines, which are considered as a fixed effect, and six employees, which are considered a random effect, are studied. Each employee operates each machine for either one, two, or three different times. The dependent variable is an overall rating, which takes into account the number and quality of components produced.

The following statements form the data set and perform a mixed model analysis of variance by requesting the TEST option in the RANDOM statement. Note that the machine*person interaction is declared as a random effect; in general, when an interaction involves a random effect, it too should be declared as random. The results of the analysis are shown in **Output 32.8.1** through **Output 32.8.4**.

    data machine;
    input machine person rating @@;
Example 32.8. Mixed Model Analysis of Variance Using the RANDOM Statement

```
datalines;
1 1 52.0 1 2 51.8 1 2 52.8 1 3 60.0 1 4 51.1 1 4 52.3
1 5 50.9 1 5 51.8 1 5 51.4 1 6 46.4 1 6 44.8 1 6 49.2
2 1 64.0 2 2 59.7 2 2 60.0 2 2 59.0 2 3 68.6 2 3 65.8
2 4 63.2 2 4 62.8 2 4 62.2 2 5 64.8 2 5 65.0 2 6 43.7
2 6 44.2 2 6 43.0 3 1 67.5 3 1 67.2 3 1 66.9 3 2 61.5
3 2 61.7 3 2 62.3 3 3 70.8 3 3 70.6 3 3 71.0 3 4 64.1
3 4 66.2 3 4 64.0 3 5 72.1 3 5 72.0 3 5 71.1 3 6 62.0
3 6 61.4 3 6 60.5
;
proc glm data=machine;
   class machine person;
   model rating=machine person machine*person;
   random person machine*person / test;
run;
```

The TEST option in the RANDOM statement requests that PROC GLM determine the appropriate F-tests based on person and machine*person being treated as random effects. As you can see in Output 32.8.4, this requires that a linear combination of mean squares be constructed to test both the machine and person hypotheses; thus, F-tests using Satterthwaite approximations are used.

**Output 32.8.1.** Summary Information on Groups

```
   Number of Observations Read        44
   Number of Observations Used         44
```

The advantage of PROC MIXED is that it offers more versatility for mixed models; the disadvantage is that it can be less computationally efficient for large data sets. See Chapter 46, “The MIXED Procedure,” for more details.

**Example 32.9. Analyzing a Doubly-multivariate Repeated Measures Design**

This example shows how to analyze a doubly-multivariate repeated measures design by using PROC GLM with an IDENTITY factor in the REPEATED statement. Note that this differs from previous releases of PROC GLM, in which you had to use a MANOVA statement to get a doubly repeated measures analysis.

Two responses, Y1 and Y2, are each measured three times for each subject (pretreatment, posttreatment, and in a later follow-up). Each subject receives one of three treatments; A, B, or the control. In PROC GLM, you use a REPEATED factor of type IDENTITY to identify the different responses and another repeated factor to identify the different measurement times. The repeated measures analysis includes multivariate tests for time and treatment main effects, as well as their interactions, across responses. The following statements produce Output 32.9.1 through Output 32.9.3.
Example 32.9. Analyzing a Doubly-multivariate Repeated Measures Design

data Trial;
  input Treatment $ Repetition PreY1 PostY1 FollowY1 PreY2 PostY2 FollowY2;
datalines;
A  1 3 13 9 0 0 9

NOTE: F Statistic for Roy’s Greatest Root is an upper bound.
NOTE: F Statistic for Wilks’ Lambda is exact.

The table for Response*Treatment tests for an overall treatment effect across the two responses; likewise, the tables for Response*Time and Response*Treatment*Time test for time and the treatment-by-time interaction, respectively. In this case, there is a strong main effect for time and possibly for the interaction, but not for treatment.
In previous releases (before the IDENTITY transformation was introduced), in order to perform a doubly repeated measures analysis, you had to use a MANOVA statement with a customized transformation matrix M. You might still want to use this approach to see details of the analysis, such as the univariate ANOVA for each transformed variate. The following statements demonstrate this approach by using the MANOVA statement to test for the overall main effect of time and specifying the SUMMARY option.

```sas
proc glm data=Trial;
  class Treatment;
  model PreY1 PostY1 FollowY1
       PreY2 PostY2 FollowY2 = Treatment / nouni;
  manova h=intercept m=prey1 - posty1,
       prey1 - followy1,
       prey2 - posty2,
       prey2 - followy2 / summary;
run;
```

The M matrix used to perform the test for time effects is displayed in Output 32.9.4, while the results of the multivariate test are given in Output 32.9.5. Note that the test results are the same as for the Response*Time effect in Output 32.9.3.

The SUMMARY option in the MANOVA statement creates an ANOVA table for each transformed variable as defined by the M matrix. MVAR1 and MVAR2 contrast the pretreatment measurement for $Y_1$ with the posttreatment and follow-up measurements for $Y_1$, respectively; MVAR3 and MVAR4 are the same contrasts for $Y_2$. Output 32.9.6 displays these univariate ANOVA tables and shows that the contrasts are all strongly significant except for the pre-versus-post difference for $Y_2$.

### Example 32.10. Testing for Equal Group Variances

This example demonstrates how you can test for equal group variances in a one-way design. The data come from the University of Pennsylvania Smell Identification Test (UPSIT), reported in O’Brien and Heft (1995). The study is undertaken to explore how age and gender are related to sense of smell. A total of 180 subjects 20 to 89 years old are exposed to 40 different odors: for each odor, subjects are asked to choose which of four words best describes the odor. The Freeman-Tukey modified arcsine transformation (Bishop et al. 1975) is applied to the proportion of correctly identified odors to arrive at an olfactory index. For the following analysis, subjects
are divided into five age groups:

\[
\text{agegroup} = \begin{cases} 
1 & \text{if age} \leq 25 \\
2 & \text{if } 25 < \text{age} \leq 40 \\
3 & \text{if } 40 < \text{age} \leq 55 \\
4 & \text{if } 55 < \text{age} \leq 70 \\
5 & \text{if } 70 < \text{age}
\end{cases}
\]

The following statements create a data set named `upsit`, containing the age group and olfactory index for each subject.

```plaintext
data upsit;
  input agegroup smell @@;

;
```

Older people are more at risk for problems with their sense of smell, and this should be reflected in significant differences in the mean of the olfactory index across the different age groups. However, many older people also have an excellent sense of smell, which implies that the older age groups should have greater variability. In order to test this hypothesis and to compute a one-way ANOVA for the olfactory index that is robust to the possibility of unequal group variances, you can use the HOVTEST and WELCH options in the MEANS statement for the GLM procedure, as shown in the following code.
proc glm data=upsit;
  class agegroup;
  model smell = agegroup;
  means agegroup / hovtest welch;
run;

Output 32.10.1, Output 32.10.2, and Output 32.10.3 display the usual ANOVA test for equal age group means, Levene’s test for equal age group variances, and Welch’s test for equal age group means, respectively. The hypotheses of age effects for mean and variance of the olfactory index are both confirmed.

Example 32.11. Analysis of a Screening Design

Yin and Jillie (1987) describe an experiment on a nitride etch process for a single wafer plasma etcher. The experiment is run using four factors: cathode power (power), gas flow (flow), reactor chamber pressure (pressure), and electrode gap (gap). Of interest are the main effects and interaction effects of the factors on the nitride etch rate (rate). The following statements create a SAS data set named HalfFraction, containing the factor settings and the observed etch rate for each of eight experimental runs.

```sas
data HalfFraction;
  input power flow pressure gap rate;
datalines;
  0.8 4.5 125 275 550
  0.8 4.5 200 325 650
  0.8 550.0 125 325 642
  0.8 550.0 200 275 601
  1.2 4.5 125 325 749
  1.2 4.5 200 275 1052
  1.2 550.0 125 275 1075
  1.2 550.0 200 325 729;
```

Notice that each of the factors has just two values. This is a common experimental design when the intent is to screen from the many factors that might affect the response the few that actually do. Since there are $2^4 = 16$ different possible settings of four two-level factors, this design with only eight runs is called a “half fraction.” The eight runs are chosen specifically to provide unambiguous information on main effects at the cost of confounding interaction effects with each other.

One way to analyze this data is simply to use PROC GLM to compute an analysis of variance, including both main effects and interactions in the model. The following statements demonstrate this approach.

```sas
proc glm data=HalfFraction;
  class power flow pressure gap;
  model rate=power|flow|pressure|gap@2;
run;
```

The ‘@2’ notation on the model statement includes all main effects and two-factor interactions between the factors. The output is shown in Output 32.11.1.

</tbody>
</table>
Notice that there are no error degrees of freedom. This is because there are 10 effects in the model (4 main effects plus 6 interactions) but only 8 observations in the data set. This is another cost of using a fractional design: not only is it impossible to estimate all the main effects and interactions, but there is also no information left to estimate the underlying error rate in order to measure the significance of the effects that are estimable.

Another thing to notice in Output 32.11.1 is the difference between the Type I and Type III ANOVA tables. The rows corresponding to main effects in each are the same, but no Type III interaction tests are estimable, while some Type I interaction tests are estimable. This indicates that there is aliasing in the design: some interactions are completely confounded with each other.

In order to analyze this confounding, you should examine the aliasing structure of the design using the ALIASING option in the MODEL statement. Before doing so, however, it is advisable to code the design, replacing low and high levels of each factor with the values -1 and +1, respectively. This puts each factor on an equal footing in the model and makes the aliasing structure much more interpretable. The following statements code the data, creating a new data set named Coded.

```sas
data Coded; set HalfFraction;
power = -1*(power =0.80) + 1*(power =1.20);
flow = -1*(flow =4.50) + 1*(flow =550 );
pressure = -1*(pressure=125 ) + 1*(pressure=200 );
gap = -1*(gap =275 ) + 1*(gap =325 );
run;
```

The following statements use the GLM procedure to reanalyze the coded design, displaying the parameter estimates as well as the functions of the parameters that they each estimate.

```sas
proc glm data=Coded;
   model rate=power|flow|pressure|gap@2 / solution aliasing;
run;
```

The parameter estimates table is shown in Output 32.11.2.
Output 32.11.2. Parameter Estimates and Aliases for Nitride Etch Process Half Fraction

The GLM Procedure
Dependent Variable: rate

| Parameter       | Estimate | Standard Error | t Value | Pr > |t| | Expected Value         |

| Intercept       | 756.00000000 | .               | .       | .     | .                       | Intercept                |
| power           | 145.25000000 | .               | .       | .     | .                       | power                    |
| flow            | 5.75000000  | .               | .       | .     | .                       | flow                     |
| power*flow      | -5.00000000 B | .             | .       | .     | .                       | power*flow + pressure*gap |
| pressure        | 2.00000000  | .               | .       | .     | .                       | pressure                 |
| power*pressure  | -12.75000000 B | .             | .       | .     | .                       | power*pressure + flow*gap |
| flow*pressure   | -98.75000000 B | .            | .       | .     | .                       | flow*pressure + power*gap |
| gap             | -63.50000000 | .              | .       | .     | .                       | gap                      |
| power*gap       | 0.00000000   | .              | .       | .     | .                       | (no expected value)       |
| flow*gap        | 0.00000000   | .              | .       | .     | .                       | (no expected value)       |
| pressure*gap    | 0.00000000   | .              | .       | .     | .                       | (no expected value)       |

NOTE: The X'X matrix has been found to be singular, and a generalized inverse was used to solve the normal equations. Terms whose estimates are followed by the letter 'B' are not uniquely estimable.

Looking at the “Expected Value” column, notice that, while each of the main effects is unambiguously estimated by its associated term in the model, the expected values of the interaction estimates are more complicated. For example, the relatively large effect (-98.75) corresponding to \( \text{flow} \times \text{pressure} \) actually estimates the combined effect of \( \text{flow} \times \text{pressure} \) and \( \text{power} \times \text{gap} \). Without further information, it is impossible to disentangle these aliased interactions; however, since the main effects of both \( \text{power} \) and \( \text{gap} \) are large and those for \( \text{flow} \) and \( \text{pressure} \) are small, it is reasonable to suspect that \( \text{power} \times \text{gap} \) is the more “active” of the two interactions.

Fortunately, eight more runs are available for this experiment (the other half fraction.) The following statements create a data set containing these extra runs and add it to the previous eight, resulting in a full \( 2^4 = 16 \) run replicate. Then PROC GLM displays the analysis of variance again.
Example 32.11. Analysis of a Screening Design

```sas
data OtherHalf;
    input power flow pressure gap rate;
data lines;
0.8 4.5 125 325 669
0.8 4.5 200 275 604
0.8 550.0 125 275 633
0.8 550.0 200 325 635
1.2 4.5 125 275 1037
1.2 4.5 200 325 868
1.2 550.0 125 325 860
1.2 550.0 200 275 1063;
;
run;
```

```sas
proc glm data=FullRep;
    class power flow pressure gap;
    model rate=power|flow|pressure|gap@2;
run;
```

The results are displayed in Output 32.11.3.

</table>
With sixteen runs, the analysis of variance tells the whole story: all effects are estimable and there are five degrees of freedom left over to estimate the underlying error. The main effects of power and gap and their interaction are all significant, and no other effects are. Notice that the Type I and Type III ANOVA tables are the same; this is because the design is orthogonal and all effects are estimable.

This example illustrates the use of the GLM procedure for the model analysis of a screening experiment. Typically, there is much more involved in performing an experiment of this type, from selecting the design points to be studied to graphically assessing significant effects, optimizing the final model, and performing subsequent experimentation. Specialized tools for this are available in SAS/QC software, in particular the ADX Interface and the FACTEX and OPTEX procedures. Refer to SAS/QC User’s Guide for more information.

Chapter 33
The GLMMOD Procedure

Overview

The GLMMOD procedure constructs the design matrix for a general linear model; it essentially constitutes the model-building front end for the GLM procedure. You can use the GLMMOD procedure in conjunction with other SAS/STAT software regression procedures or with SAS/IML software to obtain specialized analyses for general linear models that you cannot obtain with the GLM procedure.

While some of the regression procedures in SAS/STAT software provide for general linear effects modeling with classification variables and interaction or polynomial effects, many others do not. For such procedures, you must specify the model directly in terms of distinct variables. For example, if you want to use the REG procedure to fit a polynomial model, you must first create the crossproduct and power terms as new variables, usually in a DATA step. Alternatively, you can use the GLMMOD procedure to create a data set that contains the design matrix for a model as specified using the effects modeling facilities of the GLM procedure.

Note that the TRANSREG procedure provides alternative methods to construct design matrices for full-rank and less-than-full-rank models, polynomials, and splines. See Chapter 75, “The TRANSREG Procedure,” for more information.

Getting Started

A One-Way Design

A one-way analysis of variance considers one treatment factor with two or more treatment levels. This example employs PROC GLMMOD together with PROC REG to perform a one-way analysis of variance to study the effect of bacteria on the nitrogen content of red clover plants. The treatment factor is bacteria strain, and it has six levels. Red clover plants are inoculated with the treatments, and nitrogen content is later measured in milligrams. The data are derived from an experiment by Erdman (1946) and are analyzed in Chapters 7 and 8 of Steel and Torrie (1980). PROC GLMMOD is used to create the design matrix. The following DATA step creates the SAS data set Clover.
title 'Nitrogen Content of Red Clover Plants';
data Clover;
  input Strain $ Nitrogen @@;
datalines;
3DOK1 19.4 3DOK1 32.6 3DOK1 27.0 3DOK1 32.1 3DOK1 33.0

COMPOS 17.3 COMPOS 19.4 COMPOS 19.1 COMPOS 16.9 COMPOS 20.8
;

The variable Strain contains the treatment levels, and the variable Nitrogen contains the response. The following statements produce the design matrix:

```
proc glmmod data=Clover;
  class Strain;
  model Nitrogen = Strain;
run;
```

The classification variable, or treatment factor, is specified in the CLASS statement. The MODEL statement defines the response and independent variables. The design matrix produced corresponds to the model

\[ Y_{i,j} = \mu + \alpha_i + \epsilon_{i,j} \]

where \( i = 1, \ldots, 6 \), and \( j = 1, \ldots, 5 \).

Figure 33.1 and Figure 33.2 display the output produced by these statements. Figure 33.1 displays information about the data set, which is useful for checking your data.

**Figure 33.1.** Class Level Information and Parameter Definitions

The design matrix, shown in Figure 33.2, consists of seven columns: one for the mean and six for the treatment levels. The vector of responses, Nitrogen, is also displayed.
Figure 33.2. Design Matrix

Usually, you will find PROC GLMMOD most useful for the data sets it can create rather than for its displayed output. For example, the following statements use PROC GLMMOD to save the design matrix for the clover study to the data set CloverDesign instead of displaying it.

```
proc glmmod data=Clover outdesign=CloverDesign noprint;
  class Strain;
  model Nitrogen = Strain;
run;
```

Now you can use the REG procedure to analyze the data, as the following statements demonstrate:

```
proc reg data=CloverDesign;
  model Nitrogen = Col2-Col7;
run;
```
The results are shown in Figure 33.3.

**Figure 33.3.** Regression Analysis

### Syntax

The following statements are available in PROC GLMMOD.

```plaintext
PROC GLMMOD < options >;  
    BY variables;  
    CLASS variables;  
    FREQ variable;  
    MODEL dependents=independents / < options >;  
    WEIGHT variable;
```
The PROC GLMMOD and MODEL statements are required. If classification effects are used, the class variables must be declared in a CLASS statement, and the CLASS statement must appear before the MODEL statement.

**PROC GLMMOD Statement**

```
PROC GLMMOD < options > ;
```

The PROC GLMMOD statement invokes the GLMMOD procedure. It has the following options:

- **DATA=SAS-data-set**
  specifies the SAS data set to be used by the GLMMOD procedure. If you do not specify the DATA= option, the most recently created SAS data set is used.

- **NAMELEN=n**
  specifies the maximum length for an effect name. Effect names are listed in the table of parameter definitions and stored in the EFFNAME variable in the OUTPARM= data set. By default, \( n = 20 \). You can specify \( 20 < n \leq 200 \) if 20 characters are not enough to distinguish between effects, which may be the case if the model includes a high-order interaction between variables with relatively long, similar names.

- **NOPRINT**
  suppresses the normal display of results. This option is generally useful only when one or more output data sets are being produced by the GLMMOD procedure. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

- **ORDER=DATA | FORMATTED | FREQ | INTERNAL**
  specifies the order in which you want the levels of the classification variables (specified in the CLASS statement) to be sorted. This ordering determines which parameters in the model correspond to each level in the data. Note that the ORDER= option applies to the levels for all classification variables. The exception is the default ORDER=FORMATTED for numeric variables for which you have supplied no explicit format. In this case, the levels are ordered by their internal (numeric) value. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the affected classification variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or ORDER=INTERNAL to get the more natural ordering.

The ORDER= option can take the following values.
<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric</td>
</tr>
<tr>
<td></td>
<td>variables with no explicit format, which are</td>
</tr>
<tr>
<td></td>
<td>sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the</td>
</tr>
<tr>
<td></td>
<td>most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

If you omit the ORDER= option, PROC GLMMOD orders by the external formatted value.

**OUTPARM=** *SAS-data-set*

names an output data set to contain the information regarding the association between model effects and design matrix columns.

**OUTDESIGN=** *SAS-data-set*

names an output data set to contain the columns of the design matrix.

**PREFIX=** *name*

specifies a prefix to use in naming the columns of the design matrix in the OUTDESIGN= data set. The default prefix is `Col` and the column name is formed by appending the column number to the prefix, so that by default the columns are named `Col1`, `Col2`, and so on. If you specify the ZEROBASED option, the column numbering starts at zero, so that with the default value of PREFIX= the columns of the design matrix in the OUTDESIGN= data set are named `Col0`, `Col1`, and so on.

**ZEROBASED**

specifies that the numbering for the columns of the design matrix in the OUTDESIGN= data set should begin at 0. By default it begins at 1, so that with the default value of PREFIX= the columns of the design matrix in the OUTDESIGN= data set are named `Col1`, `Col2`, and so on. If you use the ZEROBASED option, the column names are instead `Col0`, `Col1`, and so on.

**BY Statement**

```
BY variables;
```

You can specify a BY statement with the GLMMOD procedure to obtain separate designs for observations in groups defined by the BY variables. When you specify a BY statement, the procedure expects the input DATA= data set to be sorted in the order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
• Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the GLMMOD procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

• Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

**CLASS Statement**

```
CLASS variables < option > ;
```

The CLASS statement names the classification variables to be used in the analysis. Typical classification variables are Treatment, Sex, Race, Group, and Replication. If you specify the CLASS statement, it must appear before the MODEL statement.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option on the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the SAS Procedures Guide and the discussions for the FORMAT statement and SAS formats in SAS Language Reference: Dictionary.

You can specify the following option in the CLASS statement after a slash(/):

**TRUNCATE**

specifies that class levels should be determined using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

**FREQ and WEIGHT Statements**

```
FREQ variable ;
WEIGHT variable ;
```

FREQ and WEIGHT variables are transferred to the output data sets without change.
**MODEL Statement**

```
MODEL dependents=independents / <options> ;
```

The MODEL statement names the dependent variables and independent effects. For the syntax of effects, see the “Specification of Effects” section on page 1784 in Chapter 32, “The GLM Procedure.”

You can specify the following option in the MODEL statement after a slash (/).

**NOINT**

requests that the intercept parameter not be included in the model.

---

**Details**

**Displayed Output**

For each pass of the data (that is, for each BY group and for each pass required by the pattern of missing values for the dependent variables), the GLMMOD procedure displays the definitions of the columns of the design matrix along with the following:

- the number of the column
- the name of the associated effect
- the values that the class variables take for this level of the effect

The design matrix itself is also displayed, along with the following:

- the observation number
- the dependent variable values
- the FREQ and WEIGHT values, if any
- the columns of the design matrix

---

**Missing Values**

If some variables have missing values for some observations, then PROC GLMMOD handles missing values in the same way as PROC GLM; see the “Missing Values” section on page 1837 in Chapter 32, “The GLM Procedure,” for further details.

---

**OUTPARM= Data Set**

An output data set containing information regarding the association between model effects and design matrix columns is created whenever you specify the OUTPARM= option in the PROC GLMMOD statement. The OUTPARM= data set contains an observation for each column of the design matrix with the following variables:

- a numeric variable, _COLNUM_, identifying the number of the column of the design matrix corresponding to this observation
• a character variable, `EFFNAME`, containing the name of the effect that generates the column of the design matrix corresponding to this observation

• the CLASS variables, with the values they have for the column corresponding to this observation, or blanks if they are not involved with the effect associated with this column

If there are BY-group variables or if the pattern of missing values for the dependent variables requires it, the single data set defines several design matrices. In this case, for each of these design matrices, the `OUTPARM=` data set also contains the following:

• the current values of the BY variables, if you specify a BY statement

• a numeric variable, `_YPASS_`, containing the current pass of the data, if the pattern of missing values for the dependent variables requires multiple passes

**OUTDESIGN= Data Set**

An output data set containing the design matrix is created whenever you specify the `OUTDESIGN=` option in the PROC `GLMMOD` statement. The `OUTDESIGN=` data set contains an observation for each observation in the `DATA=` data set, with the following variables:

• the dependent variables

• the FREQ variable, if any

• the WEIGHT variable, if any

• a variable for each column of the design matrix, with names `COL1`, `COL2`, and so forth

If there are BY-group variables or if the pattern of missing values for the dependent variables requires it, the single data set contains several design matrices. In this case, for each of these, the `OUTDESIGN=` data set also contains the following:

• the current values of the BY variables, if you specify a BY statement

• a numeric variable, `_YPASS_`, containing the current pass of the data, if the pattern of missing values for the dependent variables requires multiple passes

**ODS Table Names**

PROC `GLMMOD` assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Examples

Example 33.1. A Two-Way Design

The following program uses the GLMMOD procedure to produce the design matrix for a two-way design. The two classification factors have seven and three levels, respectively, so the design matrix contains $1 + 7 + 3 + 21 = 32$ columns in all.

```plaintext
data Plants;
  input Type $ @;
  do Block=1 to 3;
    input StemLength @;
    output;
  end;
datalines;
Clarion 32.7 32.3 31.5
Clinton 32.1 29.7 29.1
Knox 35.7 35.9 33.1
O’Neill 36.0 34.2 31.2
Compost 31.8 28.0 29.2
Wabash 38.2 37.8 31.9
Webster 32.5 31.1 29.7
;
proc glmmmod outparm=Parm outdesign=Design;
  class Type Block;
  model StemLength = Type|Block;
run;

proc print data=Parm;
run;

proc print data=Design;
run;
```

Example 33.2. Factorial Screening

Screening experiments are undertaken to select from among the many possible factors that might affect a response the few that actually do, either simply (main effects) or in conjunction with other factors (interactions). One method of selecting significant factors is forward model selection, in which the model is built by successively adding the most statistically significant effects. Forward selection is an option in the REG procedure, but the REG procedure does not allow you to specify interactions directly (as the GLM procedure does, for example). You can use the GLMMOD procedure to create the screening model for a design and then use the REG procedure on the results to perform the screening.
The following statements create the SAS data set Screening, which contains the results of a screening experiment:

```plaintext
title 'PROC GLMMOD and PROC REG for Forward Selection Screening';
data Screening;
   input a b c d e y;
datalines;
-1 -1 -1 -1 1 -6.688
-1 -1 -1 1 -1 -10.664
-1 -1 1 -1 -1 -1.459
-1 -1 1 1 1 2.042
-1 1 -1 -1 -1 -8.561
-1 1 -1 1 1 -7.095
-1 1 1 -1 1 0.553
-1 1 1 1 -1 -2.352
1 -1 -1 -1 -1 -4.802
1 -1 1 1 1 5.705
1 -1 1 -1 1 14.639
1 -1 1 1 -1 2.151
1 1 -1 -1 1 4.048
1 1 1 -1 -1 15.248
;
run;
```

The data set contains a single dependent variable (y) and five independent factors (a, b, c, d, and e). The design is a half-fraction of the full 2^5 factorial, the precise half-fraction having been chosen to provide uncorrelated estimates of all main effects and two-factor interactions.

The following statements use the GLMMOD procedure to create a design matrix data set containing all the main effects and two factor interactions for the preceding screening design:

```plaintext
ods output DesignPoints = DesignMatrix;
proc glmmod data=Screening;
   model y = a|b|c|d|e@2;
run;
```

Notice that the preceding statements use ODS to create the design matrix data set, instead of the OUTDESIGN= option in the PROC GLMMOD statement. The results are equivalent, but the columns of the data set produced by ODS have names that are directly related to the names of their corresponding effects.

Finally, the following statements use the REG procedure to perform forward model selection for the screening design. Two MODEL statements are used, one without the selection options (which produces the regression analysis for the full model) and one with the selection options.
Example 33.2. Factorial Screening

```plaintext
proc reg data=DesignMatrix;
  model y = a--d_e;
  model y = a--d_e / selection = forward
details = summary
    slentry = 0.05;
run;
```

</tr>
</tbody>
</table>

Output 33.2.1 and Output 33.2.2 contain the results of the REG analysis. The full model has 16 parameters (the intercept + 5 main effects + 10 interactions). These are all estimable, but since there are only 16 observations in the design, there are no degrees of freedom left to estimate error; consequently, there is no way to use the full model to test for the statistical significance of effects. However, the forward selection method chooses only four effects for the model: the main effects of factors $a$, $c$, and $e$, and the interaction between $a$ and $e$. Using this reduced model enables you to estimate the underlying level of noise, although note that the selection method biases this estimate somewhat.

Chapter 34
The GLMPOWER Procedure
Overview

Power and sample size analysis optimizes the resource usage and design of a study, improving chances of conclusive results with maximum efficiency. The GLMPOWER procedure performs prospective power analysis for linear models, with a variety of goals:

- determining the sample size required to get a significant result with adequate probability (power)
- characterizing the power of a study to detect a meaningful effect
- conducting what-if analyses to assess sensitivity of the power or required sample size to other factors

Here *prospective* indicates that the analysis pertains to planning for a future study. This is in contrast to *retrospective* analysis for a past study, which is not supported by this procedure.

The statistical analyses that are covered include Type III tests and contrasts of fixed class effects in univariate linear models, optionally with covariates. The covariates can be continuous or categorical. Tests and contrasts involving random effects are not supported. For power and sample size analyses in a variety of other statistical situations, see Chapter 57, “The POWER Procedure.”

Input for PROC GLMPOWER includes the components considered in study planning:

- design (including subject profiles and their allocation weights)
- statistical model
- contrasts of class effects
- significance level (alpha)
- surmised response means for subject profiles (often called “cell means”)
- surmised variability
- power
- sample size

In order to identify power or sample size as the result parameter, you designate it by a missing value in the input. The procedure calculates this result value over one or more scenarios of input values for all other components.
You specify the design and the cell means using an exemplary data set, a data set of artificial values constructed to represent the intended sampling design and the surmised response means in the underlying population. You specify the model and contrasts using MODEL and CONTRAST statements similar to those in the GLM, ANOVA, and MIXED procedures. You specify the remaining parameters with the POWER statement, which is similar to analysis statements in the POWER procedure.

