The *effects* following the equal sign are the covariates in the model. Higher-order effects, such as interactions and nested terms, are allowed in the list, similar to the GLM procedure. Variable names and combinations of variable names representing higher-order terms are allowed to appear in this list. Class variables can be used as effects, and indicator variables are generated for the class levels. If you do not specify any covariates following the equal sign, an intercept-only model is fit.

Examples of three valid MODEL statements are

```
a: model time*flag(1,3)=temp;
b: model (start, finish)=;  
c: model r/n=dose;
```

Model statement *a* indicates that the response is contained in a variable named *time* and that, if the variable *flag* takes on the values 1 or 3, the observation is right-censored. The explanatory variable is *temp*, which could be a class variable. Model statement *b* indicates that the response is known to be in the interval between the values of the variables *start* and *finish* and that there are no covariates except for a default intercept term. Model statement *c* indicates a binary response, with the variable *r* containing the number of responses and the variable *n* containing the number of trials.

The following options can appear in the MODEL statement.
### Task Option

</tr>
</tbody>
</table>

**ALPHA=value**

sets the significance level for the confidence intervals for regression parameters and estimated survival probabilities. The value must be between 0 and 1. By default, ALPHA = 0.05.

**CONVERGE=value**

sets the convergence criterion. Convergence is declared when the maximum change in the parameter estimates between Newton-Raphson steps is less than the value specified. The change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E−8.

**CONVG=value**

sets the relative Hessian convergence criterion. value must be between 0 and 1. After convergence is determined with the change in parameter criterion specified with the CONVERGE= option, the quantity \( tc = \frac{g'\mathbf{H}^{-1}g}{|f|} \) is computed and compared to value, where \( g \) is the gradient vector, \( \mathbf{H} \) is the Hessian matrix for the model parameters, and \( f \) is the log-likelihood function. If \( tc \) is greater than value, a warning that the relative Hessian convergence criterion has been exceeded is displayed. This criterion detects the occasional case where the change in parameter convergence criterion is satisfied, but a maximum in the log-likelihood function has not been attained. By default, CONVG=1E−4.
CORRB
produces the estimated correlation matrix of the parameter estimates.

COVB
produces the estimated covariance matrix of the parameter estimates.

\textbf{DISTRIBUTION} = \textit{distribution-type}
\textbf{DIST} = \textit{distribution-type}
\textbf{D} = \textit{distribution-type}

specifies the distribution type assumed for the failure time. By default, PROC LIFEREG fits a type 1 extreme value distribution to the log of the response. This is equivalent to fitting the Weibull distribution, since the scale parameter for the extreme value distribution is related to a Weibull shape parameter and the intercept is related to the Weibull scale parameter in this case. When the NOLOG option is specified, PROC LIFEREG models the untransformed response with a type 1 extreme value distribution as the default. See the section “Supported Distributions” on page 2111 for descriptions of the distributions. The following are valid values for \textit{distribution-type}:

- \textbf{EXPONENTIAL} the exponential distribution, which is treated as a restricted Weibull distribution
- \textbf{GAMMA} a generalized gamma distribution (Lawless, 1982, p. 240). The standard two-parameter gamma distribution is not available in PROC LIFEREG.
- \textbf{LLOGISTIC} a loglogistic distribution
- \textbf{LNORMAL} a lognormal distribution
- \textbf{LOGISTIC} a logistic distribution (equivalent to LLOGISTIC when the NOLOG option is specified)
- \textbf{NORMAL} a normal distribution (equivalent to LNORMAL when the NOLOG option is specified)
- \textbf{WEIBULL} a Weibull distribution. If NOLOG is specified, it fits a type 1 extreme value distribution to the raw, untransformed data.