In addition to tabular results, PROC GLMPOWER produces graphs. You can produce the most common types of plots easily with default settings and use a variety of options for more customized graphics. For example, you can control the choice of axis variables, axis ranges, number of plotted points, mapping of graphical features (such as color, line style, symbol, and panel) to analysis parameters, and legend appearance.

The GLMPOWER procedure is one of several tools available in SAS/STAT software for power and sample size analysis. PROC POWER covers a variety of more basic analyses such as t tests, equivalence tests, confidence intervals, binomial proportions, multiple regression, and one-way ANOVA. The Power and Sample Size application provides a user interface and implements many of the analyses supported in the procedures.

The following sections of this chapter describe how to use PROC GLMPOWER and discuss the underlying statistical methodology. The “Getting Started” section on page 1930 introduces PROC GLMPOWER with examples of power computation for a two-way analysis of variance. The “Syntax” section on page 1935 describes the syntax of the procedure. The “Details” section on page 1945 summarizes the methods employed by PROC GLMPOWER and provides details on several special topics. The “Examples” section on page 1951 illustrates the use of the GLMPOWER procedure with several applications.

For more discussion and examples on power and sample size analysis for linear models, refer to Castelloe and O’Brien (2001), O’Brien and Shieh (1992), Muller et al. (1992), and O’Brien and Muller (1993). For additional discussion on general power and sample size concepts, refer to Castelloe (2000), Muller and Benignus (1992), and Lenth (2001).

**Getting Started**

**Simple Two-Way ANOVA**

This example demonstrates how to use PROC GLMPOWER to compute and plot power for each effect test in a two-way analysis of variance (ANOVA).

Suppose you are planning an experiment to study the effect of light exposure on the growth of two varieties of flowers. The planned data analysis is a two-way ANOVA with flower height (measured at two weeks) as the response and a model consisting of the effects of light exposure, flower variety, and their interaction. You want to calculate the power of each effect test using a balanced design with a total of 60 specimens (10 for each combination of exposure and variety) and \( \alpha = 0.05 \) for each test.
As a first step, create an *exemplary data set* describing your conjectures about the underlying population means. You believe that the mean flower height for each combination of variety and exposure level (i.e., for each design profile, or for each *cell* in the design) roughly follows Table 34.1.

**Table 34.1.** Mean Flower Height (in cm) by Variety and Exposure

<table>
<thead>
<tr>
<th>Variety</th>
<th>Exposure 1</th>
<th>Exposure 2</th>
<th>Exposure 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>14</td>
<td>16</td>
<td>21</td>
</tr>
<tr>
<td>2</td>
<td>10</td>
<td>15</td>
<td>16</td>
</tr>
</tbody>
</table>

The following statements create a data set *Exemplary* containing these cell means.

```sas
data Exemplary;
  do Variety = 1 to 2;
    do Exposure = 1 to 3;
      input Height @@;
      output;
    end;
  end;
datalines;
  14 16 21
  10 15 16
;run;
```

You also conjecture that the error standard deviation is about 5 cm.

Use the DATA= option in the PROC GLMPOWER statement to specify *Exemplary* as the exemplary data set. Identify the class variables (Variety and Exposure) using the CLASS statement. Specify the model using the MODEL statement. Use the POWER statement to specify power as the result parameter and provide values for the other analysis parameters, error standard deviation and total sample size.

```sas
proc glmpower data=Exemplary;
  class Variety Exposure;
  model Height = Variety | Exposure;
  power
    stddev = 5
    ntotal = 60
    power = .;
run;
```

The MODEL statement defines the full model including both main effects and the interaction. The POWER= option in the POWER statement identifies power as the result parameter with a missing value (POWER=.). The STDDEV= option specifies an error standard deviation of 5, and the NTOTAL= option specifies a total sample size of 60. The default value for the ALPHA= option sets the significance level to \( \alpha = 0.05 \).

*Figure 34.1* shows the output.

</tbody>
</table>

Figure 34.1. Sample Size Analysis for Two-Way ANOVA

The power is about 0.72 for the test of the Variety effect. In other words, there is a probability of 0.72 that the test of the Variety effect will produce a significant result (given the assumptions for the means and error standard deviation). The power is 0.96 for the test of the Exposure effect and 0.19 for the interaction test.

Now, suppose you want to account for some of your uncertainty in conjecturing the true error standard deviation by evaluating the power at reasonable low and high values, 4 and 6.5. You also want to plot power for sample sizes between 30 and 90. The following statements perform the analysis:

```plaintext
proc glmpower data=Exemplary;
   class Variety Exposure;
   model Height = Variety | Exposure;
   power
      stddev = 4 6.5
      ntotal = 60
      power = .;
   plot x=n min=30 max=90;
run;
```

The PLOT statement with the X=N option requests a plot with sample size on the x-axis. (The result parameter, here power, is always plotted on the other axis.) The MIN= and MAX= options in the PLOT statement specify the sample size range.

Figure 34.2 shows the output, and Figure 34.3 shows the plot.
The GLMPOWER Procedure

Fixed Scenario Elements

Dependent Variable : Height
Total Sample Size : 60
Alpha : 0.05
Error Degrees of Freedom : 54

Computed Power

<table>

</tbody>
</table>

**Figure 34.2.** Sample Size Analysis for Two-Way ANOVA with Input Ranges

**Figure 34.3.** Plot of Power versus Sample Size for Two-Way ANOVA with Input Ranges

Figure 34.2 reveals that the power ranges from about 0.130 to 0.996 for the different effect tests and scenarios for standard deviation, with a sample size of 60. In Figure 34.3, the line style identifies the effect test, and the plotting symbol identifies the standard deviation. The locations of the plotting symbols identify actual computed
powers; the curves are linear interpolations of these points. Note that the computed points in the plot occur at sample size multiples of 6, because there are 6 cells in the design (and by default, sample sizes are rounded to produce integer cell sizes).

**Incorporating Contrasts, Unbalanced Designs, and Multiple Means Scenarios**

Suppose you want to compute power for the two-way ANOVA described in “Simple Two-Way ANOVA,” but you want to

- Try an unbalanced sample size allocation with respect to Exposure, using twice as many samples for levels 2 and 3 as for level 1.
- Consider an additional, less optimistic scenario for the cell means, shown in Table 34.2.
- Test a contrast of Exposure comparing levels 1 and 3.

**Table 34.2. Additional Cell Means Scenario**

<table>
<thead>
<tr>
<th>Variety</th>
<th>Exposure</th>
<th>HeightOrig</th>
<th>HeightNew</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>15</td>
<td>16</td>
<td>20</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>11</td>
<td>14</td>
<td>15</td>
</tr>
</tbody>
</table>

To specify the unbalanced design and the additional cell means scenario, you can add two new variables to the exemplary data set (Weight for the sample size weights, and HeightNew for the new cell means scenario). Rename the original cell means scenario to HeightOrig.

```plaintext
data Exemplary;
  input Variety $ Exposure $ HeightOrig HeightNew Weight;
datalines;
  1 1 14 15 1
  1 2 16 16 2
  1 3 21 20 2
  2 1 10 11 1
  2 2 15 14 2
  2 3 16 15 2
;run;
```

In PROC GLMPOWER, specify the name of the weight variable using the WEIGHT statement, and specify the name of the cell means variables as dependent variables in the MODEL statement. Use the CONTRAST statement to specify the contrast as you would in PROC GLM. The following statements perform the sample size analysis.

```plaintext
proc glmpower data=Exemplary;
  class Variety Exposure;
  model HeightOrig HeightNew = Variety | Exposure;
  weight Weight;
  contrast 'Exposure=1 vs Exposure=3' Exposure 1 0 -1;
```
Figure 34.4 shows the output.

![The GLMPOWER Procedure]

The power of the contrast of Exposure levels 1 and 3 is about 0.95 for the original cell means scenario (HeightOrig) and only 0.71 for the new one (HeightNew). The power is higher for the test of Variety, but lower for the tests of Exposure and of Variety*Exposure for the new cell means scenario compared to the original one. Note also for the HeightOrig scenario that the power for the unbalanced design (Figure 34.4) compared to the balanced design (Figure 34.1) is slightly lower for the tests of Variety and Exposure, but slightly higher for the test of Variety*Exposure.

**Syntax**

The following statements are available in PROC GLMPOWER.

```plaintext
PROC GLMPOWER < options > ;
CLASS variables ;
MODEL dependent-variables = effects ;
WEIGHT variable ;
CONTRAST 'label' effect values < . . . effect values > < / options > ;
POWER < options > ;
PLOT < plot-options > < / graph-options > ;
```
The PROC GLMPOWER statement, the MODEL statement, and the POWER statement are required. If your model contains classification effects, the classification variables must be listed in a CLASS statement, and the CLASS statement must appear before the MODEL statement. In addition, CONTRAST statements must appear after the MODEL statement. PLOT statements must appear after the POWER statement defining the analysis for the plot.

You can use multiple CONTRAST, POWER, and PLOT statements. Each CONTRAST statement defines a separate contrast. Each POWER statement produces a separate analysis and uses the information contained in the CLASS, MODEL, WEIGHT, and all CONTRAST statements. Each PLOT statement refers to the previous POWER statement and generates a separate graph (or set of graphs).

Table 34.3 summarizes the basic functions of each statement in PROC GLMPOWER. The syntax of each statement in Table 34.3 is described in the following pages.

<table>
<thead>
<tr>
<th>Statement</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>PROC GLMPOWER</td>
<td>invokes procedure and specifies exemplary data set</td>
</tr>
<tr>
<td>CLASS</td>
<td>declares classification variables</td>
</tr>
<tr>
<td>CONTRAST</td>
<td>defines linear tests of model parameters</td>
</tr>
<tr>
<td>MODEL</td>
<td>defines model and specifies dependent variable(s) used for cell means scenarios</td>
</tr>
<tr>
<td>WEIGHT</td>
<td>specifies variable for allocating sample sizes to different subject profiles</td>
</tr>
<tr>
<td>POWER</td>
<td>identifies parameter to solve for and provides one or more scenarios for values of other analysis parameters</td>
</tr>
<tr>
<td>PLOT</td>
<td>displays graphs for preceding POWER statement</td>
</tr>
</tbody>
</table>

**PROC GLMPOWER Statement**

```
PROC GLMPOWER < options > ;
```

The PROC GLMPOWER statement invokes the GLMPOWER procedure. You can specify the following options.

**DATA=SAS-data-set**

names a SAS data set to be used as the exemplary data set, which is an artificial data set constructed to represent the intended sampling design and the conjectured response means for the underlying population.

**PLOTONLY**

specifies that only graphical results from the PLOT statement should be produced.
CLASS Statement

CLASS variables;

The CLASS statement names the classification variables to be used in the analysis. Classification variables can be either character or numeric.

CONTRAST Statement

CONTRAST 'label' effect values < . . . effect values > < / options >;

The CONTRAST statement enables you to define custom hypothesis tests by specifying an $L$ vector or matrix for testing the hypothesis $L\beta = 0$. Thus, to use this feature you must be familiar with the details of the model parameterization used in PROC GLM. For more information, see the “Parameterization of PROC GLM Models” section on page 1787 of Chapter 32, “The GLM Procedure.” All of the elements of the $L$ vector may be given, or if only certain portions of the $L$ vector are given, the remaining elements are constructed by PROC GLMPOWER from the context (in a manner similar to rule 4 discussed in the “Construction of Least-Squares Means” section on page 1820 of Chapter 32, “The GLM Procedure”).

There is no limit to the number of CONTRAST statements you can specify. Each sample size analysis includes tests for all CONTRAST statements.

In the CONTRAST statement,

- $label$ identifies the contrast on the output. A label is required for every contrast specified. Labels must be enclosed in quotes.
- $effect$ identifies an effect that appears in the MODEL statement, or the INTERCEPT effect. You do not need to include all effects that are in the MODEL statement.
- $values$ are constants that are elements of the $L$ vector associated with the effect.

You can specify the following option in the CONTRAST statement after a slash(/):

SINGULAR=number

tunes the estimability checking. If $\text{ABS}(L - LH) > C \times \text{number}$ for any row in the contrast, then $L$ is declared nonestimable. $H$ is the $(X'X)^{-1}X'X$ matrix, and $C$ is $\text{ABS}(L)$ except for rows where $L$ is zero, and then it is 1. The default value for the SINGULAR= option is $10^{-4}$. Values for the SINGULAR= option must be between 0 and 1.

The CONTRAST statement enables you to perform custom hypothesis tests. If the hypothesis is estimable, then the sum of squares due to it, $SS(H_0: L\beta = 0)$, is computed as

$$(Lb)'(L(X'X)^{-1}L')^{-1}(Lb)$$

where $b = (X'X)^{-1}X'y$ is the estimated solution vector.
The degrees of freedom associated with the hypothesis is equal to the row rank of $L$. The sum of squares computed in this situation is equivalent to the sum of squares computed using an $L$ matrix with any row deleted that is a linear combination of previous rows.

Multiple-degree-of-freedom hypotheses can be specified by separating the rows of the $L$ matrix with commas.

---

**MODEL Statement**

```
MODEL dependent-variables = classification-effects ;
```

The MODEL statement serves two basic purposes.

- The `dependent-variables` specify scenarios for the cell means.
- The `classification-effects` specify the model effects.

The `classification-effects` specification defines the model effects. You can include main effects and interactions using the effects notation of PROC GLM; see the “Specification of Effects” section on page 1784 in Chapter 32, “The GLM Procedure” for further details.

All variables in the `classification-effects` specification must be contained in the CLASS statement, since power and sample size analyses cover only tests and contrasts of class effects. You can account for covariates in the model by using the `NCOVARIATES=`, `CORRXY=`, and `PROPVARREDUCTION=` options in the POWER statement.

Each dependent variable refers to a set of surmised cell means in the exemplary data set (named by the `DATA=` option of the PROC GLMPOWER statement). These cell means are response means for all of the subject profiles. Multiple dependent variables correspond to multiple scenarios for these cell means. All models are univariate; the GLMPOWER procedure currently does not support multivariate analyses.

The MODEL statement is required. You can specify only one MODEL statement.

---

**WEIGHT Statement**

```
WEIGHT variable ;
```

The WEIGHT statement names a variable that provides a profile weight (“cell weight”) for each observation in the exemplary data set specified by the `DATA=` option in the PROC GLMPOWER statement.

If the WEIGHT statement is not used, then a balanced design is assumed with default cell weights of 1.
The POWER statement performs power and sample size analyses for the Type III test of each effect in the model defined by the MODEL statements and for the contrasts defined by all CONTRAST statements.

### Summary of Options

Table 34.4 summarizes categories of options available in the POWER statement.

### Dictionary of Options

**ALPHA=number-list**

specifies the level of significance of each test. The default is 0.05, corresponding to the usual $0.05 \times 100\% = 5\%$ level of significance. Note that this is a test-wise significance level with the same value for all tests, not incorporating any corrections for multiple testing. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**CORRXY=number-list**

specifies the multiple correlation $\rho$ between all covariates and the response. The error standard deviation given by the STDDEV= option is consequently reduced by multiplying it by a factor of $(1 - \rho^2)^{1/2}$, provided that the number of covariates (as determined by the NCOVARIATES= option) is greater than zero. You cannot use the CORRXY= and the PROPVARREDUCTION= options simultaneously. See the
“Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**NCOVARIATES=number-list**
**NCOVARIATE=number-list**
**NCOVS=number-list**
**NCOV=number-list**

specifies the number of additional degrees of freedom to accommodate covariate effects—both class and continuous—not listed in the MODEL statement. The error degrees of freedom is consequently reduced by the value of the NCOVARIATES= option, and the error standard deviation (whose unadjusted value is provided with the STDDEV= option) is reduced according to the value of the CORRXY= or PROPVARREDUCTION= option. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**NFRATIONAL**
**NFRAC**

enables fractional input and output for sample sizes. See the “Sample Size Adjustment Options” section on page 1946 for information on the ramifications of the presence (and absence) of the NFRATIONAL option.

**NTOTAL= number-list**

specifies the sample size or requests a solution for the sample size with a missing value (NTOTAL=.). Values for the sample size must be no smaller than the model degrees of freedom (counting the covariates). See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**OUTPUTORDER=INTERNAL**
**OUTPUTORDER=REVERSE**
**OUTPUTORDER=SYNTAX**

controls how the input and default analysis parameters are ordered in the output. OUTPUTORDER=INTERNAL (the default) produces the following order:

- weight variable (from the WEIGHT statement)
- source (contrasts from CONTRAST statements, and model effects)
- ALPHA
- dependent variable (from the MODEL statement, representing scenarios for cell means)
- NCOVARIATES
- CORRXY
- PROPVARREDUCTION
- STDDEV
- NTOTAL
- POWER
The OUTPUTORDER=SYNTAX option arranges the parameters in the output in the same order that their corresponding options are specified in the POWER statement. The OUTPUTORDER=REVERSE option arranges the parameters in the output in the reverse of the order that their corresponding options are specified in the POWER statement.

**POWER=** number-list

specifies the desired power of each test or requests a solution for the power with a missing value (POWER=.). The power is expressed as a probability (for example, 0.9) rather than a percentage. Note that this is a test-wise power with the same value for all tests, without any correction for multiple testing. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**PROPVARREDUCTION=** number-list

**PVRED=** number-list

specifies the proportional reduction ($\rho$) in total $R^2$ incurred by the covariates; in other words, the amount of additional variation explained by the covariates. The error standard deviation given by the STDDEV= option is consequently reduced by multiplying it by a factor of $(1 - \rho)^{1/2}$, provided that the number of covariates (as determined by the NCOVARIATES= option) is greater than zero. You cannot use the PROPVARREDUCTION= and the CORRXY= options simultaneously. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**STDDEV=** number-list

specifies the error standard deviation, or root MSE. If covariates are specified using the NCOVARIATES= option, then the STDDEV= option denotes the error standard deviation before accounting for these covariates. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

**Restrictions on Option Combinations**

For the relationship between covariates and response, specify either the multiple correlation (using the CORRXY= option) or the proportional reduction in total $R^2$ (using the PROPVARREDUCTION= option).
PLOT Statement

PLOT < plot-options > < / graph-options > ;

The PLOT statement produces a graph or set of graphs for the sample size analysis defined by the previous POWER statement. The plot-options define the plot characteristics, and the graph-options are SAS/GRAPH-style options.

Options

You can specify the following plot-options in the PLOT statement.

INTERPOL=JOIN
INTERPOL=NONE
specifies the type of curve to draw through the computed points. The INTERPOL=JOIN option connects computed points by straight lines. The INTERPOL=NONE option leaves computed points unconnected.

KEY=BYCURVE < ( bycurve-options ) >
KEY=BYFEATURE < ( byfeature-options ) >
KEY=ONCURVES
specifies the style of key (or “legend”) for the plot. The default is KEY=BYFEATURE, which specifies a key with a column of entries for each plot feature (line style, color, and/or symbol). Each entry shows the mapping between a value of the feature and the value(s) of the analysis parameter(s) linked to that feature. The KEY=BYCURVE option specifies a key with each row identifying a distinct curve in the plot. The KEY=ONCURVES option places a curve-specific label adjacent to each curve.

You can specify the following byfeature-options in parentheses after the KEY=BYFEATURE option.

NUMBERS=OFF
NUMBERS=ON
specifies how the key should identify curves. If NUMBERS=OFF, then the key includes symbol, color, and line style samples to identify the curves. If NUMBERS=ON, then the key includes numbers matching numeric labels placed adjacent to the curves. The default is NUMBERS=ON.

POS=BOTTOM
POS=INSET
specifies the position of the key. The POS=BOTTOM option places the key below the x-axis. The POS=INSET option places the key inside the plotting region and attempts to choose the least crowded corner. The default is POS=BOTTOM.

You can specify the following byfeature-options in parentheses after KEY=BYFEATURE option.
PLOT Statement

POS=BOTTOM
specifies the position of the key. The POS=BOTTOM option places the key below the x-axis. The POS=INSET option places the key inside the plotting region and attempts to choose the least crowded corner. The default is POS=BOTTOM.

MARKERS=ANALYSIS
MARKERS=COMPUTED
MARKERS=NICE
MARKERS=NONE

specifies the locations for plotting symbols.

The MARKERS=ANALYSIS option places plotting symbols at locations corresponding to the values of the relevant input parameter from the POWER statement preceding the PLOT statement.

The MARKERS=COMPUTED option (the default) places plotting symbols at the locations of actual computed points from the sample size analysis.

The MARKERS=NICE option places plotting symbols at tick mark locations (corresponding to the argument axis).

The MARKERS=NONE option disables plotting symbols.

MAX=number
specifies the maximum of the range of values for the parameter associated with the “argument” axis (the axis that is not representing the parameter being solved for). The default is the maximum value occurring for this parameter in the POWER statement preceding the PLOT statement.

MIN=number
specifies the minimum of the range of values for the parameter associated with the “argument” axis (the axis that is not representing the parameter being solved for). The default is the minimum value occurring for this parameter in the POWER statement preceding the PLOT statement.

NPOINTS=number
NPTS=number

specifies the number of values for the parameter associated with the “argument” axis (the axis that is not representing the parameter being solved for). You cannot use the NPOINTS= and STEP= options simultaneously. The default value for typical situations is 20.

STEP=number

specifies the increment between values of the parameter associated with the “argument” axis (the axis that is not representing the parameter being solved for). You cannot use the STEP= and NPOINTS= options simultaneously. By default, the NPOINTS= option is used instead of the STEP= option.
VARY (feature < BY parameter-list > ... feature < BY parameter-list > )

specifies how plot features should be linked to varying analysis parameters. Available plot features are COLOR, LINESTYLE, PANEL, and SYMBOL. A “panel” refers to a separate plot with a heading identifying the subset of values represented in the plot.

The parameter-list is a list of one or more names separated by spaces. Each name must match the name of an analysis option used in the POWER statement preceding the PLOT statement, or one of the following keywords: SOURCE (for the tests) and DEPENDENT (for the cell means scenarios). Also, the name must be the primary name for the analysis option, that is, the one listed first in the syntax description.

If you omit the < BY parameter-list > portion for a feature, then one or more multi-valued parameters from the analysis will be automatically selected for you.

X=N

X=POWER

specifies a plot with the requested type of parameter on the x-axis and the parameter being solved for on the y-axis. When X=N, sample size is assigned to the x-axis. When X=POWER, power is assigned to the y-axis. You cannot use the X= and Y= options simultaneously. The default is X=POWER, unless the result parameter is power, in which case the default is X=N.

XOPTS= (x-options)

specifies plot characteristics pertaining to the x-axis.

You can specify the following x-options in parentheses.

CROSSREF=NO

CROSSREF=YES specifies whether the reference lines defined by the REF= x-option should be crossed with a reference line on the y-axis that indicates the solution point on the curve.

REF=number-list specifies locations for reference lines extending from the x-axis across the entire plotting region. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

Y=N

Y=POWER

specifies a plot with the requested type of parameter on the y-axis and the parameter being solved for on the x-axis. When Y=N, sample size is assigned to the y-axis. When Y=POWER, power is assigned to the y-axis. You cannot use the Y= and X= options simultaneously. By default, the X= option is used instead of the Y= option.

YOPTS= (y-options)

specifies plot characteristics pertaining to the y-axis.

You can specify the following y-options in parentheses.
CROSSREF=NO
CROSSREF=YES specifies whether the reference lines defined by the REF= y-option should be crossed with a reference line on the x-axis that indicates the solution point on the curve.

REF=number-list specifies locations for reference lines extending from the y-axis across the entire plotting region. See the “Specifying Value Lists in the POWER Statement” section on page 1945 for information on specifying the number-list.

You can specify the following graph-options in the PLOT statement after a slash (/).

DESCRIPTION="string" specifies a descriptive string of up to 40 characters that appears in the “Description” field of the graphics catalog. The description does not appear on the plots. By default, PROC GLMPOWER assigns a description either of the form “Y versus X” (for a single-panel plot) or of the form “Y versus X (S),” where Y is the parameter on the y-axis, X is the parameter on the x-axis, and S is a description of the subset represented on the current panel of a multipanel plot.

NAME="string" specifies a name of up to eight characters for the catalog entry for the plot. The default name is PLOTn, where n is the number of the plot statement within the current invocation of PROC GLMPOWER. If the name duplicates the name of an existing entry, SAS/GRAF software adds a number to the duplicate name to create a unique entry, for example, PLOT11 and PLOT12 for the second and third panels of a multipanel plot generated in the first PLOT statement in an invocation of PROC GLMPOWER.

Details

Specifying Value Lists in the POWER Statement

To specify one or more scenarios for an analysis parameter (or set of parameters) in the POWER statement, you provide a list of values for the option that corresponds to the parameter(s). To identify the parameter you wish to solve for, you place missing values in the appropriate list.

Scenarios for scalar-valued parameters, such as power, are represented by a number-list.

Number-lists

A number-list can be one of two things: a series of one or more numbers expressed in the form of one or more DOLISTs, or a missing value indicator ( . ).

The DOLIST format is the same as in the DATA step language. For example, you can specify four scenarios (30, 50, 70, and 100) for a total sample size in any of the following ways.

\[
\begin{align*}
\text{NTOTAL} & = 30 \quad 50 \quad 70 \quad 100 \\
\text{NTOTAL} & = 30 \text{ to } 70 \text{ by } 20 \quad 100
\end{align*}
\]
A missing value identifies a parameter as the result parameter; it is valid only with options representing parameters you can solve for in a given analysis. For example, you can request a solution for NTOTAL:

\[ \text{NTOTAL} = . \]

**Sample Size Adjustment Options**

By default, PROC GLMPOWER rounds sample sizes conservatively (down in the input, up in the output) so that all total sizes and sample sizes for individual design profiles are integers. This is generally considered conservative because it selects the closest realistic design providing at most the power of the (possibly fractional) input or mathematically optimized design. In addition, all design profile sizes are adjusted to be multiples of their corresponding weights. If a design profile is present more than once in the exemplary data set, then the weights for that design profile are summed. For example, if a particular design profile is present twice in the exemplary data set with weight values 2 and 6, then all sample sizes for this design profile become multiples of \( 2 + 6 = 8 \).

With the NFRACTIONAL option, sample size input is not rounded, and sample size output is reported in two versions, a raw “fractional” version and a “ceiling” version rounded up to the nearest integer.

Whenever an input sample size is adjusted, both the original (“nominal”) and adjusted (“actual”) sample sizes are reported. Whenever computed output sample sizes are adjusted, both the original input (“nominal”) power and the achieved (“actual”) power at the adjusted sample size are reported.

**Error and Information Output**

The Error column in the main output table explains reasons for missing results and flags numerical results that are bounds rather than exact answers.

The Information column provides further details about Error entries, warnings about any boundary conditions detected, and notes about any adjustments to input. Note that the Information column is hidden by default in the main output. You can view it by using the ODS OUTPUT statement to save the output as a dataset and the PRINT procedure. For example, the following SAS statements print both the Error and Info columns for a power computation in a one-way ANOVA.

```sas
data MyExemp;
    input A $ Y1 Y2;
datalines;
    1 10 11
    2 12 11
    3 15 11
;run;
```
proc glmpower data=MyExemp;
  class A;
  model Y1 Y2 = A;
  power
    stddev = 2
    ntotal = 3 10
    power = .;
  ods output output=Power;
proc print noobs data=Power;
  var NominalNTotal NTotal Dependent Power Error Info;
run;

The output is shown in Figure 34.5.

<table>
<thead>
<tr>
<th>NominalNTotal</th>
<th>NTotal</th>
<th>Dependent</th>
<th>Power</th>
<th>Error</th>
<th>Info</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>3</td>
<td>Y1</td>
<td>.</td>
<td>Invalid input</td>
<td>Error DF=0</td>
</tr>
<tr>
<td>10</td>
<td>9</td>
<td>Y1</td>
<td>0.557</td>
<td>Invalid input</td>
<td>Error DF=0 / No effect</td>
</tr>
<tr>
<td>3</td>
<td>3</td>
<td>Y2</td>
<td>.</td>
<td>Invalid input</td>
<td>Error DF=0</td>
</tr>
<tr>
<td>10</td>
<td>9</td>
<td>Y2</td>
<td>0.050</td>
<td>Input N adjusted / No effect</td>
<td></td>
</tr>
</tbody>
</table>

**Figure 34.5.** Error and Information Columns

The sample size of 3 specified with the NTOTAL= option leads to an “Invalid input” message in the Error column and an “Error DF=0” message in the Info column, because a sample size of 3 is so small that there are no degrees of freedom left for the error term. The sample size of 10 leads to an “Input N adjusted” message in the Info column, because it is rounded down to 9 to produce integer group sizes of 3 per cell. The cell means scenario represented by the dependent variable Y2 leads to a “No effect” message to appear in the Info column, because the means in this scenario are all equal.

**Displayed Output**

If you use the PLOTONLY option in the PROC GLMPOWER statement, the procedure only displays graphical output. Otherwise, the displayed output of the GLMPOWER procedure includes the following:

- the “Fixed Scenario Elements” table, which shows all applicable single-valued analysis parameters, in the following order: the weight variable, the source of the test, parameters input explicitly, parameters supplied with defaults, and ancillary results
- an output table showing the following when applicable (in order): the index of the scenario, the source of the test, all multivalued input, ancillary results, the primary computed result, and error descriptions
- plots (if requested)

Ancillary results include the following:
• Actual Power, the achieved power, if it differs from the input (Nominal) power value
• fractional sample size, if the N FRACTIONAL option is used in the analysis statement

If sample size is the result parameter and the N FRACTIONAL option is used in the analysis statement, then both “Fractional” and “Ceiling” sample size results are displayed. Fractional sample sizes correspond to the “Nominal” values of power or precision probability. Ceiling sample sizes are simply the fractional sample sizes rounded up to the nearest integer; they correspond to “Actual” values of power or precision probability.

**ODS Table Names**

PROC GLMPOWER assigns a name to each table that it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in Table 34.6. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

<table>
<thead>
<tr>
<th>ODS Table Name</th>
<th>Description</th>
<th>Statement</th>
</tr>
</thead>
<tbody>
<tr>
<td>FixedElements</td>
<td>factoid with single-valued analysis parameters</td>
<td>default</td>
</tr>
<tr>
<td>Output</td>
<td>all input and computed analysis parameters, error messages, and information messages for each scenario</td>
<td>default</td>
</tr>
<tr>
<td>PlotContent</td>
<td>data contained in plots, including analysis parameters and indices identifying plot features. (Note: This table is saved as a dataset and not displayed in PROC GLMPOWER output.)</td>
<td>PLOT</td>
</tr>
</tbody>
</table>

The ODS path names are created as follows:

• Glmpower.Power< n >.FixedElements
• Glmpower.Power< n >.Output
• Glmpower.Power< n >.PlotContent
• Glmpower.Power< n >.Plot< m >

where

• The Plot< m > objects are the graphs.
• The < n > indexing the Power statement is only used if there is more than one instance.
Computational Methods and Formulas

This section describes the approaches used in PROC GLMPOWER to compute power and sample size.

**Contrasts in Fixed-Effect Univariate Models**

The univariate linear model has the form

\[ y = X\beta + \epsilon \]

where \( y \) is the \( N \times 1 \) vector of responses, \( X \) is the \( N \times p \) design matrix, \( \beta \) is the \( p \times 1 \) vector of model parameters corresponding to the columns of \( X \), and \( \epsilon \) is an \( N \times 1 \) vector of errors with

\[ \epsilon_1, \ldots, \epsilon_N \sim N(0, \sigma^2) \quad \text{(i.i.d.)} \]

In PROC GLMPOWER, the model parameters \( \beta \) are not specified directly, but rather indirectly as \( y^* \), which represents either conjectured response means or typical response values for each design profile. The \( y^* \) values are manifested as the dependent variable in the MODEL statement. The vector \( \beta \) is obtained from \( y^* \) according to the least squares equation,

\[ \beta = (X'X)^{-1}X'y^* \]

Note that, in general, there is not a 1 to 1 mapping between \( y^* \) and \( \beta \). Many different scenarios for \( y^* \) may lead to the same \( \beta \). If you specify \( y^* \) with the intention of representing cell means, keep in mind that PROC GLMPOWER allows scenarios that are not valid cell means according to the model specified in the MODEL statement. For example, if \( y^* \) exhibits an interaction effect but the corresponding interaction term is left out of the model, then the cell means \( (X\beta) \) derived from \( \beta \) differ from \( y^* \). In particular, the cell means thus derived are the projection of \( y^* \) onto the model space.

It is convenient in power analysis to parameterize the design matrix \( X \) in three parts, \( \{ \bar{X}, w, N \} \), defined as follows:

1. The \( q \times p \) essence design matrix \( \bar{X} \) is the collection of unique rows of \( X \). Its rows are sometimes referred to as “design profiles.” Here, \( q \leq N \) is defined simply as the number of unique rows of \( X \).
2. The \( q \times 1 \) weight vector \( w \) reveals the relative proportions of design profiles. Row \( i \) of \( \bar{X} \) is to be included in the design \( w_i \) times for every \( w_j \) times row \( j \) is included. The weights are assumed to be standardized (i.e., sum up to 1).
3. The total sample size is \( N \). This is the number of rows in \( X \). If you gather \( Nw_i = n_i \) copies of the \( i \)th row of \( \tilde{X} \), for \( i = 1, \ldots, q \), then you end up with \( X \).

It is useful to express the crossproduct matrix \( X'X \) in terms of these three parts,

\[
X'X = N\tilde{X}'\text{diag}(w)\tilde{X}
\]

since this factors out the portion \( (N) \) depending on sample size and the portion \( (\tilde{X}'\text{diag}(w)\tilde{X}) \) depending only on the design structure.

A general linear hypothesis for the univariate model has the form

\[
H_0 : \quad L\beta = \theta_0 \\
H_A : \quad L\beta \neq \theta_0
\]

where \( L \) is an \( r_L \times p \) contrast matrix (assumed to be full rank), and \( \theta_0 \) is the null value (usually just a vector of zeroes). Note that effect tests are just contrasts using special forms of \( L \). Thus, this scheme covers both effect tests and custom contrasts.

The test statistic is

\[
F = \left( \frac{SS_H}{\hat{\sigma}^2} \right)
\]

where

\[
SS_H = \frac{1}{N} \left( L\hat{\beta} - \theta_0 \right)' \left( L (X'X)^{-1} L' \right)^{-1} \left( L\hat{\beta} - \theta_0 \right)
\]

\[
\hat{\beta} = (X'X)^{-1}X'y
\]

\[
\hat{\sigma}^2 = \frac{1}{DF_E} \left( y - X\hat{\beta} \right)' \left( y - X\hat{\beta} \right)
\]

where \( DF_E = N - \text{rank}(X) \). Note that \( DF_E = N - p \) if \( X \) has full rank.

Under \( H_0 \), \( F \sim F(r_L, DF_E) \). Under \( H_A \), \( F \) is distributed as \( F(r_L, DF_E, \lambda) \) with noncentrality

\[
\lambda = N (L\beta - \theta_0)' \left( L (\tilde{X}'\text{diag}(w)\tilde{X})^{-1} L' \right)^{-1} (L\beta - \theta_0) \sigma^{-2}
\]

Muller and Peterson (1984) give the exact power of the test as

\[
\text{power} = P \left( F(r_L, DF_E, \lambda) \geq F_{1-\alpha}(r_L, DF_E) \right)
\]

Sample size is computed by inverting the power equation.

Refer to Muller et al. (1992) and O’Brien and Shieh (1992) for additional discussion.
Adjustments for Covariates

If you specify covariates in the model (whether continuous or categorical), then two adjustments are made in order to compute approximate power in the presence of the covariates. Let \( n_\nu \) denote the number of covariates (counting dummy variables for categorical covariates individually). In other words, \( n_\nu \) is the total degrees of freedom used by the covariates. The adjustments are the following:

1. The error degrees of freedom decreases by \( n_\nu \).
2. The error standard deviation \( \sigma \) shrinks by a factor of \( (1 - \rho^2)^{\frac{1}{2}} \) (if the \texttt{CORRXY=} option to specify the correlation \( \rho \) between covariates and response) or \( (1 - r)^{\frac{1}{2}} \) (if the \texttt{PROPVARREDUCTION=} option is used to specify the proportional reduction in total \( R^2 \) incurred by the covariates). Let \( \sigma^* \) represent the updated value of \( \sigma \).

As a result of these changes, the power is computed as

\[
\text{power} = P \left( F \left( r_L, \text{DF}_E - n_\nu, \lambda^* \right) \geq F_{1 - \alpha} \left( r_L, N - r_x - n_\nu \right) \right)
\]

where \( \lambda^* \) is calculated using \( \sigma^* \) rather than \( \sigma \):

\[
\lambda^* = N (L\beta - \theta_0)' \left( L \left( \bar{X}' \text{diag}(w) \bar{X} \right)^{-1} L' \right)^{-1} (L\beta - \theta_0) (\sigma^*)^{-2}
\]

Examples

Example 34.1. One-Way ANOVA

This example deals with the same situation as in Example 57.1 on page 3536 of Chapter 57, “The POWER Procedure.”

Hocking (1985, p. 109) describes a study of the effectiveness of electrolytes in reducing lactic acid buildup for long-distance runners. You are planning a similar study in which you will allocate five different fluids to runners on a 10-mile course and measure lactic acid buildup immediately after the race. The fluids consist of water and two commercial electrolyte drinks, EZDure and LactoZap, each prepared at two concentrations, low (EZD1 and LZ1) and high (EZD2 and LZ2).

You conjecture that the standard deviation of lactic acid measurements given any particular fluid is about 3.75, and that the expected lactic acid values will correspond roughly to Table 34.7. You are least familiar with the LZ1 drink and hence decide to consider a range of reasonable values for that mean.

Table 34.7. Mean Lactic Acid Buildup by Fluid

<table>
<thead>
<tr>
<th>Fluid</th>
<th>EZD1</th>
<th>EZD2</th>
<th>LZ1</th>
<th>LZ2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Water</td>
<td>35.6</td>

<td>33.7</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>EZD2</td>
<td>30.2</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>LZ1</td>
<td></td>
<td>29 or 28</td>
<td>25.9</td>
<td></td>
</tr>
<tr>
<td>LZ2</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

You are interested in four different comparisons, shown in Table 34.8 with appropriate contrast coefficients.
Table 34.8. Planned Comparisons

<table>
<thead>
<tr>
<th>Comparison</th>
<th>Contrast Coefficients</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Water</td>
</tr>
<tr>
<td>Water versus electrolytes</td>

<td>0</td>
</tr>
<tr>
<td>EZD1 versus EZD2</td>
<td>0</td>
</tr>
<tr>
<td>LZ1 versus LZ2</td>
<td>0</td>
</tr>
</tbody>
</table>

For each of these contrasts you want to determine the sample size required to achieve a power of 0.9 for detecting an effect with magnitude in accord with Table 34.7. You are not yet attempting to choose a single sample size for the study, but rather checking the range of sample sizes needed for individual contrasts. You plan to test each contrast at $\alpha = 0.025$. In the interests of reducing costs, you will provide twice as many runners with water as with any of the electrolytes; that is, you will use a sample size weighting scheme of 2:1:1:1:1.

Before calling PROC GLMPOWER, you need to create the exemplary data set to specify means and weights for the design profiles:

```plaintext
data Fluids;
  input Fluid $ LacticAcid1 LacticAcid2 CellWgt;
datalines;
  Water 35.6 35.6  2
  EZD1 33.7 33.7  1
  EZD2 30.2 30.2  1
  LZ1  29   28   1
  LZ2  25.9 25.9  1;
run;
```

The variable `LacticAcid1` represents the cell means scenario with the larger LZ1 mean (29), and `LacticAcid2` represents the scenario with the smaller LZ1 mean (28). The variable `CellWgt` contains the sample size allocation weights.

Use the DATA= option in the PROC GLMPOWER statement to specify `Fluids` as the exemplary data set. The following statements perform the sample size analysis:

```plaintext
class Fluid;
model LacticAcid1 LacticAcid2 = Fluid;
weight CellWgt;
contrast "Water vs. others" Fluid -1 -1 -1 -1 4;  
contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;  
contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;  
contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;  
power
  stddev = 3.75
  alpha  = 0.025
  ntotal = .
  power  = 0.9;
run;
```
The CLASS statement identifies Fluid as a classification variable. The MODEL statement specifies the model and the two cell means scenarios LacticAcid1 and LacticAcid2. The WEIGHT statement identifies CellWgt as the weight variable. The CONTRAST statement specifies the contrasts. Since PROC GLMPOWER processes class levels in order of formatted values, the contrast coefficients correspond to the following order: EZD1, EZD2, LZ1, LZ2, Water. The POWER statement specifies total sample size as the result parameter and provides values for the other analysis parameters (error standard deviation, alpha, and power).

Output 34.1.1 displays the results.

### Output 34.1.1. Sample Sizes for One-Way ANOVA Contrasts

<td>0.902</td>
<td>480</td>
</tr>
</tbody>
</table>

The sample sizes range from 24 for the comparison of water versus electrolytes to 480 for the comparison of LZ1 versus LZ2, both assuming the smaller LZ1 mean. The sample size for the latter comparison is relatively large because the small mean difference of $28 - 25.9 = 2.1$ is hard to detect. PROC GLMPOWER also includes the effect test for Fluid. Note that, in this case, it is equivalent to TEST=OVERALL_F in the ONEWAYANOVA statement of PROC POWER, since there is only one effect in the model.

The Nominal Power of 0.9 in the Fixed Scenario Elements table in Output 34.1.1 represents the input target power, and the Actual Power column in the Computed N Total table is the power at the sample size (N Total) adjusted to achieve the specified sample weighting. Note that all of the sample sizes are rounded up to multiples of 6 to preserve integer group sizes (since the group weights add up to 6). You can use the NFRACTIONAL option in the POWER statement to compute raw fractional sample sizes.
Suppose you want to plot the required sample size for the range of power values from 0.5 to 0.95. First, define the analysis by specifying the same statements as before, but add the PLOTONLY option to the PROC GLMPOWER statement to disable the non-graphical results. Next, specify the PLOT statement with X=POWER to request a plot with power on the x-axis. (The result parameter, here sample size, is always plotted on the other axis.) Use the MIN= and MAX= options in the PLOT statement to specify the power range.

```plaintext
proc glmpower data=Fluids plotonly;
  class Fluid;
  model LacticAcid1 LacticAcid2 = Fluid;
  weight CellWgt;
  contrast "Water vs. others" Fluid -1 -1 -1 -1 4;
  contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;
  contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;
  contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;
  power
    stddev = 3.75
    alpha  = 0.025
    ntotal = .
    power  = 0.9;
  plot x=power min=.5 max=.95;
run;
```

See Output 34.1.2 for the resulting plot.

**Output 34.1.2.** Plot of Sample Size versus Power for One-Way ANOVA Contrasts
In Output 34.1.2, the line style identifies the test, and the plotting symbol identifies the cell means scenario. The plotting symbol locations identify actual computed powers; the curves are linear interpolations of these points. The plot shows that the required sample size is highest for the test of LZ1 versus LZ2 that was previously found to require the most resources, in either cell means scenario.

Note that some of the plotted points in Output 34.1.2 are unevenly spaced. This is because the plotted points are the rounded sample size results at their corresponding actual power levels. The range specified with the MIN= and MAX= values in the PLOT statement correspond to nominal power levels. In some cases, actual power is substantially higher than nominal power. To obtain plots with evenly spaced points (but with fractional sample sizes at the computed points), you can use the NFRATIONAL option in the POWER statement preceding the PLOT statement.

Finally, suppose you want to plot the power for the range of sample sizes you will likely consider for the study (the range of 24 to 480 that achieves 0.9 power for different comparisons). In the POWER statement, identify power as the result (POWER=.), and specify NTOTAL=24. Specify the PLOT statement with X=N to request a plot with sample size on the x-axis.

```plaintext
proc glmpower data=Fluids plotonly;
   class Fluid;
   model LacticAcid1 LacticAcid2 = Fluid;
   weight CellWgt;
   contrast "Water vs. others" Fluid -1 -1 -1 -1 4;
   contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;
   contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;
   contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;
   power
      stddev = 3.75
      alpha = 0.025
      ntotal = 24
      power = .;
   plot x=n min=24 max=480;
run;
```

Note that the value specified with the NTOTAL=24 option is not used. It is overridden in the plot by the MIN= and MAX= options in the PLOT statement, and the PLOTONLY option in the PROC GLMPower statement disables non-graphical results. But the NTOTAL= option (along with a value) is still needed in the POWER statement as a placeholder, to identify the desired parameterization for sample size.

See Output 34.1.3 for the plot.
Although Output 34.1.2 and Output 34.1.3 surface essentially the same computations for practical power ranges, they each provide a different quick visual assessment. Output 34.1.2 reveals the range of required sample sizes for powers of interest, and Output 34.1.3 reveals the range of achieved powers for sample sizes of interest.

**Example 34.2. Two-Way ANOVA with Covariate**

Suppose you can enhance the planned study discussed in Example 34.1 on page 1951 in two ways:

- Incorporate results from races at two different altitudes (“high” and “low”).
- Measure the body mass index of each runner before the race.

This is equivalent to adding a second fixed effect and a continuous covariate to your model.

Since lactic acid buildup is more pronounced at higher altitudes, you will include altitude as a factor in the model along with fluid, extending the one-way ANOVA to a two-way ANOVA. In doing so, you expect to lower the residual standard deviation from about 3.75 to 3.5 (in addition to generalizing the study results). You assume there is negligible interaction between fluid and altitude and plan to use a main-effects-only model. You conjecture that the mean lactic acid buildup follows Table 34.9.
Table 34.9. Mean Lactic Acid Buildup by Fluid and Altitude

<table>
<thead>
<tr>
<th>Altitude</th>
<th>Fluid</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Water</td>
</tr>
<tr>
<td>High</td>
<td>36.9</td>
</tr>
<tr>
<td>Low</td>
<td>34.3</td>
</tr>
</tbody>
</table>

By including a measurement of body mass index as a covariate in the study, you hope to further reduce the error variability. The extent of this reduction in variability is commonly expressed in two alternative ways: (1) the correlation between the covariates and the response or (2) the proportional reduction in total $R^2$ incurred by the covariates. You prefer the former and guess that the correlation between body mass index and lactic acid buildup is between 0.2 and 0.3. You specify these estimates with the `NCOVARIATES=` and `CORRXY=` options in the `POWER` statement. The covariate is not included in the `MODEL` statement.

You are interested in the same four fluid comparisons as in Example 34.1, shown in Table 34.8 on page 1951, except this time you want to marginalize over the effect of altitude.

For each of these contrasts, you want to determine the sample size required to achieve a power of 0.9 to detect an effect with magnitude according to Table 34.9. You are not yet attempting to choose a single sample size for the study, but rather checking the range of sample sizes needed by individual contrasts. You plan to test each contrast at $\alpha = 0.025$. You will provide twice as many runners with water as with any of the electrolytes, and you predict that you can study approximately 2/3 as many runners at the high altitude than at the low altitude. The resulting planned sample size weighting scheme is shown in Table 34.10. Since the scheme is only approximate, you use the `NFRACTIONAL` option in the `POWER` statement to disable the rounding of sample sizes up to integers satisfying the weights exactly.

Table 34.10. Approximate Sample Size Allocation Weights

<table>
<thead>
<tr>
<th>Altitude</th>
<th>Fluid</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Water</td>
</tr>
<tr>
<td>High</td>
<td>4</td>
</tr>
<tr>
<td>Low</td>
<td>6</td>
</tr>
</tbody>
</table>

First, you create the exemplary data set to specify means and weights for the design profiles:
The variables `Altitude`, `Fluid`, and `LacticAcid` specify the factors and cell means in Table 34.9. The variable `CellWgt` contains the sample size allocation weights in Table 34.10.

Use the `DATA=` option in the `PROC GLMPOWER` statement to specify `Fluids2` as the exemplary data set. The following statements perform the sample size analysis:

```plaintext
proc glmpower data=Fluids2;
  class Altitude Fluid;
  model LacticAcid = Altitude Fluid;
  weight CellWgt;
  contrast "Water vs. others" Fluid -1 -1 -1 -1 4;
  contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;
  contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;
  contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;
  power
    nfractional
    stddev  = 3.5
    ncovariates = 1
    corrxy  = 0.2 0.3 0
    alpha   = 0.025
    ntotal  = .
    power   = 0.9;
run;
```

The CLASS statement identifies `Altitude` and `Fluid` as classification variables. The MODEL statement specifies the model, and the WEIGHT statement identifies `CellWgt` as the weight variable. The CONTRAST statement specifies the contrasts in Table 34.8 on page 1951. As in Example 34.1, the order of the contrast coefficients corresponds to the formatted class levels (EZD1, EZD2, LZ1, LZ2, Water). The POWER statement specifies total sample size as the result parameter and provides values for the other analysis parameters. The NCOVARIATES= option specifies the single covariate (body mass index), and the CORRXY= option specifies the two scenarios for its correlation with lactic acid buildup (0.2 and 0.3). Output 34.2.1 displays the results.
The sample sizes in Output 34.2.1 range from 21 for the comparison of water versus electrolytes (assuming a correlation of 0.3 between body mass and lactic acid
buildup) to 275 for the comparison of LZ1 versus LZ2 (assuming a correlation of 0.2). PROC GLMPOWER also includes the effect tests for Altitude and Fluid. Note that the required sample sizes for this study are lower than those for the study in Example 34.1.

Note that the error standard deviation has been reduced from 3.5 to 3.43 (when correlation is 0.2) or 3.34 (when correlation is 0.3) in the approximation of the effect of the body mass index covariate. The error degrees of freedom has also been automatically adjusted, lowered by 1 (the number of covariates).

Suppose you want to plot the required sample size for the range of power values from 0.5 to 0.95. First, define the analysis by specifying the same statements as before, but add the PLOTONLY option to the PROC GLMPOWER statement to disable the nongraphical results. Next, specify the PLOT statement with X=POWER to request a plot with power on the x-axis. Sample size is automatically placed on the y-axis. Use the MIN= and MAX= options in the PLOT statement to specify the power range.

```plaintext
proc glmpower data=Fluids2 plotonly;
   class Altitude Fluid;
   model LacticAcid = Altitude Fluid;
   weight CellWgt;
   contrast "Water vs. others" Fluid -1 -1 -1 -1 4;
   contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;
   contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;
   contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;
   power
      nfractional
      stddev = 3.5
      ncovariates = 1
      corrxy = 0.2 0.3 0
      alpha = 0.025
      ntotal = .
      power = 0.9;
   plot x=power min=.5 max=.95;
run;

See Output 34.2.2 for the plot.
```
In Output 34.1.2, the line style identifies the test, and the plotting symbol identifies the scenario for the correlation between covariate and response. The plotting symbol locations identify actual computed powers; the curves are linear interpolations of these points. As in Example 34.1, the required sample size is highest for the test of LZ1 versus LZ2.

Finally, suppose you want to plot the power for the range of sample sizes you will likely consider for the study (the range of 21 to 275 that achieves 0.9 power for different comparisons). In the POWER statement, identify power as the result (POWER=.), and specify NTOTAL=21. Specify the PLOT statement with X=N to request a plot with sample size on the x-axis.
proc glmpower data=Fluids2 plotonly;
  class Altitude Fluid;
  model LacticAcid = Altitude Fluid;
  weight CellWgt;
  contrast "Water vs. others" Fluid -1 -1 -1 -1 4;
  contrast "EZD vs. LZ" Fluid 1 1 -1 -1 0;
  contrast "EZD1 vs. EZD2" Fluid 1 -1 0 0 0;
  contrast "LZ1 vs. LZ2" Fluid 0 0 1 -1 0;
  power
    nfractional
    stddev = 3.5
    ncovariates = 1
    corrxy = 0.2 0.3 0
    alpha = 0.025
    ntotal = 21
    power = .;
    plot x=n min=21 max=275;
run;

The MAX=275 option in the PLOT statement sets the maximum sample size value. The MIN= option automatically defaults to the value of 21 from the NTOTAL= option in the POWER statement.

See Output 34.2.3 for the plot.

Output 34.2.3. Plot of Power versus Sample Size for Two-Way ANOVA Contrasts

Although Output 34.2.2 and Output 34.2.3 surface essentially the same computations for practical power ranges, they each provide a different quick visual assessment.
Output 34.2.2 reveals the range of required sample sizes for powers of interest, and Output 34.2.3 reveals the range of powers achieved for sample sizes of interest.

Chapter 35
The INBREED Procedure

Overview

The INBREED procedure calculates the covariance or inbreeding coefficients for a pedigree. PROC INBREED is unique in that it handles very large populations.

The INBREED procedure has two modes of operation. One mode carries out analysis on the assumption that all the individuals belong to the same generation. The other mode divides the population into nonoverlapping generations and analyzes each generation separately, assuming that the parents of individuals in the current generation are defined in the previous generation.

PROC INBREED also computes averages of the covariance or inbreeding coefficients within sex categories if the sex of individuals is known.

Getting Started

This section demonstrates how you can use the INBREED procedure to calculate the inbreeding or covariance coefficients for a pedigree, how you can control the analysis mode if the population consists of nonoverlapping generations, and how you can obtain averages within sex categories.

For you to use PROC INBREED effectively, your input data set must have a definite format. The following sections first introduce this format for a fictitious population and then demonstrate how you can analyze this population using the INBREED procedure.

The Format of the Input Data Set

The SAS data set used as input to the INBREED procedure must contain an observation for each individual. Each observation must include one variable identifying the individual and two variables identifying the individual’s parents. Optionally, an observation can contain a known covariance coefficient and a character variable defining the gender of the individual.

For example, consider the following data:

```sas
data Population;
    input Individual $ Parent1 $ Parent2 $ Covariance Sex $ Generation;
    datalines;
    MARK GEORGE LISA . M 1
    KELLY SCOTT LISA . F 1
    MIKE GEORGE AMY . M 1
    . MARK KELLY 0.50 . 1
```
It is important to order the pedigree observations so that individuals are defined before they are used as parents of other individuals. The family relationships between individuals cannot be ascertained correctly unless you observe this ordering. Also, older individuals must precede younger ones. For example, ‘MARK’ appears as the first parent of ‘DAVID’ at observation 5; therefore, his observation needs to be defined prior to observation 5. Indeed, this is the case (see observation 1). Also, ‘DAVID’ is older than ‘JIM’, whose observation appears after the observation for ‘DAVID’, as is appropriate.

In populations with distinct, nonoverlapping generations, the older generation (parents) must precede the younger generation. For example, the individuals defined in Generation=1 appear as parents of individuals defined in Generation=2.

PROC INBREED produces warning messages when a parent cannot be found. For example, ‘JANE’ appears as the second parent of the individual ‘MERLE’ even though there are no previous observations defining her own parents. If the population is treated as an overlapping population, that is, if the generation grouping is ignored, then the procedure inserts an observation for ‘JANE’ with missing parents just before the sixth observation, which defines ‘MERLE’ as follows:

\[
\begin{align*}
\text{JANE} & \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad F \quad 2 \\
\text{MERLE} & \quad \text{MIKE} \quad \text{JANE} \quad . \quad . \quad . \quad . \quad . \quad . \quad F \quad 2
\end{align*}
\]

However, if generation grouping is taken into consideration, then ‘JANE’ is defined as the last observation in Generation=1, as follows:

\[
\begin{align*}
\text{MIKE} & \quad \text{GEORGE} \quad \text{AMY} \quad . \quad M \quad 1 \\
\text{JANE} & \quad . \quad . \quad . \quad . \quad . \quad . \quad F \quad 1
\end{align*}
\]

In this latter case, however, the observation for ‘JANE’ is inserted after the computations are reported for the first generation. Therefore, she does not appear in the covariance/inbreeding matrix, even though her observation is used in computations for the second generation (see the example on page 1970).

If the data for an individual are duplicated, only the first occurrence of the data is used by the procedure, and a warning message is displayed to note the duplication. For example, individual ‘MARK’ is defined twice, at observations 1 and 8. If generation grouping is ignored, then this is an error and observation 8 is skipped. However, if the population is processed with respect to two distinct generations, then ‘MARK’ refers to two different individuals, one in Generation=1 and the other in Generation=2.

If a covariance is to be assigned between two individuals, then those individuals must be defined prior to the assignment observation. For example, a covariance of 0.50
can be assigned between ‘MARK’ and ‘KELLY’ since they are previously defined. Note that assignment statements must have different formats depending on whether the population is processed with respect to generations (see the “DATA= Data Set” section on page 1976 for further information). For example, while observation 4 is valid for nonoverlapping generations, it is invalid for a processing mode that ignores generation grouping. In this latter case, observation 7 indicates a valid assignment, and observation 4 is skipped.

The latest covariance specification between any given two individuals overrides the previous one between the same individuals.

**Performing the Analysis**

To compute the covariance coefficients for the overlapping generation mode, use the following statements:

```
proc inbreed data=Population covar matrix init=0.25;
  run;
```

Here, the DATA= option names the SAS data set to be analyzed, and the COVAR and MATRIX options tell the procedure to output the covariance coefficients matrix. If you omit the COVAR option, the inbreeding coefficients are output instead of the covariance coefficients.

Note that the PROC INBREED statement also contains the INIT= option. This option gives an initial covariance between any individual and unknown individuals. For example, the covariance between any individual and ‘JANE’ would be 0.25, since ‘JANE’ is unknown, except when ‘JANE’ appears as a parent (see Figure 35.1).
Figure 35.1. Analysis for an Overlapping Population

In the previous example, PROC INBREED treats the population as a single generation. However, you may want to process the population with respect to distinct, nonoverlapping generations. To accomplish this, you need to identify the generation variable in a CLASS statement, as shown by the following statements.

```sas
proc inbreed data=Population covar matrix init=0.25;
class Generation;
run;
```
Performing the Analysis

Note that, in this case, the covariance matrix is displayed separately for each generation (see Figure 35.2).