By default, PROC LIFEREG transforms the response with the natural logarithm before fitting the specified model when you specify the GAMMA, LLOGISTIC, LNORMAL, or WEIBULL option. You can suppress the log transformation with the NOLOG option. The following table summarizes the resulting distributions when the preceding distribution options are used in combination with the NOLOG option.
### DISTRIBUTION= NOLOG specified? Resulting distribution

</tr>
</tbody>
</table>

**INITIAL=values**

sets initial values for the regression parameters. This option can be helpful in the case of convergence difficulty. Specified values are used to initialize the regression coefficients for the covariates specified in the MODEL statement. The intercept parameter is initialized with the INTERCEPT= option and is not included here. The values are assigned to the variables in the MODEL statement in the same order in which they are listed in the MODEL statement. Note that a class variable requires \(k - 1\) values when the class variable takes on \(k\) different levels. The order of the class levels is determined by the ORDER= option. If there is no intercept term, the first class variable requires \(k\) initial values. If a BY statement is used, all class variables must take on the same number of levels in each BY group or no meaningful initial values can be specified. The INITIAL= option can be specified as follows.

<table>
<thead>
<tr>
<th>Type of List</th>
<th>Specification</th>
</tr>
</thead>
<tbody>
<tr>
<td>list separated by blanks</td>
<td>initial=3 4 5</td>
</tr>
<tr>
<td>list separated by commas</td>
<td>initial=3,4,5</td>
</tr>
<tr>
<td>x to y</td>
<td>initial=3 to 5</td>
</tr>
<tr>
<td>x to y by z</td>
<td>initial=3 to 5 by 1</td>
</tr>
<tr>
<td>combination of methods</td>
<td>initial=1,3 to 5,9</td>
</tr>
</tbody>
</table>

By default, PROC LIFEREG computes initial estimates with ordinary least squares. See the section “Computational Method” on page 2108 for details.

**Note:** The INITIAL= option is overwritten by the INEST= option. See the section “INEST= Data Set” on page 2121 for details.
INTERCEPT=value
initializes the intercept term to value. By default, the intercept is initialized by an ordinary least squares estimate.

ITPRINT
displays the iteration history, the final evaluation of the gradient, and the final evaluation of the negative of the second derivative matrix, that is, the negative of the Hessian.

MAXITER=n
sets the maximum allowable number of iterations during the model estimation. By default, MAXITER=50.

NOINT
holds the intercept term fixed. Because of the usual log transformation of the response, the intercept parameter is usually a scale parameter for the untransformed response, or a location parameter for a transformed response.

NOLOG
requests that no log transformation of the response variable be performed. By default, PROC LIFEREG models the log of the response variable for the GAMMA, LLOGISTIC, LOGNORMAL, and WEIBULL distribution options.

NOSCALE
holds the scale parameter fixed. Note that if the log transformation has been applied to the response, the effect of the scale parameter is a power transformation of the original response. If no SCALE= value is specified, the scale parameter is fixed at the value 1.

NOSHAPE1
holds the first shape parameter, SHAPE1, fixed. If no SHAPE1= value is specified, SHAPE1 is fixed at a value that depends on the DISTRIBUTION type.

SCALE=value
initializes the scale parameter to value. If the Weibull distribution is specified, this scale parameter is the scale parameter of the type 1 extreme value distribution, not the Weibull scale parameter. Note that, with a log transformation, the exponential model is the same as a Weibull model with the scale parameter fixed at the value 1.

SHAPE1=value
initializes the first shape parameter to value. If the specified distribution does not depend on this parameter, then this option has no effect. The only distribution that depends on this shape parameter is the generalized gamma distribution. See the “Supported Distributions” section on page 2111 for descriptions of the parameterizations of the distributions.

SINGULAR=value
sets the tolerance for testing singularity of the information matrix and the crossproducts matrix for the initial least-squares estimates. Roughly, the test requires that a pivot be at least this value times the original diagonal value. By default, SINGULAR=1E−12.
**OUTPUT Statement**

```
OUTPUT <OUT=SAS-data-set> keyword=name <...keyword=name> ;
```

The OUTPUT statement creates a new SAS data set containing statistics calculated after fitting the model. At least one specification of the form `keyword=name` is required.

All variables in the original data set are included in the new data set, along with the variables created as options to the OUTPUT statement. These new variables contain fitted values and estimated quantiles. If you want to create a permanent SAS data set, you must specify a two-level name (refer to *SAS Language Reference: Concepts* for more information on permanent SAS data sets). Each OUTPUT statement applies to the preceding MODEL statement. See Example 39.1 for illustrations of the OUTPUT statement.