You may also want to see covariance coefficient averages within sex categories. This is accomplished by indicating the variable defining the gender of individuals in a GENDER statement and by adding the AVERAGE option to the PROC INBREED statement. For example, the following statements produce the covariance coefficient averages shown in Figure 35.3.

```plaintext
proc inbreed data=Population covar average init=0.25;

Syntax

The following statements are available in PROC INBREED.

```plaintext
PROC INBREED < options >;
   BY variables;
   CLASS variable;
   GENDER variable;
   MATINGS individual-list1 / mate-list <, . . . >;
   VAR variables;
```

The PROC INBREED statement is required. Items within angle brackets (< >) are optional. The syntax of each statement is described in the following sections.
PROC INBREED Statement

PROC INBREED < options > ;

You can specify the following options in the PROC INBREED statement.

AVERAGE
A produces a table of averages of coefficients for each pedigree of offspring. The AVERAGE option is used together with the GENDER statement to average the in-breeding/covariance coefficients within sex categories.

COVAR
C specifies that all coefficients output consist of covariance coefficients rather than in-breeding coefficients.

DATA=SAS-data-set
names the SAS data set to be used by PROC INBREED. If you omit the DATA= option, the most recently created SAS data set is used.

IND
I displays the individuals’ inbreeding coefficients (diagonal of the inbreeding coefficients matrix) for each pedigree of offspring. If you also specify the COVAR option, the individuals’ covariance coefficients (diagonal of the covariance coefficients matrix) are displayed.

INDL
displays individuals’ coefficients for only the last generation of a multiparous population.

INIT= cov
specifies the covariance value cov if any of the parents are unknown; a value of 0 is assumed if you do not specify the INIT= option.

MATRIX
M displays the inbreeding coefficient matrix for each pedigree of offspring. If you also specify the COVAR option, the covariance matrices are displayed instead of inbreeding coefficients matrices.

MATRIXL
displays coefficients for only the last generation of a multiparous population.

NOPRINT
suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS).

For more information on ODS, see Chapter 14, “Using the Output Delivery System.”
OUTCOV=SAS-data-set
names an output data set to contain the inbreeding coefficients. When the COVAR option is also specified, covariance estimates are output to the OUTCOV= data set instead of inbreeding coefficients.

**BY Statement**

```
BY variables;
```

You can specify a BY statement with PROC INBREED to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Use the SORT procedure with a similar BY statement to sort the data.
- Use the BY statement options NOTSORTED or DESCENDING in the BY statement for the INBREED procedure. As a cautionary note, the NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables), and these groups are not necessarily in alphabetical or increasing numeric order.
- Use the DATASETS procedure (in base SAS software) to create an index on the BY variables.

For more information on the BY statement, see the discussion in *SAS Language Reference: Concepts*.

**CLASS Statement**

```
CLASS variable;
```

To analyze the population within nonoverlapping generations, you must specify the variable that identifies generations in a CLASS statement. Values of the generation variable, called *generation numbers*, must be integers, but generations are assumed to occur in the order of their input in the input data set rather than in numerical order of the generation numbers. The name of an individual needs to be unique only within its generation.

When the MATRIXL option or the INDL option is specified, each generation requires a unique generation number in order for the specified option to work correctly. If generation numbers are not unique, all the generations with a generation number that is the same as the last generation’s are output.
GENDER Statement

GENDER  variable ;

The GENDER statement specifies a variable that indicates the sex of the individuals. Values of the sex variable must be character beginning with ‘M’ or ‘F’, for male or female. The GENDER statement is needed only when you specify the AVERAGE option to average the inbreeding/covariance coefficients within sex categories or when you want to include a gender variable in the OUTCOV= data set.

PROC INBREED makes the following assumptions regarding the gender of individuals:

- The first parent is always assumed to be the male. See the “VAR Statement” section on page 1975.
- The second parent is always assumed to be the female. See the “VAR Statement” section on page 1975.
- If the gender of an individual is missing or invalid, this individual is assumed to be a female unless the population is overlapping and this individual appears as the first parent in a later observation.

Any contradictions to these rules are reported in the SAS log.

MATINGS Statement

MATINGS  individual-list1 / mate-list1 <, . . . , individual-listn / mate-listn >;

You can specify the MATINGS statement with PROC INBREED to specify selected matings of individuals. Each individual given in individual-list is mated with each individual given in mate-list. You can write multiple mating specifications if you separate them by commas or asterisks. The procedure reports the inbreeding coefficients or covariances for each pair of mates. For example, you can use the following statement to specify the mating of an individual named ‘DAVID’ with an individual named ‘JANE’:

matings david / jane;

VAR Statement

VAR  individual parent1 parent2 < covariance > ;

The VAR statement specifies three or four variables: the first variable contains an individual’s name, the second variable contains the name of the individual’s first parent, and the third variable contains the name of the individual’s second parent. An optional fourth variable assigns a known value to the covariance of the individual’s first and second parents in the current generation.

The first three variables in the VAR statement can be either numeric or character; however, only the first 12 characters of a character variable are recognized by the procedure. The fourth variable, if specified, must be numeric.
If you omit the VAR statement, then the procedure uses the first three unaddressed variables as the names of the individual and its parents. (Unaddressed variables are those that are not referenced in any other PROC INBREED statement.) If the input data set contains an unaddressed fourth variable, then it becomes the covariance variable.

Details

Missing Values

A missing value for a parent implies that the parent is unknown. Unknown parents are assumed to be unrelated and not inbred unless you specify the INIT= option (see the INIT= option on page 1973).

When the value of the variable identifying the individual is missing, the observation is not added to the list of individuals. However, for a multiparous population, an observation with a missing individual is valid and is used for assigning covariances.

Missing covariance values are determined from the INIT=cov option, if specified. Observations with missing generation variables are excluded.

If the gender of an individual is missing, it is determined from the order in which it is listed on the first observation defining its progeny for an overlapping population. If it appears as the first parent, it is set to ‘M’; otherwise, it is set to ‘F’. When the gender of an individual cannot be determined, it is assigned a default value of ‘F’.

DATA= Data Set

Each observation in the input data set should contain necessary information such as the identification of an individual and the first and second parents of an individual. In addition, if a CLASS statement is specified, each observation should contain the generation identification; and, if a GENDER statement is specified, each observation should contain the gender of an individual. Optionally, each observation may also contain the covariance between the first and the second parents. Depending on how many statements are specified with the procedure, there should be enough variables in the input data set containing this information.

If you omit the VAR statement, then the procedure uses the first three unaddressed variables in the input data set as the names of the individual and his or her parents. Unaddressed variables in the input data set are those variables that are not referenced by the procedure in any other statements, such as CLASS, GENDER, or BY statements. If the input data set contains an unaddressed fourth variable, then the procedure uses it as the covariance variable.

If the individuals given by the variables associated with the first and second parents are not in the population, they are added to the population. However, if they are in the population, they must be defined prior to the observation that gives their progeny.

When there is a CLASS statement, the functions of defining new individuals and assigning covariances must be separated. This is necessary because the parents of
any given individual are defined in the previous generation, while covariances are assigned between individuals in the current generation.

Therefore, there could be two types of observations for a multiparous population:

- one to define new individuals in the current generation whose parents have been defined in the previous generation, as in the following, where the missing value is for the covariance variable:

  
  ```
  MARK GEORGE LISA . M 1
  KELLY SCOTT LISA . F 1
  ```

- one to assign covariances between two individuals in the current generation, as in the following, where the individual’s name is missing, ‘MARK’ and ‘KELLY’ are in the current generation, and the covariance coefficient between these two individuals is 0.50:

  
  ```
  . MARK KELLY 0.50 . 1
  ```

Note that the observations defining individuals must precede the observation assigning a covariance value between them. For example, if a covariance is to be assigned between ‘MARK’ and ‘KELLY’, then both of them should be defined prior to the assignment observation.

### Computational Details

This section describes the rules that the INBREED procedure uses to compute the covariance and inbreeding coefficients. Each computational rule is explained by an example referring to the fictitious population introduced in the “Getting Started” section on page 1967.

#### Coancestry (or Kinship Coefficient)

To calculate the inbreeding coefficient and the covariance coefficients, use the degree of relationship by descent between the two parents, which is called coancestry or kinship coefficient (Falconer and Mackay 1996, p.85), or coefficient of parentage (Kempthorne 1957, p.73). Denote the coancestry between individuals X and Y by $f_{XY}$. For information on how to calculate the coancestries among a population, see the section “Calculation of Coancestry.”

#### Covariance Coefficient (or Coefficient of Relationship)

The covariance coefficient between individuals X and Y is defined by

$$\text{Cov}(X,Y) = 2f_{XY}$$

where $f_{XY}$ is the coancestry between X and Y. The covariance coefficient is sometimes called the coefficient of relationship or the theoretical correlation (Falconer and Mackay 1996, p.153; Crow and Kimura 1970, p.134). If a covariance coefficient
cannot be calculated from the individuals in the population, it is assigned to an initial value. The initial value is set to 0 if the INIT= option is not specified or to \( cov \) if INIT=\( cov \). Therefore, the corresponding initial coancestry is set to 0 if the INIT= option is not specified or to \( \frac{1}{2}cov \) if INIT=\( cov \).

### Inbreeding Coefficients

The inbreeding coefficient of an individual is the probability that the pair of alleles carried by the gametes that produced it are identical by descent (Falconer and Mackay 1996, Chapter 5; Kempthorne 1957, Chapter 5). For individual X, denote its inbreeding coefficient by \( F_X \). The inbreeding coefficient of an individual is equal to the coancestry between its parents. For example, if X has parents A and B, then the inbreeding coefficient of X is

\[
F_X = f_{AB}
\]

### Calculation of Coancestry

Given individuals X and Y, assume that X has parents A and B and that Y has parents C and D. For nonoverlapping generations, the basic rule to calculate the coancestry between X and Y is given by the following formula (Falconer and Mackay 1996, p.86):

\[
f_{XY} = \frac{1}{4}(f_{AC} + f_{AD} + f_{BC} + f_{BD})
\]

And the inbreeding coefficient for an offspring of X and Y, called Z, is the coancestry between X and Y:

\[
F_Z = f_{XY}
\]

![Figure 35.4](image)

**Figure 35.4. Inbreeding Relationship for Nonoverlapping Population**

For example, in Figure 35.4, ‘JIM’ and ‘MARK’ from Generation 2 are progenies of ‘MARK’ and ‘KELLY’ and of ‘MIKE’ and ‘KELLY’ from Generation 1, respectively. The coancestry between ‘JIM’ and ‘MARK’ is
\[ f_{\text{JIM}, \text{MARK}} = \frac{1}{4} \left( f_{\text{MARK}, \text{MIKE}} + f_{\text{MARK}, \text{KELLY}} + f_{\text{KELLY}, \text{MIKE}} + f_{\text{KELLY}, \text{KELLY}} \right) \]

From the covariance matrix for Generation=1 in Figure 35.2 (page 1971) and the relationship that coancestry is half of the covariance coefficient,

\[ f_{\text{JIM}, \text{MARK}} = \frac{1}{4} \left( \frac{0.4688}{2} + \frac{0.5}{2} + \frac{0.25}{2} + \frac{1.125}{2} \right) = 0.29298 \]

For overlapping generations, if \( X \) is older than \( Y \), then the basic rule (on page 1978) can be simplified to

\[ F_Z = f_{XY} = \frac{1}{2} (f_{XC} + f_{XD}) \]

That is, the coancestry between \( X \) and \( Y \) is the average of coancestries between older \( X \) with younger \( Y \)'s parents. For example, in Figure 35.5, the coancestry between ‘KELLY’ and ‘DAVID’ is

\[ f_{\text{KELLY}, \text{DAVID}} = \frac{1}{2} \left( f_{\text{KELLY}, \text{MARK}} + f_{\text{KELLY}, \text{KELLY}} \right) \]

![Figure 35.5. Inbreeding Relationship for Overlapping Population](image)

This is so because ‘KELLY’ is defined before ‘DAVID’; therefore, ‘KELLY’ is not younger than ‘DAVID’, and the parents of ‘DAVID’ are ‘MARK’ and ‘KELLY’. The covariance coefficient values \( \text{Cov}(\text{KELLY}, \text{MARK}) \) and \( \text{Cov}(\text{KELLY}, \text{KELLY}) \) from
Chapter 35. The INBRED Procedure

the matrix in Figure 35.1 on page 1970 yield that the coancestry between ‘KELLY’ and ‘DAVID’ is

\[
f_{KELLY, DAVID} = \frac{1}{2} \left( \frac{0.5}{2} + \frac{1.125}{2} \right) = 0.40625
\]

The numerical values for some initial coancestries must be known in order to use these rule. Either the parents of the first generation have to be unrelated, with \( f = 0 \) if the INIT= option is not specified in the PROC statement, or their coancestries must have an initial value of \( \frac{1}{2} \text{cov} \), where \( \text{cov} \) is set by the INIT= option. Then the subsequent coancestries among their progenies and the inbreeding coefficients of their progenies in the rest of the generations are calculated using these initial values.

Special rules need to be considered in the calculations of coancestries for the following cases.

**Self-Mating**

The coancestry for an individual X with itself, \( f_{XX} \), is the inbreeding coefficient of a progeny that is produced by self-mating. The relationship between the inbreeding coefficient and the coancestry for self-mating is

\[
f_{XX} = \frac{1}{2} (1 + F_X)
\]

The inbreeding coefficient \( F_X \) can be replaced by the coancestry between X’s parents A and B, \( f_{AB} \), if A and B are in the population:

\[
f_{XX} = \frac{1}{2} (1 + f_{AB})
\]

If X’s parents are not in the population, then \( F_X \) is replaced by the initial value \( \frac{1}{2} \text{cov} \) if \( \text{cov} \) is set by the INIT= option, or \( F_X \) is replaced by 0 if the INIT= option is not specified. For example, the coancestry of ‘JIM’ with himself is

\[
f_{JIM, JIM} = \frac{1}{2} \left(1 + f_{MARK, KELLY} \right)
\]

where ‘MARK’ and ‘KELLY’ are the parents of ‘JIM’. Since the covariance coefficient \( \text{Cov}(MARK,KELLY) \) is 0.5 in Figure 35.1 on page 1970 and also in the covariance matrix for GENDER=1 in Figure 35.2 on page 1971, the coancestry of ‘JIM’ with himself is

\[
f_{JIM, JIM} = \frac{1}{2} \left(1 + \frac{0.5}{2} \right) = 0.625
\]

When INIT=0.25, then the coancestry of ‘JANE’ with herself is

\[
f_{JANE, JANE} = \frac{1}{2} \left(1 + \frac{0.25}{2} \right) = 0.5625
\]

because ‘JANE’ is not an offspring in the population.
Offspring and Parent Mating

Assuming that X’s parents are A and B, the coancestry between X and A is

\[ f_{XA} = \frac{1}{2} (f_{AB} + f_{AA}) \]

The inbreeding coefficient for an offspring of X and A, denoted by Z, is

\[ F_Z = f_{XA} = \frac{1}{2} (f_{AB} + f_{AA}) \]

For example, ‘MARK’ is an offspring of ‘GEORGE’ and ‘LISA’, so the coancestry between ‘MARK’ and ‘LISA’ is

\[ f_{MARK, LISA} = \frac{1}{2} (f_{LISA, GEORGE} + f_{LISA, LISA}) \]

From the covariance coefficient matrix in Figure 35.1 on page 1970, \( f_{LISA, GEORGE} = 0.25/2 = 0.125 \), \( f_{LISA, LISA} = 1.125/2 = 0.5625 \), so that

\[ f_{MARK, LISA} = \frac{1}{2} (0.125 + 0.5625) = 0.34375 \]

Thus, the inbreeding coefficient for an offspring of ‘MARK’ and ‘LISA’ is 0.34375.

Full Sibs Mating

This is a special case for the basic rule given at the beginning of the section “Calculation of Coancestry” on page 1978. If X and Y are full sibs with same parents A and B, then the coancestry between X and Y is

\[ f_{XY} = \frac{1}{4} (2f_{AB} + f_{AA} + f_{BB}) \]

and the inbreeding coefficient for an offspring of A and B, denoted by Z, is

\[ F_Z = f_{XY} = \frac{1}{4} (2f_{AB} + f_{AA} + f_{BB}) \]

For example, ‘DAVID’ and ‘JIM’ are full sibs with parents ‘MARK’ and ‘KELLY’, so the coancestry between ‘DAVID’ and ‘JIM’ is

\[ f_{DAVID, JIM} = \frac{1}{4} \left( 2f_{MARK, KELLY} + f_{MARK, MARK} + f_{KELLY, KELLY} \right) \]

Since the coancestry is half of the covariance coefficient, from the covariance matrix in Figure 35.1 on page 1970,

\[ f_{DAVID, JIM} = \frac{1}{4} \left( 2 \times \frac{0.5}{2} + \frac{1.125}{2} + \frac{1.125}{2} \right) = 0.40625 \]
Unknown or Missing Parents

When individuals or their parents are unknown in the population, their coancestries are assigned by the value $\frac{1}{2} cov$ if $cov$ is set by the INIT= option or by the value 0 if the INIT= option is not specified. That is, if either A or B is unknown, then

$$f_{AB} = \frac{1}{2} cov$$

For example, ‘JANE’ is not in the population, and since ‘JANE’ is assumed to be defined just before the observation at which ‘JANE’ appears as a parent (that is, between observations 4 and 5), then ‘JANE’ is not older than ‘SCOTT’. The coancestry between ‘JANE’ and ‘SCOTT’ is then obtained by using the simplified basic rule (see page 1979):

$$f_{SCOTT,JANE} = \frac{1}{2} \left( f_{SCOTT,} + f_{SCOTT,-} \right)$$

Here, dots (-) indicate JANE’s unknown parents. Therefore, $f_{SCOTT,}$ is replaced by $\frac{1}{2} cov$, where $cov$ is set by the INIT= option. If INIT=0.25, then

$$f_{SCOTT,JANE} = \frac{1}{2} \left( \frac{0.25}{2} + \frac{0.25}{2} \right) = 0.125$$

For a more detailed discussion on the calculation of coancestries, inbreeding coefficients, and covariance coefficients, refer to Falconer and Mackay (1996), Kempthorne (1957), and Crow and Kimura (1970).

OUTCOV= Data Set

The OUTCOV= data set has the following variables:

- a list of BY variables, if there is a BY statement
- the generation variable, if there is a CLASS statement
- the gender variable, if there is a GENDER statement
- _Type_, a variable indicating the type of observation. The valid values of the _Type_ variable are ‘COV’ for covariance estimates and ‘INBREED’ for inbreeding coefficients.
- _Panel_, a variable indicating the panel number used when populations delimited by BY groups contain different numbers of individuals. If there are $n$ individuals in the first BY group and if any subsequent BY group contains a larger population, then its covariance/inbreeding matrix is divided into panels, with each panel containing $n$ columns of data. If you put these panels side by side in increasing _Panel_ number order, then you can reconstruct the covariance or inbreeding matrix.
• _Col_, a variable used to name columns of the inbreeding or covariance matrix. The values of this variable start with ‘COL’, followed by a number indicating the column number. The names of the individuals corresponding to any given column $i$ can be found by reading the individual’s name across the row that has a _Col_ value of ‘COL$i’’. When the inbreeding or covariance matrix is divided into panels, all the rows repeat for the first $n$ columns, all the rows repeat for the next $n$ columns, and so on.

• the variable containing the names of the individuals, that is, the first variable listed in the VAR statement

• the variable containing the names of the first parents, that is, the second variable listed in the VAR statement

• the variable containing the names of the second parents, that is, the third variable listed in the VAR statement

• a list of covariance variables Col1-Col$n$, where $n$ is the maximum number of individuals in the first population

The functions of the variables _Panel_ and _Col_ can best be demonstrated by an example. Assume that there are three individuals in the first BY group and that, in the current BY group (Byvar=2), there are five individuals with the following covariance matrix.

<table>
<thead>
<tr>
<th>COV</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>

<tr>
<td>2</td>
<td>2</td>
<td>COL2</td>
<td>5</td>
<td></td>
<td></td>
<td>Cov(4,4)</td>
<td>Cov(4,5)</td>
<td>.</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>Cov(5,4)</td>
<td>Cov(5,5)</td>
<td>.</td>
</tr>
</tbody>
</table>
Notice that the first three columns go to the first panel (Panel=1), and the remaining two go to the second panel (Panel=2). Therefore, in the first panel, ‘COL1’, ‘COL2’, and ‘COL3’ correspond to individuals 1, 2, and 3, respectively, while in the second panel, ‘COL1’ and ‘COL2’ correspond to individuals 4 and 5, respectively.

**Displayed Output**

The INBREED procedure can output either covariance coefficients or inbreeding coefficients. Note that the following items can be produced for each generation if generations do not overlap.

The output produced by PROC INBREED can be any or all of the following items:

- a matrix of coefficients
- coefficients of the individuals
- coefficients for selected matings

**ODS Table Names**

PROC INBREED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table.

For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

### Example 35.2. Pedigree Analysis

In the following example, an inbreeding analysis is performed for a complicated pedigree. This analysis includes computing selective matings of some individuals and inbreeding coefficients of all individuals. Also, inbreeding coefficients are averaged within sex categories. The result appears in Output 35.2.1.

</tr>
<tr>
<td>4</td>
<td>1</td>
<td>3</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

**Number of Individuals** 4

Note that, since the parents of the first generation are unknown, off-diagonal elements of the covariance matrix are all 0s and on-diagonal elements are all 1s. If there is an INIT=COV value, then the off-diagonal elements would be equal to COV, while on-diagonal elements would be equal to 1 + COV/2.

In the third generation, individuals 2 and 4 are full siblings, so they belong to the same family. Since PROC INBREED computes covariance coefficients between families, the second and fourth columns of inbreeding coefficients are the same, except that their intersections with the second and fourth rows are reordered. Notice that, even though there is an observation to assign a covariance of 0.50 between individuals 2 and 3 in the third generation, the covariance between 2 and 3 is set to 1.135, the same value assigned between 4 and 3. This is because families get the same covariances, and later specifications override previous ones.

  matings 2501 / 3501 3504 ,
            3712 / 3121;
  gender Sex;
run;

Note the following from Output 35.2.1:

- Observation 4, which defines Swine_Number=2501, should precede the first and third observations where the progeny for 2501 are given. PROC INBREED ignores observation 4 since it is given out of order. As a result, the parents of 2501 are missing or unknown.

- The first column in the “Inbreeding Averages” table corresponds to the averages taken over the on-diagonal elements of the inbreeding coefficients matrix, and the second column gives averages over the off-diagonal elements.

Chapter 36
The KDE Procedure
Overview

The KDE procedure performs either univariate or bivariate kernel density estimation. Statistical density estimation involves approximating a hypothesized probability density function from observed data. Kernel density estimation is a nonparametric technique for density estimation in which a known density function (the kernel) is averaged across the observed data points to create a smooth approximation. Refer to Silverman (1986) for a thorough review and discussion.

PROC KDE uses a Gaussian density as the kernel, and its assumed variance determines the smoothness of the resulting estimate. PROC KDE outputs the kernel density estimate into a SAS data set, which you can then use with other procedures for plotting or analysis. PROC KDE also computes a variety of common statistics, including estimates of the percentiles of the hypothesized probability density function.

Experimental graphics are now available with the KDE procedure. For more information, see the “ODS Graphics” section on page 2009.

Getting Started

The following example illustrates the basic features of PROC KDE. Assume that 1000 observations are simulated from a bivariate normal density with means (0, 0), variances (10, 10), and covariance 9. The SAS DATA step to accomplish this is as follows:

```
data bivnormal;
  seed = 1283470;
  do i = 1 to 1000;
    z1 = rannor(seed);
    z2 = rannor(seed);
    z3 = rannor(seed);
    x = 3*z1+z2;
    y = 3*z1+z3;
    output;
  end;
  drop seed;
run;
```
The following statements request a bivariate kernel density estimate for the variables $x$ and $y$.

```plaintext
ods html;
ods graphics on;

proc kde data=bivnormal;
   bivar x y / plots=contour surface;
run;

ods graphics off;
ods html close;
```

A contour plot and a surface plot of the estimate are displayed in Figure 36.1 and Figure 36.2, respectively. Note that the correlation of 0.9 in the original data results in oval-shaped contours. These graphical displays are requested by specifying the experimental ODS GRAPHICS statement and the experimental PLOTS= option in the BIVAR statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the KDE procedure, see the “ODS Graphics” section on page 2009.

**Figure 36.1.** Contour Plot of Estimated Density (Experimental)
**Figure 36.2.** Surface Plot of Estimated Density (Experimental)

The default output tables for this analysis are as follows.

<table>
<thead>
<tr>
<th>Inputs</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data Set</td>
</tr>
<tr>
<td>Number of Observations Used</td>
</tr>
<tr>
<td>Variable 1</td>
</tr>
<tr>
<td>Variable 2</td>
</tr>
<tr>
<td>Bandwidth Method</td>
</tr>
</tbody>
</table>

The “Inputs” table lists basic information about the density fit, including the input data set, the number of observations, and the variables. The bandwidth method is the technique used to select the amount of smoothing in the estimate. A simple normal reference rule is used for bivariate smoothing.

<table>
<thead>
<tr>
<th>Controls</th>
</tr>
</thead>
<tbody>
<tr>
<td>x y</td>
</tr>
<tr>
<td>Grid Points</td>
</tr>
<tr>
<td>Lower Grid Limit</td>
</tr>
<tr>
<td>Upper Grid Limit</td>
</tr>
<tr>
<td>Bandwidth Multiplier</td>
</tr>
</tbody>
</table>
The “Controls” table lists the primary numbers controlling the kernel density fit. Here a 60 × 60 grid is fit to the entire range of the data, and no adjustment is made to the default bandwidth.

**Syntax**

You can use the following statements with the KDE procedure.

```plaintext
PROC KDE < options > ;
  BIVAR (variable < (v-options) > variable < (v-options) > <)>
  < . . . <(variable < (v-options) > variable < (v-options) > <)>
  > < / options > ;
  UNIVAR variable < (v-options) > < . . . variable < (v-options) > >
  < / options > ;
  BY variables ;
  FREQ variable ;
  WEIGHT variable ;
```

The PROC KDE statement invokes the procedure. The BIVAR statement requests that one or more bivariate kernel density estimates be computed. The UNIVAR statement requests one or more univariate kernel density estimates.

**PROC KDE Statement**

```plaintext
PROC KDE < options > ;
```

The PROC KDE statement invokes the procedure and specifies the input data set.

**DATA=SAS-data-set**

specifies the input SAS data set to be used by PROC KDE. The default is the most recently created data set.

**Note:** The following options, which were available in the PROC KDE statement in Version 8, are now obsolete. These options are now available in the UNIVAR and BIVAR statements.

<table>

</tbody>
</table>
The basic syntax for the BIVAR statement is

```
BIVAR variable1 variable2 ;
```

This statement requests a bivariate kernel density estimate for the variables `variable1` and `variable2`.

The general form of this syntax is as follows:

```
BIVAR <(> variable <(v-options) > variable <(v-options) > <)>
   < . . . <(> variable <(v-options) > variable <(v-options) > <)>
   > < / options > ;
```

The BIVAR statement lists variables in the input data set for which bivariate kernel density estimates are to be computed. You can specify a list of variables or a list of variable pairs, where each pair is enclosed in parentheses. If you specify a variable list, a kernel density estimate is computed for each distinct combination of two variables in the list. If you specify variable pairs, a kernel density estimate is computed for each pair.

For example, if you specify

```
bivar x y z;
```

then a bivariate kernel density estimate is computed for each of the pairs \((x, y)\), \((x, z)\), and \((y, z)\). On the other hand, if you specify

```
bivar (x y) (z w);
```

then only two bivariate kernel density estimates are computed, one for \((x, y)\) and one for \((z, w)\).

You can specify various `v-options` for each variable by enclosing them in parentheses after the variable name. You can also specify global `options` among the BIVAR statement options following a slash (/). Global `options` are applied to all the variables specified in the BIVAR statement. However, individual variable `v-options` override the global `options`.

**Note:** The VAR statement for PROC KDE in Version 8 is now obsolete. The VAR statement has been replaced by the UNIVAR and the BIVAR statements, which provide more control and flexibility for specifying the variables to be analyzed.

You can specify the following `options` in the BIVAR statement (as noted, some `options` can be used as `v-options`).

---

**BIVAR Statement**

The basic syntax for the BIVAR statement is

```
BIVAR variable1 variable2 ;
```

This statement requests a bivariate kernel density estimate for the variables `variable1` and `variable2`.

The general form of this syntax is as follows:

```
BIVAR <(> variable <(v-options) > variable <(v-options) > <)>
   < . . . <(> variable <(v-options) > variable <(v-options) > <)>
   > < / options > ;
```

The BIVAR statement lists variables in the input data set for which bivariate kernel density estimates are to be computed. You can specify a list of variables or a list of variable pairs, where each pair is enclosed in parentheses. If you specify a variable list, a kernel density estimate is computed for each distinct combination of two variables in the list. If you specify variable pairs, a kernel density estimate is computed for each pair.

For example, if you specify

```
bivar x y z;
```

then a bivariate kernel density estimate is computed for each of the pairs \((x, y)\), \((x, z)\), and \((y, z)\). On the other hand, if you specify

```
bivar (x y) (z w);
```

then only two bivariate kernel density estimates are computed, one for \((x, y)\) and one for \((z, w)\).

You can specify various `v-options` for each variable by enclosing them in parentheses after the variable name. You can also specify global `options` among the BIVAR statement options following a slash (/). Global `options` are applied to all the variables specified in the BIVAR statement. However, individual variable `v-options` override the global `options`.

**Note:** The VAR statement for PROC KDE in Version 8 is now obsolete. The VAR statement has been replaced by the UNIVAR and the BIVAR statements, which provide more control and flexibility for specifying the variables to be analyzed.

You can specify the following `options` in the BIVAR statement (as noted, some `options` can be used as `v-options`).
BIVSTATS
requests the covariance and correlation between the two variables.

BWM=number
specifies the bandwidth multiplier for the kernel density estimate. The default value is 1. Larger multipliers produce a smoother estimate, and smaller ones produce a rougher estimate. You can specify BWM= as a v-option.

GRIDL=number
specifies the lower grid limit for the kernel density estimate. The default value equals the minimum observed values of the variables. You can specify GRIDL= as a v-option.

GRIDU=number
specifies the upper grid limit for the kernel density estimate. The default value equals the maximum observed values of the variables. You can specify GRIDU= as a v-option.

LEVELS
LEVELS=numlist
requests a table of levels for contours of the bivariate density. The contours are defined in such a way that the density has a constant level along each contour, and the volume enclosed by each contour corresponds to a specified percent. In other words, the contours correspond to slices or levels of the density surface taken along the density axis. You can use the LEVELS= option to specify the percents. By default, the percents are 1, 5, 10, 50, 90, 95, 99, and 100. The table also provides the minimum and maximum values for each contour along the directions of the two data variables.

NGRID=number
NG=number
specifies the number of grid points associated with a variable in the BIVAR statement. The default value is 60. You can specify NGRID= as a v-option.

OUT=SAS-data-set
specifies the output SAS data set containing the kernel density estimate. This output data set contains the following variables:

- var1, whose value is the name of the first variable in a bivariate kernel density estimate
- var2, whose value is the name of the second variable in a bivariate kernel density estimate
- value1, with values corresponding to grid coordinates for the first variable
- value2, with values corresponding to grid coordinates for the second variable
- density, with values equal to kernel density estimates at the associated grid point
- count, containing the number of original observations contained in the bin corresponding to a grid point
PERCENTILES
PERCENTILES=numlist
lists percentiles to be computed for each BIVAR variable. The default percentiles are 0.5, 1, 2.5, 5, 10, 25, 50, 75, 90, 95, 97.5, 99, and 99.5.

UNISTATS
requests standard univariate statistics for each variable, as well as statistics associated with the density estimate.

UNIVAR Statement

UNIVAR variable < (v-options) > < . . . variable < (v-options) > > < / options > ;

The UNIVAR statement lists variables in the input data set for which univariate kernel density estimates are to be computed. You can specify various v-options for each variable by enclosing them in parentheses after the variable name. You can also specify global options among the UNIVAR statement options following a slash (/). Global options are applied to all the variables specified in the UNIVAR statement. However, individual variable v-options override the global options.

Note: The VAR statement for PROC KDE in Version 8 is now obsolete. The VAR statement has been replaced by the UNIVAR and the BIVAR statements, which provide more control and flexibility for specifying the variables to be analyzed.

You can specify the following options in the UNIVAR statement (as noted, some options can be used as v-options.)

BWM=number
specifies the bandwidth multiplier for the kernel density estimate. The default value is 1. Larger multipliers produce a smoother estimate, and smaller ones produce a rougher estimate. You can specify BWM= as a v-option.

GRIDL=number
specifies the lower grid limit for the kernel density estimate. The default value equals the minimum observed values of the variables. You can specify GRIDL= as a v-option.

GRIDU=number
specifies the upper grid limit for the kernel density estimate. The default value equals the maximum observed values of the variables. You can specify GRIDU= as a v-option.

METHOD= SJPI | SNR | SROT | OS
specifies the method used to compute the bandwidth. Available methods are Sheather-Jones plug-in (SJPI), simple normal reference (SNR), Silverman’s rule of thumb (SROT), and oversmoothed (OS). Refer to Jones, Marron, and Sheather (1996) for a description of each of these methods. SJPI is the default method.
Chapter 36. The KDE Procedure

`NGRID=number`

specifies the number of grid points associated with a variable in the UNIVAR statement. The default value is 401. You can specify `NGRID=` as a v-option.

`OUT=SAS-data-set`

specifies the output SAS data set containing the kernel density estimate. This output data set contains the following variables:

- `var`, whose value is the name of the variable in the kernel density estimate
- `value`, with values corresponding to grid coordinates for the variable
- `density`, with values equal to kernel density estimates at the associated grid point
- `count`, containing the number of original observations contained in the bin corresponding to a grid point

`PERCENTILES`

`PERCENTILES=numlist`

lists percentiles to be computed for each UNIVAR variable. The default percentiles are 0.5, 1, 2.5, 5, 10, 25, 50, 75, 90, 95, 97.5, 99, and 99.5.

`SJPIMAX=number`

specifies the maximum grid value in determining the Sheather-Jones plug-in bandwidth. The default value is two times the oversmoothed estimate.

`SJPIMIN=number`

specifies the minimum grid value in determining the Sheather-Jones plug-in bandwidth. The default value is the maximum value divided by 18.

`SJPINUM=number`

specifies the number of grid values used in determining the Sheather-Jones plug-in bandwidth. The default is 21.

`SJPITOL=number`

specifies the tolerance for termination of the bisection algorithm used in computing the Sheather-Jones plug-in bandwidth. The default value is 0.001.

`UNISTATS`

requests standard univariate statistics for each variable, as well as statistics associated with the density estimate.

**Examples**

Suppose you have the variables `x1`, `x2`, `x3`, `x4` in the SAS data set `MyData`. You can request a kernel density estimate for each of these variables with the following statements.

```sas
proc kde data=MyData;
   univar x1 x2 x3 x4;
run;
```
You can also specify different bandwidths and other options for each variable. For example, the following statements request kernel density estimates using Silverman’s rule of thumb (SROT) method for all variables. The option NGRID=200 applies to the variables x1, x3, and x4, but the v-option NGRID=100 is applied to x2. Bandwidth multipliers of 2 and 0.5 are specified for the variables x1 and x2, respectively.

```
proc kde data=MyData;
  univar x1 (bwm=2)
       x2 (bwm=0.5 ngrid=100)
       x3 x4 / ngrid=200 method=srot;
run;
```

**BY Statement**

```
BY variables ;
```

You can specify a BY statement with PROC KDE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the KDE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in the *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**FREQ Statement**

```
FREQ variable ;
```

The FREQ statement specifies a variable that provides frequencies for each observation in the DATA= data set. Specifically, if \( n \) is the value of the FREQ variable for a given observation, then that observation is used \( n \) times. If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.
WEIGHT Statement

**WEIGHT** variable ;

The WEIGHT statement specifies a variable that weights the observations in computing the kernel density estimate. Observations with higher weights have more influence in the computations. If an observation has a nonpositive or missing weight, then the entire observation is omitted from the analysis. You should be cautious in using data sets with extreme weights, as they can produce unreliable results.

**Details**

**Computational Overview**

The two main computational tasks of PROC KDE are automatic bandwidth selection and the construction of a kernel density estimate once a bandwidth has been selected. The primary computational tools used to accomplish these tasks are binning, convolutions, and the fast Fourier transform. The following sections provide analytical details on these topics, beginning with the density estimates themselves.

**Kernel Density Estimates**

A weighted univariate kernel density estimate involves a variable $X$ and a weight variable $W$. Let $(X_i, W_i), \ i = 1, 2, \ldots, n$ denote a sample of $X$ and $W$ of size $n$. The weighted kernel density estimate of $f(x)$, the density of $X$, is as follows.

$$
\hat{f}(x) = \frac{1}{\sum_{i=1}^{n} W_i} \sum_{i=1}^{n} W_i \varphi_h(x - X_i)
$$

where $h$ is the bandwidth and

$$
\varphi_h(x) = \frac{1}{\sqrt{2\pi h}} \exp \left( -\frac{x^2}{2h^2} \right)
$$

is the standard normal density rescaled by the bandwidth. If $h \to 0$ and $nh \to \infty$, then the optimal bandwidth is

$$
h_{\text{AMISE}} = \left[ \frac{1}{2\sqrt{\pi n} \int (f')^2} \right]^{1/5}
$$

This optimal value is unknown, and so approximations methods are required. For a derivation and discussion of these results, refer to Silverman (1986, Chapter 3) and Jones, Marron, and Sheather (1996).

For the bivariate case, let $X = (X, Y)$ be a bivariate random element taking values in $\mathbb{R}^2$ with joint density function $f(x, y), (x, y) \in \mathbb{R}^2$, and let $X_i = (X_i, Y_i), i =$
1, 2, . . . , n be a sample of size n drawn from this distribution. The kernel density estimate of \( f(x, y) \) based on this sample is

\[
\hat{f}(x, y) = \frac{1}{n} \sum_{i=1}^{n} \varphi_h(x - X_i, y - Y_i) \\
= \frac{1}{nh_X h_Y} \sum_{i=1}^{n} \varphi \left( \frac{x - X_i}{h_X}, \frac{y - Y_i}{h_Y} \right)
\]

where \((x, y) \in \mathbb{R}^2, h_X > 0 \) and \( h_Y > 0 \) are the bandwidths and \( \varphi_h(x, y) \) is the rescaled normal density

\[
\varphi_h(x, y) = \frac{1}{h_X h_Y} \varphi \left( \frac{x}{h_X}, \frac{y}{h_Y} \right)
\]

where \( \varphi(x, y) \) is the standard normal density function

\[
\varphi(x, y) = \frac{1}{2\pi} \exp \left( -\frac{x^2 + y^2}{2} \right)
\]

Under mild regularity assumptions about \( f(x, y) \), the mean integrated squared error (MISE) of \( \hat{f}(x, y) \) is

\[
\text{MISE}(h_X, h_Y) = E \int (\hat{f} - f)^2 \\
= \frac{1}{4\pi nh_X h_Y} + \frac{h_X^4}{4} \int \left( \frac{\partial^2 f}{\partial X^2} \right)^2 dxdy \\
+ \frac{h_Y^4}{4} \int \left( \frac{\partial^2 f}{\partial Y^2} \right)^2 dxdy + O \left( h_X + h_Y + \frac{1}{nh_X h_Y} \right)
\]

as \( h_X \to 0, h_Y \to 0 \) and \( nh_X h_Y \to \infty \).

Now set

\[
\text{AMISE}(h_X, h_Y) = \frac{1}{4\pi nh_X h_Y} + \frac{h_X^4}{4} \int \left( \frac{\partial^2 f}{\partial X^2} \right)^2 dxdy \\
+ \frac{h_Y^4}{4} \int \left( \frac{\partial^2 f}{\partial Y^2} \right)^2 dxdy
\]

which is the asymptotic mean integrated squared error (AMISE). For fixed \( n \), this has minimum at \((h_{\text{AMISE}_X}, h_{\text{AMISE}_Y})\) defined as

\[
h_{\text{AMISE}_X} = \left[ \frac{\int (\frac{\partial^2 f}{\partial X^2})^2}{4n\pi} \right]^{1/6} \left[ \frac{\int (\frac{\partial^2 f}{\partial Y^2})^2}{\int (\frac{\partial^2 f}{\partial Y^2})^2} \right]^{2/3}
\]

\[
h_{\text{AMISE}_Y} = \left[ \frac{\int (\frac{\partial^2 f}{\partial Y^2})^2}{4n\pi} \right]^{1/6} \left[ \frac{\int (\frac{\partial^2 f}{\partial X^2})^2}{\int (\frac{\partial^2 f}{\partial X^2})^2} \right]^{2/3}
\]
and

\[ h_{\text{AMISE}_Y} = \left( \frac{f(\frac{\partial^2 f}{\partial Y^2})^2}{4n\pi} \right)^{1/6} \left( \frac{f(\frac{\partial^2 f}{\partial Y^2})}{f(\frac{\partial^2 f}{\partial X^2})^2} \right)^{2/3} \]

These are the optimal asymptotic bandwidths in the sense that they minimize MISE. However, as in the univariate case, these expressions contain the second derivatives of the unknown density \( f \) being estimated, and so approximations are required. Refer to Wand and Jones (1993) for further details.

**Binning**

Binning, or assigning data to discrete categories, is an effective and fast method for large data sets (Fan and Marron 1994). When the sample size \( n \) is large, direct evaluation of the kernel estimate \( \hat{f} \) at any point would involve \( n \) kernel evaluations, as shown in the preceding formulas. To evaluate the estimate at each point of a grid of size \( g \) would thus require \( ng \) kernel evaluations. When you use \( g = 401 \) in the univariate case or \( g = 60 \times 60 = 3600 \) in the bivariate case and \( n \geq 1000 \), the amount of computation can be prohibitively large. With binning, however, the computational order is reduced to \( g \), resulting in a much quicker algorithm that is nearly as accurate as direct evaluation.

To bin a set of weighted univariate data \( X_1, X_2, \ldots, X_n \) to a grid \( x_1, x_2, \ldots, x_g \), simply assign each sample \( X_i \), together with its weight \( W_i \), to the nearest grid point \( x_j \) (also called the bin center). When binning is completed, each grid point \( x_i \) has an associated number \( c_i \), which is the sum total of all the weights that correspond to sample points that have been assigned to \( x_i \). These \( c_i \)s are known as the *bin counts*.

This procedure replaces the data \( (X_i, W_i) \), \( i = 1, 2, \ldots, n \) with the smaller set \( (x_i, c_i) \), \( i = 1, 2, \ldots, g \), and the estimation is carried out with this new data. This is so-called *simple binning*, versus the finer *linear binning* described in Wand (1994). PROC KDE uses simple binning for the sake of faster and easier implementation. Also, it is assumed that the bin centers \( x_1, x_2, \ldots, x_g \) are equally spaced and in increasing order. In addition, assume for notational convenience that \( \sum_{i=1}^{n} W_i = n \) and, therefore, \( \sum_{i=1}^{g} c_i = n \).

If you replace the data \( (X_i, W_i) \), \( i = 1, 2, \ldots, n \) with \( (x_i, c_i) \), \( i = 1, 2, \ldots, g \), the weighted estimator \( \hat{f} \) then becomes

\[ \hat{f}(x) = \frac{1}{n} \sum_{i=1}^{g} c_i \varphi_h(x - x_i) \]

with the same notation as used previously. To evaluate this estimator at the \( g \) points of the same grid vector \( \text{grid} = (x_1, x_2, \ldots, x_g) \)' is to calculate

\[ \hat{f}(x_i) = \frac{1}{n} \sum_{j=1}^{g} c_j \varphi_h(x_i - x_j) \]
for $i = 1, 2, \ldots, g$. This can be rewritten as

$$
\hat{f}(x_i) = \frac{1}{n} \sum_{j=1}^{g} c_j \varphi_h(|i-j|\delta)
$$

where $\delta = x_2 - x_1$ is the increment of the grid.

The same idea of binning works similarly with bivariate data, where you estimate $\hat{f}$ over the grid matrix $grid = grid_X \times grid_Y$ as follows.

$$
\hat{f}(x_{i,j}) = \frac{1}{n} \sum_{k=1}^{g_X} \sum_{l=1}^{g_Y} c_{k,l} \varphi_h(|i-k|\delta_X, |j-l|\delta_Y)
$$

where $\delta_X = x_2 - x_1$ and $\delta_Y = y_2 - y_1$ are the increments of the grid.

**Convolutions**

The formulas for the binned estimator $\hat{f}$ in the previous subsection are in the form of a convolution product between two matrices, one of which contains the bin counts, the other of which contains the rescaled kernels evaluated at multiples of grid increments. This section defines these two matrices explicitly, and shows that $\hat{f}$ is their convolution.

Beginning with the weighted univariate case, define the following matrices:

$$
K = \frac{1}{n} \begin{pmatrix}
\varphi_h(0), & \varphi_h(\delta), & \ldots, & \varphi_h((g-1)\delta)
\end{pmatrix}'
$$

$$
C = (c_1, c_2, \ldots, c_g)'
$$

The first thing to note is that many terms in $K$ are negligible. The term $\varphi_h(i\delta)$ is taken to be 0 when $|i\delta/h| \geq 5$, so you can define

$$
l = \min(g - 1, \text{floor}(5h/\delta))
$$

as the maximum integer multiple of the grid increment to get nonzero evaluations of the rescaled kernel. Here floor($x$) denotes the largest integer less than or equal to $x$.

Next, let $p$ be the smallest power of 2 that is greater than $g + l + 1$,

$$
p = 2^{\text{ceil}(\log_2(g+l+1))}
$$
where \( \text{ceil}(x) \) denotes the smallest integer greater than or equal to \( x \).

Modify \( K \) as follows:

\[
K = \frac{1}{n} (\varphi_h(0), \varphi_h(\delta), \ldots, \varphi_h(l\delta), 0, \ldots, 0, \varphi_h(l\delta), \ldots, \varphi_h(\delta))^\prime
\]

Essentially, the negligible terms of \( K \) are omitted, and the rest are symmetrized (except for one term). The whole matrix is then padded to size \( p \times 1 \) with zeros in the middle. The dimension \( p \) is a highly composite number, that is, one that decomposes into many factors, leading to the most efficient fast Fourier transform operation (refer to Wand 1994).

The third operation is to pad the bin count matrix \( C \) with zeros to the same size as \( K \):

\[
C = (c_1, c_2, \ldots, c_g, 0, \ldots, 0)^\prime
\]

The convolution \( K * C \) is then a \( p \times 1 \) matrix, and the preceding formulas show that its first \( g \) entries are exactly the estimates \( \hat{f}(x_i), i = 1, 2, \ldots, g \).

For bivariate smoothing, the matrix \( K \) is defined similarly as

\[
K = \begin{bmatrix}
k_{0,0} & k_{0,1} & \ldots & k_{0,l_Y} & 0 & k_{0,l_Y} & \ldots & k_{0,1} \\
k_{1,0} & k_{1,1} & \ldots & k_{1,l_Y} & 0 & k_{1,l_Y} & \ldots & k_{1,1} \\
\vdots & & & & & & & \\
k_{l_X,0} & k_{l_X,1} & \ldots & k_{l_X,l_Y} & 0 & k_{l_X,l_Y} & \ldots & k_{l_X,1} \\
0 & 0 & \ldots & 0 & 0 & 0 & \ldots & 0 \\
k_{l_X,0} & k_{l_X,1} & \ldots & k_{l_X,l_Y} & 0 & k_{l_X,l_Y} & \ldots & k_{l_X,1} \\
\vdots & & & & & & & \\
k_{1,0} & k_{1,1} & \ldots & k_{1,l_Y} & 0 & k_{1,l_Y} & \ldots & k_{1,1}
\end{bmatrix}_{p_X \times p_Y}
\]

where \( l_X = \text{min}(g_X - 1, \text{floor}(5h_X/\delta_X)), p_X = 2^\text{ceil}(\log_2(g_X+l_X+1)) \), and so forth, and \( \kappa_{i,j} = \frac{1}{n} \varphi_h(i\delta_X, j\delta_Y) \) \( i = 0, 1, \ldots, l_X, j = 0, 1, \ldots, l_Y \).

The bin count matrix \( C \) is defined as

\[
C = \begin{bmatrix}
c_{1,1} & c_{1,2} & \ldots & c_{1,g_Y} & 0 & \ldots & 0 \\
c_{2,1} & c_{2,2} & \ldots & c_{2,g_Y} & 0 & \ldots & 0 \\
\vdots & & & & & & \\
c_{g_X,1} & c_{g_X,2} & \ldots & c_{g_X,g_Y} & 0 & \ldots & 0 \\
0 & 0 & \ldots & 0 & 0 & \ldots & 0 \\
\vdots & & & & & & \\
0 & 0 & \ldots & 0 & 0 & \ldots & 0
\end{bmatrix}_{p_X \times p_Y}
\]

As with the univariate case, the \( g_X \times g_Y \) upper-left corner of the convolution \( K * C \) is the matrix of the estimates \( \hat{f}(\text{grid}) \).

Most of the results in this subsection are found in Wand (1994).
Fast Fourier Transform

As shown in the last subsection, kernel density estimates can be expressed as a sub-matrix of a certain convolution. The fast Fourier transform (FFT) is a computationally effective method for computing such convolutions. For a reference on this material, refer to Press et al. (1988).

The discrete Fourier transform of a complex vector $z = (z_0, \ldots, z_{N-1})$ is the vector $Z = (Z_0, \ldots, Z_{N-1})$, where

$$Z_j = \sum_{l=0}^{N-1} z_l e^{2\pi i lj/N}, \quad j = 0, \ldots, N - 1$$

and $i$ is the square root of $-1$. The vector $z$ can be recovered from $Z$ by applying the inverse discrete Fourier transform formula

$$z_l = N^{-1} \sum_{j=0}^{N-1} Z_j e^{-2\pi i lj/N}, \quad l = 0, \ldots, N - 1$$

Discrete Fourier transforms and their inverses can be computed quickly using the FFT algorithm, especially when $N$ is highly composite; that is, it can be decomposed into many factors, such as a power of 2. By the Discrete Convolution Theorem, the convolution of two vectors is the inverse Fourier transform of the element-by-element product of their Fourier transforms. This, however, requires certain periodicity assumptions, which explains why the vectors $K$ and $C$ require zero-padding. This is to avoid wrap-around effects (refer to Press et al. 1988, pp. 410–411). The vector $K$ is actually mirror-imaged so that the convolution of $C$ and $K$ will be the vector of binned estimates. Thus, if $S$ denotes the inverse Fourier transform of the element-by-element product of the Fourier transforms of $K$ and $C$, then the first $g$ elements of $S$ are the estimates.

The bivariate Fourier transform of an $N_1 \times N_2$ complex matrix having $(l_1 + 1, l_2 + 1)$ entry equal to $z_{l_1l_2}$ is the $N_1 \times N_2$ matrix with $(j_1 + 1, j_2 + 1)$ entry given by

$$Z_{j_1j_2} = \sum_{l_1=0}^{N_1-1} \sum_{l_2=0}^{N_2-1} z_{l_1l_2} e^{2\pi i (l_1j_1/N_1 + l_2j_2/N_2)}$$

and the formula of the inverse is

$$z_{l_1l_2} = (N_1 N_2)^{-1} \sum_{j_1=0}^{N_1-1} \sum_{j_2=0}^{N_2-1} Z_{j_1j_2} e^{-2\pi i (l_1j_1/N_1 + l_2j_2/N_2)}$$

The same Discrete Convolution Theorem applies, and zero-padding is needed for matrices $C$ and $K$. In the case of $K$, the matrix is mirror-imaged twice. Thus, if $S$ denotes the inverse Fourier transform of the element-by-element product of the Fourier transforms of $K$ and $C$, then the upper-left $g_X \times g_Y$ corner of $S$ contains the estimates.
Bandwidth Selection

Several different bandwidth selection methods are available in PROC KDE in the univariate case. Following the recommendations of Jones, Marron, and Sheather (1996), the default method follows a plug-in formula of Sheather and Jones.

This method solves the fixed-point equation

\[
h = \left[ \frac{R(\varphi)}{nR\left(\hat{f}'(h)\right) \left(\int x^2 \varphi(x) dx\right)^2} \right]^{1/5}
\]

where \( R(\varphi) = \int \varphi^2(x) dx \).

PROC KDE solves this equation by first evaluating it on a grid of values spaced equally on a log scale. The largest two values from this grid that bound a solution are then used as starting values for a bisection algorithm.

The simple normal reference rule works by assuming \( \hat{f} \) is Gaussian in the preceding fixed-point equation. This results in

\[
h = \hat{\sigma}[4/(3n)]^{1/5}
\]

where \( \hat{\sigma} \) is the sample standard deviation.

Silverman’s rule of thumb (Silverman 1986, section 3.4.2) is computed as

\[
h = 0.9 \min[\hat{\sigma}, (Q_3 - Q_1)/1.34]n^{-1/5}
\]

where \( Q_3 \) and \( Q_1 \) are the third and first sample quartiles, respectively.

The oversmoothed bandwidth is computed as

\[
h = 3\hat{\sigma}[1/(70\sqrt{\pi n})]^{1/5}
\]

When you specify a WEIGHT variable, PROC KDE uses weighted versions of \( Q_3 \), \( Q_1 \), and \( \hat{\sigma} \) in the preceding expressions. The weighted quartiles are computed as weighted order statistics, and the weighted variance takes the form

\[
\hat{\sigma}^2 = \frac{\sum_{i=1}^{n} W_i (X_i - \bar{X})^2}{\sum_{i=1}^{n} W_i}
\]

where \( \bar{X} = (\sum_{i=1}^{n} W_i X_i) / (\sum_{i=1}^{n} W_i) \) is the weighted sample mean.

For the bivariate case, Wand and Jones (1993) note that automatic bandwidth selection is both difficult and computationally expensive. Their study of various ways of specifying a bandwidth matrix also shows that using two bandwidths, one in each coordinate’s direction, is often adequate. PROC KDE enables you to adjust the two
bandwidths by specifying a multiplier for the default bandwidths recommended by Bowman and Foster (1993):

\[
\begin{align*}
 h_X &= \hat{\sigma}_X n^{-1/6} \\
 h_Y &= \hat{\sigma}_Y n^{-1/6}
\end{align*}
\]

Here \( \hat{\sigma}_X \) and \( \hat{\sigma}_Y \) are the sample standard deviations of \( X \) and \( Y \), respectively. These are the optimal bandwidths for two independent normal variables that have the same variances as \( X \) and \( Y \). They are, therefore, conservative in the sense that they tend to oversmooth the surface.

You can specify the BWM= option to adjust the aforementioned bandwidths to provide the appropriate amount of smoothing for your application.

### ODS Table Names

PROC KDE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

<table>
<thead>
<tr>
<th>ODS Table Name</th>
<th>Description</th>
<th>Statement</th>

</table>

### ODS Graphics (Experimental)

This section describes the use of ODS for creating graphics with the KDE procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the following options. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

**Bivariate Plots**

You can specify the PLOTS= option in the BIVAR statement to request graphical displays of bivariate kernel density estimates.
PLOTS= option1 < option2 ... >
requests one or more plots of the bivariate kernel density estimate. The following table shows the available plot options.

<table>
<thead>
<tr>
<th>Option</th>
<th>Plot Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ALL</td>
<td>all available displays</td>
</tr>
<tr>
<td>CONTOUR</td>
<td>contour plot of bivariate density estimate</td>
</tr>
<tr>
<td>CONTOURSCATTER</td>
<td>contour plot of bivariate density estimate overlaid with scatter plot of data</td>
</tr>
<tr>
<td>HISTOGRAM</td>
<td>bivariate histogram of data</td>
</tr>
<tr>
<td>HISTSURFACE</td>
<td>bivariate histogram overlaid with bivariate kernel density estimate</td>
</tr>
<tr>
<td>SCATTER</td>
<td>scatter plot of data</td>
</tr>
<tr>
<td>SURFACE</td>
<td>surface plot of bivariate kernel density estimate</td>
</tr>
</tbody>
</table>

By default, if you enable ODS graphics and you do not specify the PLOTS= option, then the BIVAR statement creates a contour plot. If you specify the PLOTS= option, you get only the requested plots.

Univariate Plots

You can specify the PLOTS= option in the UNIVAR statement to request graphical displays of univariate kernel density estimates.

PLOTS= option1 < option2 ... >
requests one or more plots of the univariate kernel density estimate. The following table shows the available plot options.

<table>
<thead>
<tr>
<th>Option</th>
<th>Plot Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>DENSITY</td>
<td>univariate kernel density estimate curve</td>
</tr>
<tr>
<td>HISTDENSITY</td>
<td>univariate histogram of data overlaid with kernel density estimate curve</td>
</tr>
<tr>
<td>HISTOGRAM</td>
<td>univariate histogram of data</td>
</tr>
</tbody>
</table>

By default, if you enable ODS graphics and you do not specify the PLOTS= option, then the UNIVAR statement creates a histogram overlaid with a kernel density estimate. If you specify the PLOTS= option, you get only the requested plots.

ODS Graph Names

PROC KDE assigns a name to each graph it creates using the Output Delivery System (ODS). You can use these names to reference the graphs when using ODS. The names are listed in Table 36.2.
To request these graphs you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 36.2. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

### Binning of Bivariate Histogram

Let \((X_i, Y_i), i = 1, 2, \ldots, n\) be a sample of size \(n\) drawn from a bivariate distribution. For the marginal distribution of \(X_i, i = 1, 2, \ldots, n\), the number of bins \((\text{Nbins}_X)\) in the bivariate histogram is calculated according to the formula

\[
\text{Nbins}_X = \text{ceil} \left( \frac{\text{range}_X}{\text{width}_X} \right)
\]

where \(\text{ceil}(x)\) denotes the smallest integer greater than or equal to \(x\),

\[
\text{range}_X = \max_{1 \leq i \leq n} (X_i) - \min_{1 \leq i \leq n} (X_i)
\]

and the optimal bin width is obtained, following Scott (1992, p. 84), as

\[
\text{width}_X = 3.504 \hat{\sigma}_X (1 - \hat{\rho}^2)^{3/8} n^{-1/4}
\]

Here, \(\hat{\sigma}_X\) and \(\hat{\rho}\) are the sample variance and the sample correlation coefficient, respectively. When you specify a WEIGHT variable, PROC KDE uses weighted versions of \(\hat{\sigma}_X\) and \(\hat{\rho}\) in the preceding expressions.

Similar formulas are used to compute the number of bins for the marginal distribution of \(Y_i, i = 1, 2, \ldots, n\). Further details can be found in Scott (1992).

Notice that if \(|\hat{\rho}| > 0.99\), then \(\text{Nbins}_X\) is calculated as in the univariate case (see Terrell and Scott 1985). In this case \(\text{Nbins}_Y = \text{Nbins}_X\).
Examples

Example 36.1. Computing a Basic Kernel Density Estimate

The following example illustrates the basic functionality of the UNIVAR statement. The effective channel length (in microns) is measured for 1225 field effect transistors. The channel lengths are saved as values of the variable length in a SAS data set named channel; refer to the file kdex2.sas in the SAS Sample Library.

```
data channel;
   input length @@;
datalines;
0.91 1.01 0.95 1.13 1.12 0.86 0.96 1.17 1.36 1.10
0.98 1.27 1.13 0.92 1.15 1.26 1.14 0.88 1.03 1.00
0.98 0.94 1.09 0.92 1.10 0.95 1.10 0.95 1.10 1.15
...
1.80 2.35 2.23 1.96 2.16 2.08 2.06 2.03 2.18 1.83
2.13 2.05 1.90 2.07 2.15 1.96 2.15 1.89 2.15 2.04
1.95 1.93 2.22 1.74 1.91
;
```

The following statements request a kernel density estimate of the variable length.

```
ods html;
ods graphics on;
proc kde data=channel;
   univar length;
run;
ods graphics off;
ods html close;
```

You can see a histogram with an overlaid kernel density estimate in Output 36.1.1. This graph is requested by specifying the experimental ODS GRAPHICS statement prior to the PROC KDE statements. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the KDE procedure, see the “ODS Graphics” section on page 2009.
Output 36.1.1. Histogram with Overlaid Kernel Density Estimate (Experimental)

The default output tables for this analysis are the “Inputs” and the “Controls” tables.

### Inputs

<table>
<thead>
<tr>
<th>Data Set</th>
<th>WORK.CHANNEL</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of Observations Used</td>
<td>1225</td>
</tr>
<tr>
<td>Variable</td>
<td>length</td>
</tr>
<tr>
<td>Bandwidth Method</td>
<td>Sheather-Jones Plug In</td>
</tr>
</tbody>
</table>

The “Inputs” table lists basic information about the density fit, including the input data set, the number of observations, the variable used, and the bandwidth method. The default bandwidth method is the Sheather-Jones plug-in.

### Controls

<table>
<thead>
<tr>
<th>length</th>
</tr>
</thead>
<tbody>
<tr>
<td>Grid Points</td>
</tr>
<tr>
<td>Lower Grid Limit</td>
</tr>
<tr>
<td>Upper Grid Limit</td>
</tr>
<tr>
<td>Bandwidth Multiplier</td>
</tr>
</tbody>
</table>

The “Controls” table lists the grid points, lower and upper grid limits, and bandwidth multiplier for the density estimation.
The “Controls” table lists the primary numbers controlling the kernel density fit. Here the default number of grid points is used and no adjustment is made to the default bandwidth.

**Example 36.2. Changing the Bandwidth**

Continuing with the previous example, you can specify different bandwidth multipliers that determine the smoothness of the kernel density estimate. The following statements show kernel density estimates for the variable length by specifying two different bandwidth multipliers with the BWM= option. Output 36.2.1 shows an oversmoothed estimate because the bandwidth multiplier is 2. Output 36.2.2 is created by specifying BWM=0.25, so it is an undersmoothed estimate.

```sas
ods html;
ods graphics on;

proc kde data=channel;
   univar length(bwm=2) length(bwm=0.25);
run;
ods graphics off;
ods html close;
```

**Output 36.2.1.** Histogram with Oversmoothed Kernel Density Estimate (Experimental)
Example 36.3. Changing the Bandwidth (Bivariate)

Recall the analysis from the “Getting Started” section on page 1993. Suppose that you would like a slightly smoother estimate. You could then rerun the analysis with a larger bandwidth:

```plaintext
ods html;
ods graphics on;
proc kde data=bivnormal;
  bivar x y / bwm=2;
run;
```

```plaintext
ods graphics off;
ods html close;
```

The BWM= option requests bandwidth multipliers of 2 for both x and y. By specifying the experimental ODS GRAPHICS statement you can visualize the results of this fit immediately in a contour plot, as shown in Output 36.3.1.
Multiple Bandwidths

You can also specify multiple bandwidths with only one run of the KDE procedure. Notice that by specifying pairs of variables inside parentheses, a kernel density estimate is computed for each pair. In the following statements the first kernel density is computed with the default bandwidth, but the second specifies a bandwidth multiplier of 0.5 for the variable x and a multiplier of 2 for the variable y. The effect of the latter options is shown in Output 36.3.2.

```plaintext
ods html;
ods graphics on;

proc kde data=bivnormal;
   bivar (x y)
      (x (bwm=0.5) y (bwm=2));
run;

ods graphics off;
ods html close;
```
Example 36.4. Requesting Additional Output Tables

The following example illustrates how to request output tables with summary statistics in addition to the default output tables.

Using the same data as in the “Getting Started” section on page 1993, the following statements request univariate and bivariate summary statistics, percentiles, and levels of the kernel density estimate.

```sas
proc kde data=bivnormal;
  bivar x y / bivstats levels percentiles unistats;
run;
```

<table>
<thead>
<tr>
<th>The KDE Procedure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Univariate Statistics</td>
</tr>
<tr>
<td>x</td>
</tr>
<tr>
<td>Mean</td>
</tr>
<tr>
<td>Variance</td>
</tr>
<tr>
<td>Standard Deviation</td>
</tr>
<tr>
<td>Range</td>
</tr>
<tr>
<td>Interquartile Range</td>
</tr>
<tr>
<td>Bandwidth</td>
</tr>
</tbody>
</table>
The “Univariate Statistics” table contains standard univariate statistics for each variable, as well as statistics associated with the density estimate. Note that the estimated variances for both $x$ and $y$ are fairly close to the true values of 10.

<table>
<thead>
<tr>
<th>Bivariate Statistics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Covariance</td>
</tr>
<tr>
<td>Correlation</td>
</tr>
</tbody>
</table>

The “Bivariate Statistics” table lists the covariance and correlation between the two variables. Note that the estimated correlation is equal to its true value to two decimal places.

<table>
<thead>
<tr>
<th>Percentiles</th>
</tr>
</thead>
<tbody>
<tr>
<td>$x$</td>
</tr>
<tr>
<td>0.5</td>
</tr>
<tr>
<td>1.0</td>
</tr>
<tr>
<td>2.5</td>
</tr>
<tr>
<td>5.0</td>
</tr>
<tr>
<td>10.0</td>
</tr>
<tr>
<td>25.0</td>
</tr>
<tr>
<td>50.0</td>
</tr>
<tr>
<td>75.0</td>
</tr>
<tr>
<td>90.0</td>
</tr>
<tr>
<td>95.0</td>
</tr>
<tr>
<td>97.5</td>
</tr>
<tr>
<td>99.0</td>
</tr>
<tr>
<td>99.5</td>
</tr>
</tbody>
</table>

The “Percentiles” table lists percentiles for each variable.

<table>
<thead>
<tr>
<th>Levels</th>
</tr>
</thead>
<tbody>
<tr>
<td>Percent</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>5</td>
</tr>
<tr>
<td>10</td>
</tr>
<tr>
<td>50</td>
</tr>
<tr>
<td>90</td>
</tr>
<tr>
<td>95</td>
</tr>
<tr>
<td>99</td>
</tr>
<tr>
<td>100</td>
</tr>
</tbody>
</table>

The “Levels” table lists contours of the density corresponding to percentiles of the bivariate data, and the minimum and maximum values of each variable on those contours. For example, 5% of the observed data have a density value less than 0.0030. The minimum $x$ and $y$ values on this contour are $-7.10$ and $-7.14$, respectively (the
Lower for x and Lower for y columns), and the maximum values are 7.07 and 6.77, respectively (the Upper for x and Upper for y columns).

You can also request “Percentiles” or “Levels” tables with specific percentiles. For example,

```sas
proc kde data=bivnormal;
    bivar x y / levels=2.5, 50, 97.5
    percentiles=2.5, 25, 50, 75, 97.5;
run;
```

The KDE Procedure

<table>
<thead>
<tr>
<th>Percentiles</th>
<th>x</th>
<th>y</th>
</tr>
</thead>
<tbody>
<tr>
<td>2.5</td>
<td>-6.17</td>
<td>-6.31</td>
</tr>
<tr>
<td>25.0</td>
<td>-2.24</td>
<td>-2.30</td>
</tr>
<tr>
<td>50.0</td>
<td>-0.11</td>
<td>-0.058</td>
</tr>
<tr>
<td>75.0</td>
<td>2.22</td>
<td>2.21</td>
</tr>
<tr>
<td>97.5</td>
<td>6.03</td>
<td>5.94</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

**Example 36.5. Using Output Data Set to Produce Graphics**

You can create a SAS data set containing the kernel density estimate by specifying the OUT= option. Using the same 1000 simulated observations from a bivariate normal density as in the “Getting Started” section on page 1993, you can specify

```sas
proc kde data=bivnormal;
    bivar x y / levels out=MyOut;
run;
```

The output data set MyOut from this analysis contains 3600 points containing the kernel density estimate. The variables value1 and value2 of this data set contain the grid values of the x and y variables, respectively. The variable density is the kernel density estimate. You can generate surface and contour plots of this estimate using SAS/GRAPH as follows:
Chapter 36. The KDE Procedure

```sas
proc g3d data=MyOut;
    plot value2*value1=density;
run;

proc gcontour data=MyOut;
    plot value2*value1=density;
run;
```

Output 36.5.1 and Output 36.5.2 display these plots.

**Output 36.5.1.** Surface Plot of the Bivariate Kernel Density Estimate
Output 36.5.2. Contour Plot of the Bivariate Kernel Density Estimate

The “Levels” table lists contours of the density corresponding to percentiles of the bivariate data, and the minimum and maximum values of each variable on those contours. For example, 5% of the observed data have a density value less than 0.0030. You can use the results from the “Levels” table to plot specific contours corresponding to percentiles of the data. You can use the values from the Density column of this table with PROC GCONTOUR to plot the 1, 5, 10, 50, 90, 95, and 99 percent levels of the density; this plot is displayed in Output 36.5.3.

```plaintext
proc gcontour data=MyOut;
  plot value2*value1=density / levels=0.0012 0.0030 0.0050 0.0159
          0.0239 0.0253 0.0261;
run;
```
**Output 36.5.3.** Contour Plot of the Bivariate Kernel Density Estimate with Levels Corresponding to Percentiles

The next-to-outermost contour of Output 36.5.3 represents an approximate 95% ellipsoid for x and y.

**Example 36.6. Univariate KDE Graphics (Experimental)**

This a continuation of Example 36.1, used here to illustrate the experimental ODS graphics. The following statements request the available univariate plots in PROC KDE.

``` Sas
ods html;
ods graphics on;

proc kde data=channel;
   univar length / plots=density histogram histdensity;
run;

ods graphics off;
ods html close;
```
Output 36.6.1. Histogram (Experimental)

Output 36.6.2. Kernel Density Estimate (Experimental)
Output 36.6.3. Histogram with Overlaid Kernel Density Estimate (Experimental)

Output 36.6.1, Output 36.6.2, and Output 36.6.3 show a histogram, a kernel density estimate, and a histogram with an overlaid kernel density estimate, respectively. These graphical displays are requested by specifying the experimental ODS GRAPHICS statement and the experimental PLOTS= option in the UNIVAR statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the KDE procedure, see the “ODS Graphics” section on page 2009.

Example 36.7. Bivariate KDE Graphics (Experimental)

This example illustrates the available bivariate graphics in PROC KDE. The octane dataset comes from Rodriguez and Taniguchi (1980), where it is used for predicting customer octane satisfaction using trained-rater observations. The variables in this data set are Rater and Customer. Either variable may have missing values. Refer to the file kdex3.sas in the SAS Sample Library.

```
data octane;
  input Rater Customer;
  label Rater = 'Rater'
  Customer = 'Customer';
datalines;
94.5 92.0
94.0 88.0
94.0 90.0
...```
The following statements request all the available bivariate plots in PROC KDE.

```sas
ods html;
ods graphics on;
proc kde data=octane;
   bivar Rater Customer / plots=all;
run;
ods graphics off;
ods html close;
```

Output 36.7.1 shows a scatter plot of the data, Output 36.7.2 shows a bivariate histogram of the data, Output 36.7.3 shows a contour plot of bivariate density estimate, Output 36.7.4 shows a contour plot of bivariate density estimate overlaid with a scatter plot of data, Output 36.7.5 shows a surface plot of bivariate kernel density estimate, and Output 36.7.6 shows a bivariate histogram overlaid with a bivariate kernel density estimate. These graphical displays are requested by specifying the experimental ODS GRAPHICS statement and the experimental PLOTS= option in the BIVAR statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the KDE procedure, see the “ODS Graphics” section on page 2009.
Output 36.7.1. Scatter Plot (Experimental)

Output 36.7.2. Bivariate Histogram (Experimental)

Chapter 37
The KRIGE2D Procedure

Overview

The KRIGE2D procedure performs ordinary kriging in two dimensions. PROC KRIGE2D can handle anisotropic and nested semivariogram models. Four semivariogram models are supported: the Gaussian, exponential, spherical, and power models. A single nugget effect is also supported.

You can specify the locations of kriging estimates in a GRID statement, or they can be read from a SAS data set. The grid specification is most suitable for a regular grid; the data set specification can handle any irregular pattern of points.

Local kriging is supported through the specification of a radius around a grid point or the specification of the number of nearest neighbors to use in the kriging system. When you perform local kriging, a separate kriging system is solved at each grid point using a neighborhood of the data point established by the radius or number specification.

The KRIGE2D procedure writes the kriging estimates and associated standard errors for each grid to an output data set. When you perform local kriging, PROC KRIGE2D writes the neighborhood information for each grid point to an additional, optional data set. The KRIGE2D procedure does not produce any displayed output.

Introduction to Spatial Prediction

Spatial prediction, in general, is any prediction method that incorporates spatial dependence. A simple and popular spatial prediction method is ordinary kriging.

Ordinary kriging requires a model of the spatial continuity, or dependence. This is typically in the form of a covariance or semivariogram.

Spatial prediction, then, involves two steps. First, you model the covariance or semivariogram of the spatial process. This involves choosing both a mathematical form and the values of the associated parameters. Second, you use this dependence model in solving the kriging system at a specified set of spatial points, resulting in predicted values and associated standard errors.

The KRIGE2D procedure performs the second of these steps using ordinary kriging of two-dimensional data.
Chapter 37. The KRIGE2D Procedure

Getting Started

Spatial Prediction Using Kriging, Contour Plots

After an appropriate variogram model is chosen, there are a number of choices involved in producing the kriging surface. In order to illustrate these choices, the variogram model in the section “Getting Started” on page 4852 section of Chapter 80, “The VARIOGRAM Procedure,” is used. This model is Gaussian,

\[ \gamma_z(h) = c_0 \left[ 1 - \exp \left( -\frac{h^2}{a_0^2} \right) \right] \]

with a scale of \( c_0 = 7.5 \) and a range of \( a_0 = 30 \).

The first choice is whether to use local or global kriging. Local kriging uses only data points in the neighborhood of a grid point; global kriging uses all data points.

The most important consideration in this decision is the spatial covariance structure. Global kriging is appropriate when the correlation range \( \epsilon \) is approximately equal to the length of the spatial domain. The correlation range \( \epsilon \) is the distance \( r_\epsilon \) at which the covariance is 5% of its value at zero. That is,

\[ C_Z(r_\epsilon) = 0.05C_Z(0) \]

For a Gaussian model, \( r_\epsilon \) is \( \sqrt{3a_0} \approx 52 \) (thousand ft). The data points are scattered uniformly throughout a 100 \( \times \) 100 (10^6 ft^2) area. Hence, the linear dimension of the data is nearly double the \( \epsilon \) range. This indicates that local kriging rather than global kriging is appropriate.

Local kriging is performed by using only data points within a specified radius of each grid point. In this example, a radius of 60 (thousand ft) is used. Other choices involved in local kriging are the minimum and maximum number of data points in each neighborhood (around a grid point). The minimum number is left at the default value of 20; the maximum number defaults to all observations in the data set.

The last step in contouring the data is to decide on the grid point locations. A convenient area that encompasses all the data points is a square of length 100 (thousand ft). The spacing of the grid points depends on the use of the contouring; a spacing of five distance units (thousand ft) is chosen for plotting purposes.

The following SAS code inputs the data and computes the kriged surface using these parameter and grid choices. The kriged surface is plotted in Figure 37.1, and the associated standard errors are plotted in Figure 37.2. The standard errors are smaller where more data are available.

The following statements are available in PROC KRIGE2D.

```
PROC KRIGE2D options;
  COORDINATES | COORD coordinate-variables;
  GRID grid-options;
  PREDICT | PRED | P predict-options;
  MODEL model-options;
```

The PREDICT and MODEL statements are hierarchical; the PREDICT statement is followed by one or more MODEL statements. All the MODEL statements following a PREDICT statement use the variable and neighborhood specifications in that PREDICT statement.

You must specify at least one PREDICT statement and one MODEL statement. You must supply a single COORDINATES statement to identify the $x$ and $y$ coordinate variables in the input data set. You must also specify a single GRID statement to include the grid information.
The following table outlines the options available in PROC KRIGE2D classified by function.

**Table 37.1. Options Available in the KRIGE2D Procedure**

**PROC KRIGE2D Statement**

```sas
PROC KRIGE2D options;
```

You can specify the following options in the PROC KRIGE2D statement.

**DATA=SAS-data-set**

specifies a SAS data set containing the *x* and *y* coordinate variables and the VAR= variables in the PREDICT statement.
OUTEST=SAS-data-set
OUTE=SAS-data-set
specifies a SAS data set in which to store the kriging estimates, standard errors and grid location. For details, see the section “OUTEST=SAS-data-set” on page 2060.

OUTNBHD=SAS-data-set
OUTN=SAS-data-set
specifies a SAS data set in which to store the neighborhood information for each grid point. Information is written to this data set only if one or more PREDICT statements have options specifying local kriging. For details, see the section “OUTNBHD=SAS-data-set” on page 2060.

SINGULARMSG=number
SMSG=number
controls the number of warning messages displayed for a singular matrix. When local kriging is performed, a separate kriging system is solved for each grid point. Anytime a singular matrix is encountered, a warning message is displayed up to a total of SINGULARMSG=\(n\) times. The default is SINGULARMSG=10.

COORDINATES Statement

COORDINATES | COORD  coordinate-variables ;

The following two options specify the names of the variables in the DATA= data set containing the values of the \(x\) and \(y\) coordinates of the data.

Only one COORDINATES statement is allowed, and it is applied to all PREDICT statements. In other words, it is assumed that all the VAR= variables in all PREDICT statements have the same \(x\) and \(y\) coordinates.

This is not a limitation. Since each VAR= variable is processed separately, observations for which the current VAR= variable is missing are excluded. With the next VAR= variable, the entire data are read again, this time excluding missing values in this next variable. Hence, a single run of PROC KRIGE2D can be used for variables measured at different locations without overlap.

XCOORD= (variable-name)
XC= (variable-name)
specifies the name of the variable containing the \(x\) coordinate of the data locations in the DATA= data set.

YCOORD= (variable-name)
YC= (variable-name)
specifies the name of the variable containing the \(y\) coordinate of the data locations in the DATA= data set.
GRID Statement

GRID grid-options;

You can use the following options to specify the grid of spatial locations for the kriging estimates. The grid specification is applied to all PREDICT and MODEL statements.

There are two basic methods for specifying the grid. You can specify the $x$ and $y$ coordinates explicitly, or they can be read from a SAS data set. The options for the explicit specification of grid locations are as follows.

- **X=number**
  - $X=x_1, \ldots, x_m$
  - $X=x_1 \text{ to } x_m$
  - $X=x_1 \text{ to } x_m \text{ by } \delta x$

  specifies the $x$ coordinate of the grid locations.

- **Y=number**
  - $Y=y_1, \ldots, y_m$
  - $Y=y_1 \text{ to } y_m$
  - $Y=y_1 \text{ to } y_m \text{ by } \delta y$

  specifies the $y$ coordinate of the grid locations.

For example, the following two GRID statements are equivalent.

```
grid x=1,2,3,4,5 y=0,2,4,6,8,10;
grid x=1 to 5 y=0 to 10 by 2;
```

To specify grid locations from a SAS data set, you must give the name of the data set and the variables containing the values of the $x$ and $y$ coordinates.

- **GRIDDATA=SAS-data-set**
  - GRIDGEATA=SAS-data-set
    - specifies a SAS data set containing the $x$ and $y$ grid coordinates.

- **XCOORD= (variable-name)**
  - XCOORD= (variable-name)
    - specifies the name of the variable containing the $x$ coordinate of the grid locations in the GRIDDATA= data set.

- **YCOORD= (variable-name)**
  - YCOORD= (variable-name)
    - specifies the name of the variable containing the $y$ coordinate of the grid locations in the GRIDDATA= data set.
PREDICT Statement

PREDICT | PRED | P predict-options ;

You can specify the following options in a PREDICT statement.

**MAXPOINTS=** number
**MAXPOINTS=** number
**MAXP=** number

specifies the maximum number of data points in a neighborhood. You specify this option in conjunction with the RADIUS= option. When the number of data points in the neighborhood formed at a given grid point by the RADIUS= option is greater than the MAXPOINTS= value, the RADIUS= value is decreased just enough to honor the MAXPOINTS= value unless you specify the NODECREMENT option.

**MINPOINTS=** number
**MINP=** number
**MIN=** number

specifies the minimum number of data points in a neighborhood. You specify this option in conjunction with the RADIUS= option. When the number of data points in the neighborhood formed at a given grid point by the RADIUS= option is less than the MINPOINTS= value, the RADIUS= value is increased just enough to honor the MINPOINTS= value unless you specify the NOINCREMENT option. The default is MINPOINTS=20. If enough data are available, this value should be increased to 30 to improve estimation.

**NODECREMENT | NODECR**
requests that the RADIUS= value not be decremented when the MAX= value is exceeded at a grid point. This option is relevant only when you specify both a RADIUS= value and a MAXPOINTS= value. In this case, when the number of points in the neighborhood constructed from the RADIUS= specification is greater than the MAXPOINTS= value, the RADIUS= value is decremented enough to honor the MAXPOINTS= value, and the kriging system is solved for this grid point. If you specify the NODECREMENT option, no decrementing is done, estimation is skipped at this grid point, and a message is written to the log.

**NOINCREMENT | NOINCR**
requests that the RADIUS= value not be incremented when the MIN= value is not met at a grid point. This option is relevant only when you specify both a RADIUS= value and a MINPOINTS= number. In this case, when the number of points in the neighborhood constructed from the RADIUS= specification is less than the MINPOINTS= value, the RADIUS= value is incremented enough to honor the MINPOINTS= value, and the kriging system is solved for this grid point. If you specify the NOINCREMENT option, no incrementing is done, estimation is skipped at this grid point, and a message is written to the log.

**NUMPOINTS=** number
**NPOINTS=** number
**NPTS=** number
**NP=** number
specifies the exact size of a neighborhood. This option is incompatible with all other PREDICT statement options controlling the neighborhood; it must appear by itself.

`RADIUS=number`

`R=number`

specifies the radius to use in a local kriging regression. When you specify this option, a separate kriging system is solved at each grid point by finding the neighborhood of this grid point consisting of all data points within the distance specified by the `RADIUS=` value. See the `MAXPOINTS=` and `MINPOINTS=` options for additional control on the neighborhood.

`VAR= variable-name`

specifies the single numeric variable used in the kriging system.

---

**MODEL Statement**

```plaintext
MODEL model-options;
```

You can use the following options to specify a semivariogram or covariance model. The specified model is used in the kriging system defined by the most previous PREDICT statement.

There are two ways to specify a semivariogram or covariance model. In the first method, you specify the required parameters SCALE, RANGE, and FORM, and possibly the optional parameters NUGGET, ANGLE, and RATIO, explicitly in the MODEL statement.

In the second method, you specify an MDATA= data set. This data set contains variables corresponding to the required SCALE, RANGE, and FORM parameters, and, optionally, variables for the NUGGET, ANGLE, and RATIO parameters.

The two methods are exclusive; either you specify all parameters explicitly, or they all are read from the MDATA= data set.

`ANGLE=angle`

`ANGLE=(angle1,. . . ,anglek)`

specifies the angle of the major axis for anisotropic models, measured in degrees clockwise from the N-S axis. In the case of a nested semivariogram model, you can specify an angle for each nesting. The default is ANGLE=0.

`FORM=SPHERICAL | EXPONENTIAL | GAUSSIAN | POWER`

`FORM=SPH | EXP | GAUSS | PW`

specifies the functional form of the semivariogram model. All the supported models are two-parameter models (SCALE= and RANGE=). A FORM= value is required; in the case of a nested semivariogram model, you must specify a form for each nesting.

See the section “Theoretical Semivariogram Models” beginning on page 2045 for details on how the FORM= forms are determined.
**MDATA=SAS-data-set**

specifies the input data set that contains parameter values for the covariance or semivariogram model. The MDATA= data set must contain variables named SCALE, RANGE, and FORM, and it can optionally contain variables NUGGET, ANGLE, and RATIO.

The FORM variable must be a character variable, assuming only the values allowed in the explicit FORM= syntax described previously. The RANGE and SCALE variables must be numeric. The optional variables ANGLE, RATIO, and NUGGET must also be numeric if present.

The number of observations present in the MDATA= data set corresponds to the level of nesting of the semivariogram model. For example, to specify a nonnested model using a spherical covariance, an MDATA= data set might look like

```snippet
data md1;
  input scale range form $;
  datalines;
  25 10 SPH
run;
```

The PROC KRIGE2D statement to use the MDATA= specification is of the form

```snippet
proc krige2d data=...;
  pred var=....;
  model mdata=md1;
run;
```

This is equivalent to the following explicit specification of the covariance model parameters:

```snippet
proc krige2d data=...;
  pred var=....;
  model scale=25 range=10 form=sph;
run;
```

The following MDATA= data set is an example of an anisotropic nested model:

```snippet
data md1;
  input scale range form $ nugget angle ratio;
  datalines;
  20 8 S 5 35 0.7
  12 3 G 5 0 0.8
  4 1 G 5 45 0.5
; 
```

This is equivalent to the following explicit specification of the covariance model parameters:
This example is somewhat artificial in that it is usually hard to detect different anisotropy directions and ratios for different nestings using an experimental semivariogram. Note that the NUGGET value is the same for all nestings. This is always the case; the nugget effect is a single additive term for all models. For further details, see the section “Theoretical and Computational Details of the Semivariogram” on page 4872 in the chapter on the VARIOGRAM procedure.

**NUGGET=number**

specifies the nugget effect for the model. The nugget effect is due to a discontinuity in the semivariogram as determined by plotting the sample semivariogram (see the chapter on the VARIOGRAM procedure for details). For models without any nugget effect, this option is left out; the default is NUGGET=0.

**RANGE=range**

specifies the range parameter in semivariogram models. In the case of a nested semivariogram model, you must specify a range for each nesting.

The range parameter is the divisor in the exponent in all supported models except the power model. It has the units of distance or distance squared for these models, and it is related to the correlation scale for the underlying spatial process. See the section “Theoretical Semivariogram Models” beginning on page 2045 for details on how the RANGE= values are determined.

**RATIO=ratio**

specifies the ratio of the length of the minor axis to the length of the major axis for anisotropic models. The value of the RATIO= option must be between 0 and 1. In the case of a nested semivariogram model, you can specify a ratio for each nesting. The default is RATIO=1.

**SCALE=scale**

specifies the scale parameter in semivariogram models. In the case of a nested semivariogram model, you must specify a scale for each nesting.

The scale parameter is the multiplicative factor in all supported models; it has the same units as the variance of the VAR= variable in the preceding PREDICT statement. See the section “Theoretical Semivariogram Models” beginning on page 2045 for details on how the SCALE= values are determined.

**SINGULAR=number**

gives the singularity criteria for solving kriging systems. The larger the value of the SINGULAR= option, the easier it is for a kriging system to be declared singular.
The default is SINGULAR=1E-7. See the section “Details of Ordinary Kriging” beginning on page 2056 for more detailed information.

Details

Theoretical Semivariogram Models

PROC VARIOGRAM computes the sample, or experimental semivariogram. Prediction of the spatial process at unsampled locations by techniques such as ordinary kriging requires a theoretical semivariogram or covariance.

When you use PROC VARIOGRAM and PROC KRIGE2D to perform spatial prediction, you must determine a suitable theoretical semivariogram based on the sample semivariogram. While there are various methods of fitting semivariogram models, such as least squares, maximum likelihood, and robust methods (Cressie 1993, section 2.6), these techniques are not appropriate for data sets resulting in a small number of variogram points. Instead, a visual fit of the variogram points to a few standard models is often satisfactory. Even when there are sufficient variogram points, a visual check against a fitted theoretical model is appropriate (Hohn 1988, p. 25ff).

In some cases, a plot of the experimental semivariogram suggests that a single theoretical model is inadequate. Nested models, anisotropic models, and the nugget effect increase the scope of theoretical models available. All of these concepts are discussed in this section. The specification of the final theoretical model is provided by the syntax of PROC KRIGE2D.

Note the general flow of investigation. After a suitable choice is made of the LAGDIST= and MAXLAG= options and, possibly, the NDIR= option (or a DIRECTIONS statement), the experimental semivariogram is computed. Potential theoretical models, possibly incorporating nesting, anisotropy, and the nugget effect, are computed by a DATA step, then they are plotted against the experimental semivariogram and evaluated. A suitable theoretical model is thus found visually, and the specification of the model is used in PROC KRIGE2D. This flow is illustrated in Figure 37.3; also see the “Getting Started” section on page 4852 in the chapter on the VARIOGRAM procedure for an illustration in a simple case.
The Spherical Semivariogram Model

The form of the spherical model is

\[
\gamma_z(h) = \begin{cases} 
  c_0 \left[ \frac{3}{2} \frac{h}{a_0} - \frac{1}{2} \left( \frac{h}{a_0} \right)^3 \right], & \text{for } h \leq a_0 \\
  c_0, & \text{for } h > a_0 
\end{cases}
\]

The shape is displayed in Figure 37.4 using range \(a_0 = 1\) and scale \(c_0 = 4\).
Figure 37.4. Spherical Semivariogram Model with Parameters $a_0 = 1$ and $c_0 = 4$

The vertical line at $h = 1$ is the “effective range” as defined by Duetsch and Journel (1992), or the “range $\epsilon$” defined by Christakos (1992). This quantity, denoted $r_\epsilon$, is the $h$-value where the covariance is approximately zero. For the spherical model, it is exactly zero; for the Gaussian and exponential models, the definition of $r_\epsilon$ is modified slightly.

The horizontal line at 4.0 variance units (corresponding to $c_0 = 4$) is called the “sill.” In the case of the spherical model, $\gamma_z(h)$ actually reaches this value. For the other two model forms, the sill is a horizontal asymptote.

**The Gaussian Semivariogram Model**

The form of the Gaussian model is

$$\gamma_z(h) = c_0 \left[ 1 - \exp \left( -\frac{h^2}{a_0^2} \right) \right]$$

The shape is displayed in Figure 37.5 using range $a_0 = 1$ and scale $c_0 = 4$. 
The vertical line at $h = r_ε = \sqrt{3}$ is the effective range, or the range $ε$ (that is, the $h$-value where the covariance is approximately 5% of its value at zero).

The horizontal line at 4.0 variance units (corresponding to $c_0 = 4$) is the sill; $\gamma_z(h)$ approaches the sill asymptotically.

**The Exponential Semivariogram Model**

The form of the exponential model is

$$\gamma_z(h) = c_0 \left[ 1 - \exp\left( -\frac{h}{a_0} \right) \right]$$

The shape is displayed in Figure 37.6 using range $a_0 = 1$ and scale $c_0 = 4$. 
The vertical line at $h = r_\epsilon = 3$ is the effective range, or the range $\epsilon$ (that is, the $h$-value where the covariance is approximately 5% of its value at zero).

The horizontal line at 4.0 variance units (corresponding to $c_0 = 4$) is the sill, as in the other model forms.

It is noted from Figure 37.5 and Figure 37.6 that the major distinguishing feature of the Gaussian and exponential forms is the shape in the neighborhood of the origin $h = 0$. In general, small lags are important in determining an appropriate theoretical form based on a sample semivariogram.

**The Power Semivariogram Model**

The form of the power model is

$$\gamma_z(h) = c_0 h^{a_0}$$

For this model, the parameter $a_0$ is a dimensionless quantity, with typical values $0 < a_0 < 2$. Note that the value of $a_0 = 1$ yields a straight line. The parameter $c_0$ has dimensions of the variance, as in the other models. There is no sill for the power model. The shape of the power model with $a_0 = 0.4$ and $c_0 = 4$ is displayed in Figure 37.7.
Nested Models

For a given set of spatial data, a plot of an experimental semivariogram may not seem to fit any one of the theoretical models. In such a case, the covariance structure of the spatial process may be a sum of two or more covariances. This is common in geologic applications where there are correlations at different length scales. At small lag distances \( h \), the smaller scale correlations dominate, while the large scale correlations dominate at larger lag distances.

As an illustration, consider two semivariogram models, an exponential and a spherical.

\[
\gamma_{z,1}(h) = c_{0,1} \exp\left(-\frac{h}{a_{0,1}}\right)
\]

and

\[
\gamma_{z,2}(h) = \begin{cases} 
    c_{0,2} \left[ \frac{3}{2} \frac{h}{a_{0,2}} - \frac{1}{2} \left( \frac{h}{a_{0,2}} \right)^3 \right], & \text{for } h \leq a_{0,2} \\
    c_{0,2}, & \text{for } h > a_{0,2}
\end{cases}
\]

with \( c_{0,1} = 1, a_{0,1} = 2.5, c_{0,2} = 2, \) and \( a_{0,2} = 1 \). If both of these correlation structures are present in a spatial process \( \{ Z(r), r \in D \} \), then a plot of the experimental semivariogram would resemble the sum of these two semivariograms. This is illustrated in Figure 37.8.
The Nugget Effect

**Figure 37.8.** Sum of Exponential and Spherical Structures at Different Scales

This sum of $\gamma_1(h)$ and $\gamma_2(h)$ in Figure 37.8 does not resemble any single theoretical semivariogram; however, the shape at $h = 1$ is similar to a spherical. The asymptotic approach to a sill at three variance units, along with the shape around $h = 0$, indicates an exponential structure. Note that the sill value is the sum of the individual sills $c_{0,1} = 1$ and $c_{0,2} = 2$.

Refer to Hohn (1988, p. 38ff) for further examples of nested correlation structures.

The Nugget Effect

For all the variogram models considered previously, the following property holds:

$$\gamma_z(0) = \lim_{h \to 0} \gamma_z(h) = 0$$

However, a plot of the experimental semivariogram may indicate a discontinuity at $h = 0$; that is, $\gamma_z(h) \to c_n > 0$ as $h \to 0$, while $\gamma_z(0) = 0$. The quantity $c_n$ is called the “nugget effect”; this term is from mining geostatistics where nuggets literally exist, and it represents variations at a much smaller scale than any of the measured pairwise distances, that is, at distances $h \ll h_{\text{min}}$, where

$$h_{\text{min}} = \min_{i,j} h_{ij} = \min_{i,j} | r_i - r_j |$$

There are conceptual and theoretical difficulties associated with a nonzero nugget effect; refer to Cressie (1993, section 2.3.1) and Christakos (1992, section 7.4.3) for...
details. There is no practical difficulty however; you simply visually extrapolate the experimental semivariogram as \( h \to 0 \). The importance of availability of data at small lag distances is again illustrated.

As an example, an exponential semivariogram with a nugget effect \( c_n \) has the form

\[
\gamma_z(h) = c_n + c_0 \left[ 1 - \exp \left( -\frac{h}{a_0} \right) \right], \quad h > 0
\]

and

\[
\gamma_z(0) = 0
\]

This is illustrated in Figure 37.9 for parameters \( a_0 = 1 \), \( c_0 = 4 \), and nugget effect \( c_n = 1.5 \).

You can specify the nugget effect in PROC KRIGE2D with the NUGGET= option in the MODEL statement. It is a separate, additive term independent of direction; that is, it is isotropic. There is a way to approximate an anisotropic nugget effect; this is described in the following section.
Anisotropic Models

In all the theoretical models considered previously, the lag distance \( h \) entered as a scalar value. This implies that the correlation between the spatial process at two point pairs \( P_1, P_2 \) is dependent only on the separation distance \( h = |P_1P_2| \), not on the orientation of the two points. A spatial process \( \{ Z(r), r \in D \} \) with this property is called isotropic, as is the associated covariance or semivariogram.

However, real spatial phenomena often show directional effects. Particularly in geologic applications, measurements along a particular direction may be highly correlated, while the perpendicular direction shows little or no correlation. Such processes are called anisotropic. Refer to Journel and Huijbregts (1978, section III.B.4) for more details.

There are two types of anisotropy. The simplest type occurs when the same covariance form and scale parameter \( c_0 \) is present in all directions but the range \( a_0 \) changes with direction. In this case, there is a single sill, but the semivariogram reaches the sill in a shorter lag distance along a certain direction.

This type of anisotropy is called “geometric” and is discussed in the following section.

**Geometric Anisotropy**

Geometric anisotropy is illustrated in Figure 37.10, where an anisotropic Gaussian semivariogram is plotted. The two curves displayed in this figure are generated using \( a_0 = 1 \) in the NE–SW direction and \( a_0 = 3 \) in the SE–NW direction.

![Figure 37.10. Geometric Anisotropy with Major Axis along E–W Direction](image-url)
As you can see from the figure, the SE–NW curve gets “close” to the sill at approximately $h = 2$, while the NE–SW curve does so at $h = 6$. The ratio of the shorter to longer distance is $\frac{2}{6} = \frac{1}{3}$. This is the value to use in the RATIO= parameter in the MODEL statement in PROC KRIGE2D. Since the longer, or major, axis is in the NE–SW direction, the ANGLE= parameter in the MODEL statement in PROC KRIGE2D should be 45° (all angles are measured clockwise from north).

The terminology associated with geometric anisotropy is that of ellipses. To see how this comes about, consider the following hypothetical set of calculations.

Let \( \{ Z(r), r \in D \} \) be a geometrically anisotropic process, and assume that there are sufficient data points to calculate an experimental semivariogram at a large number of angle classes \( \theta \in \{ 0, \delta \theta, 2 \delta \theta, \ldots, 180^\circ \} \). At each of these angles \( \theta \), the experimental semivariogram is plotted and the effective range \( r_e \) is recorded. A diagram, in polar coordinates, of \( (r_e, \theta) \) yields an ellipse, with the major axis in the direction of the largest \( r_e \) and the minor axis perpendicular. Denote the largest \( r_e \) by \( r_{e\max} \), the smallest by \( r_{e\min} \), and their ratio by

\[
R = \frac{r_{e\min}}{r_{e\max}}
\]

By a rotation, a new set of axes are aligned along the major and minor axis. Then, a rescaling elongates the minor axis so its length equals that of the major axis of the ellipse.

First, the angle \( \theta \) of the major axis of the ellipse (measured clockwise from north) is transformed to standard Cartesian orientation or counter-clockwise from the x-axis (east). Let \( \varphi = 90^\circ - \theta \) denote the transformed angle. The matrix to transform the distance \( h \) is in terms of \( \varphi \) and the ratio \( R \) and it is given by

\[
H = \begin{pmatrix}
\cos(\varphi) & \sin(\varphi) \\
-\sin(\varphi)/R & \cos(\varphi)/R
\end{pmatrix}
\]

For a given point pair \( P_1, P_2 \), with coordinates \( (x_1, y_1), (x_2, y_2) \), the transformed interpair distance is computed by first transforming the components \( \delta x = x_1 - x_2 \) and \( \delta y = y_1 - y_2 \) by

\[
\begin{pmatrix}
\delta x' \\
\delta y'
\end{pmatrix} = H \begin{pmatrix}
\delta x \\
\delta y
\end{pmatrix}
\]

The transformed interpair distance is then

\[
h' = \sqrt{(\delta x')^2 + (\delta y')^2}
\]

The original semivariogram, a function of both \( h \) and \( \theta \), is then transformed to a function only of \( h' \):

\[
\hat{\gamma}(h') = \gamma(h, \theta)
\]
This single semivariogram is then used for kriging purposes.

The interpretation of the major/minor axis in the case of geometric anisotropy is that the direction of the major axis is the direction in which the spatial process \( \{Z(r), r \in D\} \) is most highly correlated; the process is least correlated in the perpendicular direction.

In some cases, these directions are known a priori. This can occur in mining applications where the geology of a region is known in advance. In most cases, however, nothing is known about possible anisotropy. Depending on the amount of data available, using four to six directions is usually sufficient to determine the presence of anisotropy and find the approximate major/minor axis directions.

The most convenient way of performing this is to use the NDIR= option in the COMPUTE statement in PROC VARIOGRAM to obtain a separate experimental semivariogram for each direction. After determining the direction of the major axis, use a DIRECTIONS statement on a subsequent run of PROC VARIOGRAM with this direction and its perpendicular direction. For example, if the initial run of PROC VARIOGRAM with NDIR=6 in the COMPUTE statement indicates that \( \theta = 45^\circ \) is the major axis (has the largest \( r_e \)), then rerun PROC VARIOGRAM with

```
DIRECTIONS 45,135;
```

Then, determine the ratio of \( r_e \) for the minor and major axis for the RATIO= parameter in the COMPUTE statement of PROC KRIGE2D. This ratio is \( \leq 1 \) for modeling geometric anisotropy. In the other type of anisotropy, zonal anisotropy, the RATIO= parameter is set to a large number for reasons explained in the following section.

**Zonal Anisotropy**

In zonal anisotropy, either the form covariance structure or the parameter \( c_0 \) (or both) is different in different directions. In particular, the sill is different for different directions. In geologic applications, this is the more common type of anisotropy. It is not possible to transform such a structure into an isotropic semivariogram.

Instead, nesting and geometric anisotropy are used together to approximate zonal anisotropy. For example, suppose the spatial process has a correlation structure in the N–S direction described by \( \gamma_{z,1} \), a spherical model with sill at \( c_0 = 6 \) and range \( a_0 = 2 \), while in the E–W direction the correlation structure, described by \( \gamma_{z,2} \), is again a spherical model but with sill at \( c_0 = 3 \) and range \( a_0 = 1 \).

You can approximate this structure in PROC KRIGE2D by specifying two nested models with large RATIO= values. In particular, the appropriate MODEL statement is

```
MODEL FORM=(S,S) ANGLE=(0,90) SCALE=(6,3)
RANGE=(2,1) RATIO=(1E8,1E8);
```

The large values of the RATIO= parameter for each nested structure have the effect of an “infinite” range parameter in the direction of the minor axis. Hence, there is no variation in \( \gamma_{z,1} \) in the E–W direction and no variation in \( \gamma_{z,2} \) in the N–S direction.
Anisotropic Nugget Effect

Note that an isotropic nugget effect can be approximated by using nested models, with one of the nested models having a small range. Applying a geometric anisotropy specification to this nested structure results in an anisotropic nugget effect.

Details of Ordinary Kriging

Introduction

There are three common characteristics often observed with spatial data (that is, data indexed by their spatial locations).

(i) slowly varying, large-scale variations in the measured values
(ii) irregular, small-scale variations
(iii) similarity of measurements at locations close together

As an illustration, consider a hypothetical example in which an organic solvent leaks from an industrial site and spreads over a large area. Assume the solvent is absorbed and immobilized into the subsoil above any ground-water level, so you can ignore any time dependence.

For you to find the areal extent and the concentration values of the solvent, measurements are required. Although the problem is inherently three-dimensional, if you measure total concentration in a column of soil or take a depth-averaged concentration, it can be handled reasonably well with two-dimensional techniques.

You usually assume that measured concentrations are higher closer to the source and decrease at larger distances from the source. On top of this smooth variation, there are small-scale variations in the measured concentrations, due perhaps to the inherent variability of soil properties.

You also tend to suspect that measurements made close together yield similar concentration values, while measurements made far apart can have very different values.

These physically reasonable qualitative statements have no explicit probabilistic content, and there are a number of numerical smoothing techniques, such as inverse distance weighting and splines, that make use of large-scale variations and “close distance-close value” characteristics of spatial data to interpolate the measured concentrations for contouring purposes.

While characteristics (i) and (iii) are handled by such smoothing methods, characteristic (ii), the small-scale residual variation in the concentration field, is not accounted for.

There may be situations, due to the use of the prediction map or due to the relative magnitude of the irregular fluctuations, where you cannot ignore these small-scale irregular fluctuations. In other words, the smoothed or estimated values of the concentration field alone are not a sufficient characterization; you also need the possible spread around these contoured values.
Spatial Random Fields

One method of incorporating characteristic (ii) into the construction of a contour map is to model the concentration field as a spatial random field (SRF). The mathematical details of SRF models are given in a number of texts, for example, Cressie (1993) and Christakos (1992). The mathematics of SRFs are formidable. However, under certain simplifying assumptions, they produce classical linear estimators with very simple properties, allowing easy implementation for prediction purposes. These estimators, primarily ordinary kriging (OK), give both a prediction and a standard error of prediction at unsampled locations. This allows the construction of a map of both predicted values and level of uncertainty about the predicted values.

The key assumption in applying the SRF formalism is that the measurements come from a single realization of the SRF. However, in most geostatistical applications, the focus is on a single, unique realization. This is unlike most other situations in stochastic modeling in which there will be future experiments or observational activities (at least conceptually) under similar circumstances. This renders many traditional ideas of statistical inference ambiguous and somewhat counterintuitive.

There are additional logical and methodological problems in applying a stochastic model to a unique but partly unknown natural process; refer to the introduction in Matheron (1971) and Cressie (1993, section 2.3). These difficulties have resulted in attempts to frame the estimation problem in a completely deterministic way (Isaaks and Srivastava 1988; Journel 1985).

Additional problems with kriging, and with spatial estimation methods in general, are related to the necessary assumption of ergodicity of the spatial process. This assumption is required to estimate the covariance or semivariogram from sample data. Details are provided in Cressie (1993, pp. 52–58).

Despite these difficulties, ordinary kriging remains a popular and widely used tool in modeling spatial data, especially in generating surface plots and contour maps. An abbreviated derivation of the OK estimator for point estimation and the associated standard error is discussed in the following section. Full details are given in Journel and Huijbregts (1978), Christakos (1992), and Cressie (1993).

Ordinary Kriging

Denote the SRF by \( Z(r), r \in D \subseteq \mathbb{R}^2 \). Following the notation in Cressie (1993), the following model for \( Z(r) \) is assumed:

\[
Z(r) = \mu + \varepsilon(r)
\]

Here, \( \mu \) is the fixed, unknown mean of the process, and \( \varepsilon(r) \) is a zero mean SRF representing the variation around the mean.

In most practical applications, an additional assumption is required in order to estimate the covariance \( C_z \) of the \( Z(r) \) process. This assumption is second-order stationarity:

\[
C_z(r_1, r_2) = E[\varepsilon(r_1)\varepsilon(r_2)] = C_z(r_1 - r_2)
\]
This requirement can be relaxed slightly when you are using the semivariogram instead of the covariance. In this case, second-order stationarity is required of the differences \( \varepsilon(r_1) - \varepsilon(r_2) \) rather than \( \varepsilon(r) \):

\[
\gamma_Z(r_1, r_2) = \frac{1}{2} E[\varepsilon(r_1) - \varepsilon(r_2)]^2 = \gamma_Z(r_1 - r_2)
\]

By performing local kriging, the spatial processes represented by the previous equation for \( Z(r) \) are more general than they appear. In local kriging, at an unsampled location \( r_0 \), a separate model is fit using only data in a neighborhood of \( r_0 \). This has the effect of fitting a separate mean \( \mu \) at each point, and it is similar to the “kriging with trend” (KT) method discussed in Journel and Rossi (1989).

Given the \( N \) measurements \( Z(r_1), \ldots, Z(r_N) \) at known locations \( r_1, \ldots, r_N \), you want to obtain an estimate \( \hat{Z} \) of \( Z \) at an unsampled location \( r_0 \). When the following three requirements are imposed on the estimator \( \hat{Z} \), the OK estimator is obtained.

(i) \( \hat{Z} \) is linear in \( Z(r_1), \ldots, Z(r_N) \).
(ii) \( \hat{Z} \) is unbiased.
(iii) \( \hat{Z} \) minimizes the mean-square prediction error \( E(Z(r_0) - \hat{Z}(r_0))^2 \).

Linearity requires the following form for \( \hat{Z}(r_0) \):

\[
\hat{Z}(r_0) = \sum_{i=1}^{N} \lambda_i Z(r_i)
\]

Applying the unbiasedness condition to the preceding equation yields

\[
E\hat{Z}(r_0) = \mu \Rightarrow \mu = \sum_{i=1}^{N} \lambda_i E(Z(r_i)) \Rightarrow
\]

\[
\sum_{i=1}^{N} \lambda_i \mu = \mu \Rightarrow \sum_{i=1}^{N} \lambda_i = 1
\]

Finally, the third condition requires a constrained linear optimization involving \( \lambda_1, \ldots, \lambda_N \) and a Lagrange parameter \( 2m \). This constrained linear optimization can be expressed in terms of the function \( L(\lambda_1, \ldots, \lambda_N, m) \) given by

\[
L = E \left( Z(r_0) - \sum_{i=1}^{N} \lambda_i Z(r_i) \right)^2 - 2m \left( \sum_{i=1}^{N} \lambda_i - 1 \right)
\]
Define the $N \times 1$ column vector $\lambda$ by

$$\lambda = (\lambda_1, \cdots, \lambda_N)^T$$

and the $(N + 1) \times 1$ column vector $\lambda_0$ by

$$\lambda_0 = (\lambda_1, \cdots, \lambda_N, m)^T = \begin{pmatrix} \lambda \\ m \end{pmatrix}$$

The optimization is performed by solving

$$\frac{\partial L}{\partial \lambda_0} = 0$$

in terms of $\lambda_1, \cdots, \lambda_N$ and $m$.

The resulting matrix equation can be expressed in terms of either the covariance $C_z(r)$ or semivariogram $\gamma_z(r)$. In terms of the covariance, the preceding equation results in the following matrix equation:

$$C \lambda_0 = C_0$$

where

$$C = \begin{pmatrix} C_z(0) & C_z(r_1 - r_2) & \cdots & C_z(r_1 - r_N) & 1 \\ C_z(r_2 - r_1) & C_z(0) & \cdots & C_z(r_2 - r_N) & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ C_z(r_N - r_1) & C_z(r_N - r_2) & \cdots & C_z(0) & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{pmatrix}$$

and

$$C_0 = \begin{pmatrix} C_z(r_0 - r_1) \\ C_z(r_0 - r_2) \\ \vdots \\ C_z(r_0 - r_N) \\ 1 \end{pmatrix}$$

The solution to the previous matrix equation is

$$\hat{\lambda}_0 = C^{-1}C_0$$

Using this solution for $\lambda$ and $m$, the ordinary kriging estimate at $r_0$ is

$$\hat{Z}(r_0) = \lambda_1 Z(r_1) + \cdots + \lambda_N Z(r_N)$$
with associated prediction error

\[ \sigma_z(r_0) = C_z(0) - \lambda'c_0 + m \]

where \( c_0 \) is \( C_0 \) with the 1 in the last row removed, making it an \( N \times 1 \) vector.

These formulas are used in the best linear unbiased prediction (BLUP) of random variables (Robinson 1991). Further details are provided in Cressie (1993, pp. 119–123).

Because of possible numeric problems when solving the previous matrix equation, Duetsch and Journel (1992) suggest replacing the last row and column of 1s in the preceding matrix \( C \) by \( C_z(0) \), keeping the 0 in the \((N + 1, N + 1)\) position and similarly replacing the last element in the preceding right-hand vector \( C_0 \) with \( C_z(0) \). This results in an equivalent system but avoids numeric problems when \( C_z(0) \) is large or small relative to 1.

Output Data Sets

The KRIGE2D procedure produces two data sets: the OUTTEST=SAS-data-set and the OUTNBHD=SAS-data-set. These data sets are described as follows.

**OUTTEST=SAS-data-set**

The OUTTEST= data set contains the kriging estimates and the associated standard errors. The OUTTEST= data set contains the following variables:

- **ESTIMATE**, which is the kriging estimate for the current variable
- **GXC**, which is the x-coordinate of the grid point at which the kriging estimate is made
- **GYC**, which is the y-coordinate of the grid point at which the kriging estimate is made
- **LABEL**, which is the label for the current PREDICT/MODEL combination producing the kriging estimate. If you do not specify a label, default labels of the form Predj.Modelk are used.
- **NPOINTS**, which is the number of points used in the estimation. This number varies for each grid point if local kriging is performed.
- **STDERR**, which is the standard error of the kriging estimate
- **VARNAME**, which is the variable name

**OUTNBHD=SAS-data-set**

When you specify the RADIUS= option or the NUMPOINTS= option in the PREDICT statement, local kriging is performed. Local kriging is simply ordinary kriging at a given grid location using only those data points in a neighborhood defined by the RADIUS= value or the NUMPOINTS= value.
The OUTNBHD= data set contains one observation for each data point in each neighborhood. Hence, this data set can be large. For example, if the grid specification results in 1,000 grid points and each grid point has a neighborhood of 100 points, the resulting OUTNBHD= data set contains 100,000 points.

The OUTNBHD= data set contains the following variables:

- **GXC**, which is the x-coordinate of the grid point
- **GYC**, which is the y-coordinate of the grid point
- **LABEL**, which is the label for the current PREDICT/MODEL combination. If you do not specify a label, default labels of the form Predj.Modelk are used.
- **NPOINTS**, which is the number of points used in the estimation
- **RADIUS**, which is the radius used for each neighborhood
- **VALUE**, which is the value of the variable at the current data point
- **VARNNAME**, which is the variable name of the current variable
- **XC**, which is the x-coordinate of the current data point
- **YC**, which is the y-coordinate of the current data point

### Computational Resources

To generate a predicted value at a single grid point using $N$ data points, PROC KRIGE2D must solve the following kriging system:

$$C\lambda_0 = C_0$$

where $C$ is $(N + 1) \times (N + 1)$, and the right-hand side vector $C_0$ is $(N + 1) \times 1$.

Holding the matrix and vector associated with this system in core requires approximately $\frac{N^2}{2}$ doubles (with typically eight bytes per double). The CPU time used in solving the system is proportional to $N^3$. For large $N$, this time dominates the time to compute the $\frac{(N+1)(N+2)}{2}$ elements of the covariance matrix $C$ from the specified covariance or variogram model. This latter computation is proportional to $N^2$.

For local kriging, the kriging system is set up and solved for each grid point. Part of the set up process involves determining the neighborhood of each grid point. A fast K-D tree algorithm is used to determine neighborhoods. For $G$ grid points, the dominant CPU time factor is setting up and solving the $G$ kriging systems. The $N$ in the preceding algorithm is the number of data points in a given neighborhood, and it can differ for each grid point.

In global kriging, the entire input data set and all grid points are used to set up and solve the single system

$$C\lambda_0 = C_0$$
Again \( C \) is \((N+1) \times (N+1)\), but \( \lambda_0 \) is now \((N+1) \times G\), where \( G \) is the number of grid points, and \( N \) is the number of nonmissing observations in the input data set. The right-hand side matrix \( C_0 \) is \((N+1) \times G\). Memory requirements are approximately \( \frac{N^2}{2} + GN \) doubles. The CPU time used in solving the system is still dominated by the \( N^3 \) factorization of the left-hand side.

## Example

### Example 37.1. Investigating the Effect of Model Specification on Prediction

In the “Getting Started” section of the chapter on the VARIOGRAM procedure, a particular variogram is chosen for the coal seam thickness data. The chosen variogram is Gaussian with a scale (sill) of \( c_0 = 7.5 \), and a range of \( a_0 = 30 \). This choice of the variogram is based on a visual fit—a comparison of the plots of the regular and robust sample variograms and the Gaussian variogram for various scale (sill) and range values.

Another possible choice of model is the spherical variogram with the same scale (sill) of \( c_0 = 7.5 \) but with a range of \( a_0 = 60 \). This choice of range is again based on a visual fit; while not as good as the Gaussian model, the fit is reasonable.

It is generally held that spatial prediction is robust against model specification, while the standard error computation is not so robust.

This example investigates the effect of using these different models on the prediction and associated standard errors.

</table>
The LATTICE procedure computes the analysis of variance and analysis of simple covariance for data from an experiment with a lattice design. PROC LATTICE analyzes balanced square lattices, partially balanced square lattices, and some rectangular lattices.

In balanced square lattices, the number of treatments is equal to the square of the number of units per block. Incomplete blocks are grouped to form mutually orthogonal replications. The number of replicates in the basic plan is always 1 plus the number of units per block.

The partially balanced square lattices are similar to balanced lattices, although the number of replicates may vary. Partially balanced designs are constructed of the replicates in the basic plan, but not all replicates are included the same number of times, and some may not be included at all.

In rectangular lattices, there are $k$ units per block and $k(k+1)$ treatments. As in square lattices, blocks are grouped to form mutually orthogonal replicates in the basic plan. PROC LATTICE can analyze simple rectangular lattices (two orthogonal replications) and triple rectangular lattices (three orthogonal replications). The experiment can include several repetitions of the basic plan.

The LATTICE procedure determines from the data set which type of design has been used. It also checks to see if the design is valid and displays an appropriate message if it is not.

An example of a balanced square design is an experiment to investigate the effects of nine diets on the growth rate of pigs.

In some breeds of pigs, past experience has shown that a large part of the total variation in growth rates between animals can be attributed to the litter. Therefore, this experiment is planned so that litter differences do not contribute to the intrablock error.

First, the pigs are separated into sets of three litter-mates. Each block is assigned two sets of the three litter-mates. In a given block, one pig from each set receives a diet. Therefore, the experimental unit is a pair of pigs feeding in a particular pen on one of the nine diets. The response variable, growth rate, is the sum of the growth rates for the two pigs in a particular pen. To get the adjusted diet mean per pig, the adjusted treatment mean for the pen must be divided by 2.
The special numeric SAS variables named Group, Block, Treatmnt, and Rep must be used to define the design. In this example, the Treatmnt variable ranges from 1 to 9 and indicates the particular diet. The Block variable is 1, 2, or 3 and indicates the pen containing the two pigs. The Group variable ranges from 1 to 4 and specifies which replication within the basic plan includes the experimental unit. In this example, you would not use the Rep variable since the entire basic plan is not replicated.

You can use the following DATA step and PROC LATTICE statement to analyze this experiment. The response variable is Weight.

```sas
title 'Examining the Growth Rate of Pigs';
data Pigs;

**Figure 38.1.** Output from Example LATTICE Procedure

Diet 3 yields the highest mean growth rate at 1.9643 pounds for the two pigs (0.9822 per pig), while diet 5 has the lowest rate at 0.9393 (0.4696 per pig). The efficiency of the experiment relative to a randomized complete block design is 120.55 percent, so using the lattice design increased precision, producing more accurate estimates of the treatment effects. The different elements of the LATTICE procedure’s output are discussed in the “Displayed Output” section on page 2074.
Syntax

The following statements are available in PROC LATTICE.

```
PROC LATTICE < options >;
   BY variables ;
   VAR variables ;
```

Three specific numeric SAS variables, Group, Block, and Treatmnt, must be present in the data set to which PROC LATTICE is applied. A fourth numeric variable named Rep must be present when the design involves repetition of the entire basic plan. (See the “Input Data Set” section on page 2073 for more information.)

Every numeric variable other than Group, Block, Treatmnt, or Rep in the input SAS data set may be considered a response variable. A VAR statement tells PROC LATTICE that only the variables listed in the VAR statement are to be considered response variables. If the VAR statement is omitted, then all numeric variables, excluding Group, Block, Treatmnt, and Rep, are considered response variables. PROC LATTICE performs an analysis for each response variable.

PROC LATTICE Statement

```
PROC LATTICE < options >;
```

You can specify the following options in the PROC LATTICE statement.

- **DATA=SAS-data-set**
  names the SAS data set to be used by PROC LATTICE. If you omit the DATA= option, the most recently created SAS data set is used.

- **COVARIANCE**
  calculates sums of products for every possible pair of response variables. A sum of products is given for each source of variation in the analysis of variance table. For each pair of response variables, the one appearing later in the data set (or in the VAR statement) is the covariable.

BY Statement

```
BY variables ;
```

You can specify a BY statement with PROC LATTICE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:
- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the LATTICE procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

**VAR Statement**

```
VAR variables;
```

The VAR statement specifies the response variables. If you do not include a VAR statement, all numeric variables in the data set are considered response variables (except Group, Block, Treatmnt, and Rep).

**Details**

**Input Data Set**

Four numeric SAS variables, Group, Block, Treatmnt, and Rep, are used in the input data set to define the lattice design. The Group, Block, and Treatmnt variables are required in the data set to which PROC LATTICE is applied. The Rep variable must be present when the design involves repetition of the entire basic plan.

- **Group** specifies which orthogonal replication in the basic plan includes the experimental unit. Values of Group must be 1, 2, \ldots, n, where n is the number of replicates in the basic plan.
- **Block** specifies the block in which the experimental unit is present. Values of Block must be 1, 2, \ldots, m, where m is the number of blocks in a replication.
- **Treatmnt** specifies which treatment was applied to the experimental unit. Values of Treatmnt must be 1, 2, \ldots, i, where i is the number of treatments in a replication.
- **Rep** specifies which repetition of the basic plan includes the experimental unit. Values of Rep must be 1, 2, \ldots, p, where p is the number of replications of the entire basic plan. Thus, the experiment has a total of np replicates.
Missing Values

If a value of Group, Block, Treatment, or Rep is missing, the analysis is not performed and an appropriate error message is displayed.

If a value of a response variable is missing, this entire variable is dropped from the analysis. If other response variables exist that do not have missing values, they are analyzed.

Displayed Output

For each response variable, PROC LATTICE displays

- an “Analysis of Variance” table and related statistics, including the following as separate sources of variations:
  - Replications
  - Blocks within Replications (adjusted for treatments)
  - Treatments (unadjusted)
  - Intra Block Error
  - Randomized Complete Block Error

The Blocks within Replications sum of squares is further broken down into “Component A” and “Component B.” If there is no repetition of the basic plan, the Component B sum of squares is the same as the Blocks within Replications sum of squares. If there is repetition of the basic plan, the Component A sum of squares reflects the variation among blocks that contain the same treatments.

The source of variation called Randomized Complete Block Error is the sum of the Blocks within Replications sum of squares and the Intra Block Error sum of squares. It is the appropriate error term if the experimental design is a randomized complete block design, with the replications filling the roles of complete blocks.

- two values for the Variance of Means. For some lattice designs, these are only approximations. The first value is applicable when the two treatments appear in the same block; the other (when it appears) applies when the two treatments never appear in the same block (a possibility in partially balanced and rectangular designs).

- an Average of Variance. Except with small designs, it is sufficient to use this average variance of means for tests between treatments (whether the two treatments appear in the same block or not); refer to Cochran and Cox (1957).
• the Least Significant Differences (LSDs) at the .01 and .05 levels of significance, based on the Average of Variance

• Efficiency Relative to RCBD, the efficiency of the lattice design relative to a randomized complete block design. The efficiency is the ratio of the randomized complete block mean squared error to the effective error variance; refer to Cochran and Cox (1957).

• the Adjusted Treatment Means. These are adjusted for blocks if the relative precision is greater than 105 percent.

When you specify the COVARIANCE option, PROC LATTICE produces Sums of Products and the Mean Product for each source of variation in the analysis of variance table.

**ODS Table Names**

PROC LATTICE assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Example

Example 38.1. Analysis of Variance through PROC LATTICE

In the following example, from Cochran and Cox (1957, p. 406), the data are yields (Yield) in bushels per acre of 25 varieties (Treatment) of soybeans. The data are collected in two replications (Group) of 25 varieties in five blocks (Block) containing five varieties each. This is an example of a partially balanced square lattice design.

```sas
data Soy;
  do Group = 1 to 2;
    do Block = 1 to 5;
      do Plot = 1 to 5;
        input Treatment Yield @@;
        output;

The LIFEREG procedure fits parametric models to failure time data that can be right-, left-, or interval-censored. The models for the response variable consist of a linear effect composed of the covariates and a random disturbance term. The distribution of the random disturbance can be taken from a class of distributions that includes the extreme value, normal, logistic, and, by using a log transformation, the exponential, Weibull, lognormal, loglogistic, and three-parameter gamma distributions.

The model assumed for the response \( y \) is

\[
y = X\beta + \sigma \epsilon
\]

where \( y \) is a vector of response values, often the log of the failure times, \( X \) is a matrix of covariates or independent variables (usually including an intercept term), \( \beta \) is a vector of unknown regression parameters, \( \sigma \) is an unknown scale parameter, and \( \epsilon \) is a vector of errors assumed to come from a known distribution (such as the standard normal distribution). The distribution may depend on additional shape parameters. These models are equivalent to accelerated failure time models when the log of the response is the quantity being modeled. The effect of the covariates in an accelerated failure time model is to change the scale, and not the location, of a baseline distribution of failure times.

The LIFEREG procedure estimates the parameters by maximum likelihood using a Newton-Raphson algorithm. PROC LIFEREG estimates the standard errors of the parameter estimates from the inverse of the observed information matrix.

The accelerated failure time model assumes that the effect of independent variables on an event time distribution is multiplicative on the event time. Usually, the scale function is \( \exp(x_c'\beta_c) \), where \( x_c \) is the vector of covariate values (not including the intercept term) and \( \beta_c \) is a vector of unknown parameters. Thus, if \( T_0 \) is an event time sampled from the baseline distribution corresponding to values of zero for the covariates, then the accelerated failure time model specifies that, if the vector of covariates is \( x_c \), the event time is \( T = \exp(x_c'\beta_c)T_0 \). If \( y = \log(T) \) and \( y_0 = \log(T_0) \), then

\[
y = x_c'\beta_c + y_0
\]

This is a linear model with \( y_0 \) as the error term.

In terms of survival or exceedance probabilities, this model is

\[
\Pr(T > t \mid x_c) = \Pr(T_0 > \exp(-x_c'\beta_c)t)
\]
The probability on the left-hand side of the equal sign is evaluated given the value \( x_c \) for the covariates, and the right-hand side is computed using the baseline probability distribution but at a scaled value of the argument. The right-hand side of the equation represents the value of the baseline Survival Function evaluated at \( \exp(-x_c' \beta) t \).

Usually, an intercept parameter and a scale parameter are allowed in the model. In terms of the original untransformed event times, the effects of the intercept term and the scale term are to scale the event time and power the event time, respectively. That is, if

\[
\log(T_0) = \mu + \sigma \log(T_\epsilon)
\]

then

\[
T_0 = \exp(\mu)T_\epsilon^\sigma
\]

Although it is possible to fit these models to the original response variable using the NOLOG option, it is more common to model the log of the response variable. Because of this log transformation, zero values for the observed failure times are not allowed unless the NOLOG option is specified. Similarly, small values for the observed failure times lead to large negative values for the transformed response. The NOLOG option should only be used if you want to fit a distribution appropriate for the untransformed response, the extreme value instead of the Weibull, for example.

The parameter estimates for the normal distribution are sensitive to large negative values, and care must be taken that the fitted model is not unduly influenced by them. Likewise, values that are extremely large even after the log transformation have a strong influence in fitting the extreme value (Weibull) and normal distributions. You should examine the residuals and check the effects of removing observations with large residuals or extreme values of covariates on the model parameters. The logistic distribution gives robust parameter estimates in the sense that the estimates have a bounded influence function.

The standard errors of the parameter estimates are computed from large sample normal approximations using the observed information matrix. In small samples, these approximations may be poor. Refer to Lawless (1982) for additional discussion and references. You can sometimes construct better confidence intervals by transforming the parameters. For example, large sample theory is often more accurate for \( \log(\sigma) \) than \( \sigma \). Therefore, it may be more accurate to construct confidence intervals for \( \log(\sigma) \) and transform these into confidence intervals for \( \sigma \). The parameter estimates and their estimated covariance matrix are available in an output SAS data set and can be used to construct additional tests or confidence intervals for the parameters. Alternatively, tests of parameters can be based on log-likelihood ratios. Refer to Cox and Oakes (1984) for a discussion of the merits of some possible test methods including score, Wald, and likelihood ratio tests. It is believed that likelihood ratio tests are generally more reliable in small samples than tests based on the information matrix.

The log-likelihood function is computed using the log of the failure time as a response. This log likelihood differs from the log likelihood obtained using the failure
time as the response by an additive term of $\sum \log(t_i)$, where the sum is over the non-censored failure times. This term does not depend on the unknown parameters and does not affect parameter or standard error estimates. However, many published values of log likelihoods use the failure time as the basic response variable and, hence, differ by the additive term from the value computed by the LIFEREG procedure.

The classic Tobit model (Tobin 1958) also fits into this class of models but with data usually censored on the left. The data considered by Tobin in his original paper came from a survey of consumers where the response variable is the ratio of expenditures on durable goods to the total disposable income. The two explanatory variables are the age of the head of household and the ratio of liquid assets to total disposable income. Because many observations in this data set have a value of zero for the response variable, the model fit by Tobin is

$$y = \max(x'\beta + \epsilon, 0)$$

which is a regression model with left censoring. $x' = (1, x_{c'})$.

### Getting Started

The following examples demonstrate how you can use the LIFEREG procedure to fit a parametric model to failure time data.

Suppose you have a response variable $y$ that represents failure time, $\text{censor}$ is a binary variable with $\text{censor}=0$ indicating censored values, and $x_1$ and $x_2$ are two linearly independent variables. The following statements perform a typical accelerated failure time model analysis. Higher-order effects such as interactions and nested effects are allowed in the independent variables list, but are not shown in this example.

``` SAS
proc lifereg;
   model y*censor(0) = x1 x2;
run;
```

PROC LIFEREG can operate on interval-censored data. The model syntax for specifying the censored interval is

``` SAS
proc lifereg;
   model (begin, end) = x1 x2;
run;
```

You can also model binomial data using the `events/trials` syntax for the response, as illustrated in the following statements:

``` SAS
proc lifereg;
   model r/n=x1 x2;
run;
```

The variable $n$ represents the number of trials and the variable $r$ represents the number of events.
Modeling Right-Censored Failure Time Data

The following example demonstrates how you can use the LIFEREG procedure to fit a model to right-censored failure time data.

Suppose you conduct a study of two headache pain relievers. You divide patients into two groups, with each group receiving a different type of pain reliever. You record the time taken (in minutes) for each patient to report headache relief. Because some of the patients never report relief for the entire study, some of the observations are censored.

The following DATA step creates the SAS data set `headache`:

```sas
data headache;
  input minutes group censor @@;
datalines;
  11 1 0 12 1 0 19 1 0 19 1 0
  19 1 0 21 1 0 21 1 0 20 1 0
  20 1 0 21 1 0 25 1 0 27 1 0
  30 1 0 21 1 1 24 1 1 14 2 0
  16 2 0 16 2 0 21 2 0 21 2 0
  23 2 0 23 2 0 23 2 0 23 2 0
  25 2 1 23 2 0 24 2 0 24 2 0
  26 2 1 32 2 1 30 2 1 30 2 0
  32 2 1
;```

The data set `headache` contains the variable `minutes`, which represents the reported time to headache relief, the variable `group`, the group to which the patient is assigned, and the variable `censor`, a binary variable indicating whether the observation is censored. Valid values of the variable `censor` are 0 (no) and 1 (yes). The following figure shows the first five records of the data set `headache`.

<table>
<thead>
<tr>
<th>Obs</th>
<th>minutes</th>
<th>group</th>
<th>censor</th>
</tr>
</thead>
<tbody>

<td>19</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>5</td>
<td>19</td>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

*Figure 39.1. Headache Data*
The following statements invoke the LIFEREG procedure:

```
proc lifereg;
  class group;
  model minutes*censor(1)=group;
  output out=new cdf=prob;
run;
```

The CLASS statement specifies the variable `group` as the classification variable. The MODEL statement syntax indicates that the response variable `minutes` is right-censored when the variable `censor` takes the value 1. The MODEL statement specifies the variable `group` as the single explanatory variable. Because the MODEL statement does not specify the DISTRIBUTION= option, the LIFEREG procedure fits the default type 1 extreme value distribution using \( \log(\text{minutes}) \) as the response. This is equivalent to fitting the Weibull distribution.

The OUTPUT statement creates the output data set `new`. In addition to the variables in the original data set `headache`, the SAS data set `new` also contains the variable `prob`. This new variable is created by the CDF= option to contain the estimates of the cumulative distribution function evaluated at the observed response.

The results of this analysis are displayed in the following figures.

<table>

**Figure 39.2.** Model Fitting Information from the LIFEREG Procedure

Figure 39.2 displays the class level information and model fitting information. There are 30 noncensored observations and 8 right-censored observations. The log-likelihood for the Weibull distribution is -9.3793. The log-likelihood value can be used to compare the goodness of fit for different models.
The LIFEREG Procedure

Analysis of Parameter Estimates

<table>
<thead>
<tr>

<td>0.0304</td>
<td>0.1603 0.2809</td>
<td>.</td>
<td>.</td>
</tr>
<tr>
<td>Weibull Shape</td>
<td>1</td>
<td>4.7128</td>
<td>0.6742</td>
<td>3.5604 6.2381</td>
<td>.</td>
<td>.</td>
</tr>
</tbody>
</table>

The table of parameter estimates is displayed in Figure 39.3. Both the intercept and the slope parameter for the variable group are significantly different from 0 at the 0.05 level. Because the variable group has only one degree of freedom, parameter estimates are given for only one level of the variable group (group=1). However, the estimate for the intercept parameter provides a baseline for group=2. The resulting model is

$$\log(\text{minutes}) = \begin{cases} 3.30911843 - 0.1933025 & \text{for group}=1 \\ 3.30911843 & \text{for group}=2 \end{cases}$$

Note that the Weibull shape parameter for this model is the reciprocal of the extreme value scale parameter estimate shown in Figure 39.3 ($1/0.21219 = 4.7128$).

The following statements produce a graph of the cumulative distribution values versus the variable minutes. The LEGEND1 statement defines the appearance of the legend that displays on the plot. The two AXIS statements define the appearance of the plot axes. The SYMBOL statements control the plotting symbol, color, and method of smoothing.

```plaintext
legend1 frame cframe=ligr cborder=black
  position=center value=(justify=center);
axis1 label=(angle=90 rotate=0 'Estimated CDF') minor=none;
axis2 minor=none;
symbol1 c=white i=spline;
symbol2 c=yellow i=spline;
proc sort data=new;
  by prob;
proc gplot data=new;
  plot prob*minutes=group/ frame cframe=ligr
    legend=legend1 vaxis=axis1 haxis=axis2;
run;
```

The SORT procedure sorts the data set new by the variable prob. Then the GPLOT procedure plots the variable prob versus the variable minutes using the grouping
variable as the identification variable. The LEGEND=, VAXIS=, and HAXIS= options specify the previously defined legend and axis statements.

Figure 39.4 displays the estimated cumulative distribution function for each group.

![Plot of the Estimated Cumulative Distribution Function](image)

**Figure 39.4.** Plot of the Estimated Cumulative Distribution Function

## Syntax

The following statements are available in PROC LIFEREG.

```plaintext
PROC LIFEREG < options > ;
   BY variables ;
   CLASS variables ;
   INSET <keyword-list> < / options> ;
   MODEL response= <effects> < / options> ;
   OUTPUT <OUT=SAS-data-set >
       keyword=name < . . . keyword=name >
       < options> ;
   PROBPLOT < / options> ;
   WEIGHT variable ;
```

The PROC LIFEREG statement invokes the procedure. The MODEL statement is required and specifies the variables used in the regression part of the model as well as the distribution used for the error, or random, component of the model. Only a single MODEL statement can be used with one invocation of the LIFEREG procedure. If multiple MODEL statements are present, only the last is used. Main effects
and interaction terms can be specified in the MODEL statement, similar to the GLM procedure. Initial values can be specified in the MODEL statement or in an INEST= data set. If no initial values are specified, the starting estimates are obtained by ordinary least squares. The CLASS statement determines which explanatory variables are treated as categorical. The WEIGHT statement identifies a variable with values that are used to weight the observations. Observations with zero or negative weights are not used to fit the model, although predicted values can be computed for them. The OUTPUT statement creates an output data set containing predicted values and residuals.

**PROC LIFEREG Statement**

```latex
PROC LIFEREG < options > ;
```

The PROC LIFEREG statement invokes the procedure. You can specify the following options in the PROC LIFEREG statement.

**COVOUT**

- writes the estimated covariance matrix to the OUTEST= data set if convergence is attained.

**DATA=SAS-data-set**

- specifies the input SAS data set used by PROC LIFEREG. By default, the most recently created SAS data set is used.

**GOUT=graphics-catalog**

- specifies a graphics catalog in which to save graphics output.

**INEST=SAS-data-set**

- specifies an input SAS data set that contains initial estimates for all the parameters in the model. See the section “INEST= Data Set” on page 2121 for a detailed description of the contents of the INEST= data set.

**NAMELEN=n**

- specifies the length of effect names in tables and output data sets to be n characters, where n is a value between 20 and 200. The default length is 20 characters.

**NOPRINT**

- suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

**ORDER=DATA | FORMATTED | FREQ | INTERNAL**

- specifies the sorting order for the levels of the classification variables (specified in the CLASS statement). This ordering determines which parameters in the model correspond to each level in the data. The following table illustrates how PROC LIFEREG interprets values of the ORDER= option.
<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>formatted value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

By default, ORDER=FORMATTED. For FORMATTED and INTERNAL, the sort order is machine dependent. For more information on sorting order, refer to the chapter titled “The SORT Procedure” in the SAS Procedures Guide.

**OUTEST=SAS-data-set**

specifies an output SAS data set containing the parameter estimates, the maximized log likelihood, and, if the COVOUT option is specified, the estimated covariance matrix. See the section “OUTEST= Data Set” on page 2121 for a detailed description of the contents of the OUTEST= data set.

**XDATA= SAS-data-set**

specifies an input SAS data set that contains values for all the independent variables in the MODEL statement and variables in the CLASS statement for probability plotting. If there are covariates specified in a MODEL statement and a probability plot is requested with a PROBPLOT statement, you specify fixed values for the effects in the MODEL statement with the XDATA= data set. See the section “XDATA= Data Set” on page 2122 for a detailed description of the contents of the XDATA= data set.

### BY Statement

The BY statement is used to perform separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the LIFEREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.
CLASS Statement

CLASS variables;

Variables that are classification variables rather than quantitative numeric variables must be listed in the CLASS statement. For each explanatory variable listed in the CLASS statement, indicator variables are generated for the levels assumed by the CLASS variable. If the CLASS statement is used, it must appear before the MODEL statement.

INSET Statement

INSET < keyword-list > < / options>;

The box or table of summary information produced on plots made with the PROBPLOT statement is called an inset. You can use the INSET statement to customize the information that is displayed in the inset box as well as to customize the appearance of the inset box. To supply the information that is displayed in the inset box, you specify keywords corresponding to the information that you want shown. For example, the following statements produce a probability plot with the number of observations, the number of right-censored observations, the name of the distribution, and the estimated Weibull shape parameter in the inset.

```plaintext
proc lifereg data=epidemic;
  model life = dose / dist = Weibull;
  probplot ;
  inset nobs right dist shape;
run;
```

By default, inset entries are identified with appropriate labels. However, you can provide a customized label by specifying the keyword for that entry followed by the equal sign (=) and the label in quotes. For example, the following INSET statement produces an inset containing the number of observations and the name of the distribution, labeled “Sample Size” and “Distribution” in the inset.

```plaintext
inset nobs='Sample Size' dist='Distribution';
```

If you specify a keyword that does not apply to the plot you are creating, then the keyword is ignored.

If you specify more than one INSET statement, only the first one is used.

The following table lists keywords available in the INSET statement to display summary statistics, distribution parameters, and distribution fitting information.
Table 39.1. INSET Statement Keywords

<table>
<thead>
<tr>
<th>Keyword</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CONFIDENCE</td>
<td>confidence coefficient for all confidence intervals</td>
</tr>
<tr>
<td>DIST</td>
<td>name of the distribution</td>
</tr>
<tr>
<td>INTERVAL</td>
<td>number of interval-censored observations</td>
</tr>
<tr>
<td>LEFT</td>
<td>number of left-censored observations</td>
</tr>
<tr>
<td>NOBS</td>
<td>number of observations</td>
</tr>
<tr>
<td>NMISS</td>
<td>number of observations with missing values</td>
</tr>
<tr>
<td>RIGHT</td>
<td>number of right-censored observations</td>
</tr>
<tr>
<td>SCALE</td>
<td>value of the scale parameter</td>
</tr>
<tr>
<td>SHAPE</td>
<td>value of the shape parameter</td>
</tr>
<tr>
<td>UNCENSORED</td>
<td>number of uncensored observations</td>
</tr>
</tbody>
</table>

The following options control the appearance of the box. All options are specified after the slash (/) in the INSET statement.

**CFILL=**<code>color</code>

specifies the color for the filling box.

**CFILLH=**<code>color</code>

specifies the color for the filling box header.

**CFRAME=**<code>color</code>

specifies the color for the frame.

**CHERER=**<code>color</code>

specifies the color for text in the header.

**CTEXT=**<code>color</code>

specifies the color for the text.

**FONT=**<code>font</code>

specifies the software font for the text.

**HEIGHT=**<code>value</code>

specifies the height of the text.

**HEADER=**<code>’quoted string’</code>

specifies text for the header or box title.

**NOFRAME**

omits the frame around the box.

**POS=**<code>value <DATA | PERCENT></code>

determines the position of the inset. The value can be a compass point (N, NE, E, SE, S, SW, W, NW) or a pair of coordinates (x, y) enclosed in parentheses. The coordinates can be specified in screen percent units or axis data units. The default is screen percent units.
REFPOINT= name

specifies the reference point for an inset that is positioned by a pair of coordinates with the POS= option. You use the REFPOINT= option in conjunction with the POS= coordinates. The REFPOINT= option specifies which corner of the inset frame you have specified with coordinates (x, y), and it can take the value of BR (bottom right), BL (bottom left), TR (top right), or TL (top left). The default is REFPOINT=BL. If the inset position is specified as a compass point, then the REFPOINT= option is ignored.

MODEL Statement

\(<label:>\text{MODEL } response\ast\text{censor(list)}=effects < / options > ;\>
\n\(<label:>\text{MODEL } (lower,upper)=effects < / options > ;\>
\n\(<label:>\text{MODEL } events/trials=effects < / options > ;\>

Only a single MODEL statement can be used with one invocation of the LIFEREG procedure. If multiple MODEL statements are present, only the last is used. The optional label is used to label the model estimates in the output SAS data set and OUTEST= data set.

The first MODEL syntax is appropriate for right censoring. The variable response is possibly right-censored. If the response variable can be right-censored, then a second variable, denoted censor, must appear after the response variable with a list of parenthesized values, separated by commas or blanks, to indicate censoring. That is, if the censor variable takes on a value given in the list, the response is a right-censored value; otherwise, it is an observed value.

The second MODEL syntax specifies two variables, lower and upper, that contain values of the endpoints of the censoring interval. If the two values are the same (and not missing), it is assumed that there is no censoring and the actual response value is observed. If the lower value is missing, then the upper value is used as a left-censored value. If the upper value is missing, then the lower value is taken as a right-censored value. If both values are present and the lower value is less than the upper value, it is assumed that the values specify a censoring interval. If the lower value is greater than the upper value or both values are missing, then the observation is not used in the analysis although predicted values can still be obtained if none of the covariates are missing. The following table summarizes the ways of specifying censoring.

<table>
<thead>
<tr>
<th>lower</th>
<th>upper</th>
<th>Comparison</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>not missing</td>
<td>not missing</td>
<td>equal</td>
<td>no censoring</td>
</tr>
<tr>
<td>not missing</td>
<td>not missing</td>
<td>lower &lt; upper</td>
<td>censoring interval</td>
</tr>
<tr>
<td>missing</td>
<td>not missing</td>
<td></td>
<td>upper used as left-censoring value</td>
</tr>
<tr>
<td>not missing</td>
<td>missing</td>
<td></td>
<td>lower used as right-censoring value</td>
</tr>
<tr>
<td>not missing</td>
<td>not missing</td>
<td>lower &gt; upper</td>
<td>observation not used</td>
</tr>
<tr>
<td>missing</td>
<td>missing</td>
<td></td>
<td>observation not used</td>
</tr>
</tbody>
</table>
The third MODEL syntax specifies two variables that contain count data for a binary response. The value of the first variable, *events*, is the number of successes. The value of the second variable, *trials*, is the number of tries. The values of both *events* and *(trials-events)* must be nonnegative, and *trials* must be positive for the response to be valid. The values of the two variables do not need to be integers and are not modified to be integers.