The following specifications can appear in the OUTPUT statement:

- **OUT=SAS-data-set** specifies the new data set. By default, the procedure uses the `DATA`n convention to name the new data set.
- **keyword=name** specifies the statistics to include in the output data set and gives names to the new variables. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable to contain the statistic.

The keywords allowed and the statistics they represent are as follows:

- **CENSORED** specifies an indicator variable to signal censoring. The variable takes on the value 1 if the observation is censored; otherwise, it is 0.
- **CDF** specifies a variable to contain the estimates of the cumulative distribution function evaluated at the observed response. See the “Predicted Values” section on page 2114 for more information.
- **CONTROL** specifies a variable in the input data set to control the estimation of quantiles. See Example 39.1 for an illustration. If the specified variable has the value of 1, estimates for all the values listed in the `QUANTILE=` list are computed for that observation in the input data set; otherwise, no estimates are computed. If no `CONTROL=` variable is specified, all quantiles are estimated for all observations. If the response variable in the MODEL statement is binomial, then this option has no effect.
- **CRESIDUAL | CRES** specifies a variable to contain the Cox-Snell residuals

\[- \log(S(u_i))\]
where $S$ is the standard survival function and

$$u_i = \frac{y_i - x_i'b}{\sigma}$$

If the response variable in the corresponding model statement is binomial, then the residuals are not computed, and this variable contains missing values.

**SRESIDUAL | SRES** specifies a variable to contain the standardized residuals

$$\frac{y_i - x_i'b}{\sigma}$$

If the response variable in the corresponding model statement is binomial, then the residuals are not computed, and this variable contains missing values.

**PREDICTED | P** specifies a variable to contain the quantile estimates. If the response variable in the corresponding model statement is binomial, then this variable contains the estimated probabilities, $1 - F(-x'b)$.

**QUANTILES | QUANTILE | Q** gives a list of values for which quantiles are calculated. The values must be between 0 and 1, noninclusive. For each value, a corresponding quantile is estimated. This option is not used if the response variable in the corresponding MODEL statement is binomial. The QUANTILES option can be specified as follows.

<table>
<thead>
<tr>
<th>Type of List</th>
<th>Specification</th>
</tr>
</thead>
<tbody>
<tr>
<td>list separated by blanks</td>
<td>.2 .4 .6 .8</td>
</tr>
<tr>
<td>list separated by commas</td>
<td>.2,.4,.6,.8</td>
</tr>
<tr>
<td>x to y</td>
<td>.2 to .8</td>
</tr>
<tr>
<td>x to y by z</td>
<td>.2 to .8 by .1</td>
</tr>
<tr>
<td>combination of methods</td>
<td>.1,.2 to .8 by .2</td>
</tr>
</tbody>
</table>

By default, QUANTILES=0.5. When the response is not binomial, a numeric variable, _PROB_, is added to the OUTPUT data set whenever the QUANTILES= option is specified. The variable _PROB_ gives the probability value for the quantile estimates. These are the values taken from the QUANTILES= list and are given as values between 0 and 1, not as values between 0 and 100.

**STD_ERR | STD** specifies a variable to contain the estimates of the standard errors of the estimated quantiles or $x'b$. If the response used in the MODEL statement is a binomial response, then these are the standard errors of $x'b$. Otherwise, they are the standard errors of the
quantile estimates. These estimates can be used to compute confidence intervals for the quantiles. However, if the model is fit to the log of the event time, better confidence intervals can usually be computed by transforming the confidence intervals for the log response. See Example 39.1 for such a transformation.

XBETA specifies a variable to contain the computed value of \( x' \beta \), where \( x \) is the covariate vector and \( \beta \) is the vector of parameter estimates.

**PROBPLOT Statement**

```
PROBPLOT | PLOT < / options > ;
```

You can use the PROBPLOT statement to create a probability plot from lifetime data. The data can be uncensored, right-censored, or arbitrarily censored. You can specify any number of PROBPLOT statements after a MODEL statement. The syntax used for the response in the MODEL statement determines the type of censoring assumed in creating the probability plot. The model fit with the MODEL statement is plotted along with the data. If there are covariates in the model, they are set to constant values specified in the XDATA= data set when creating the probability plot. If no XDATA= data set is specified, continuous variables are set to their overall mean values and categorical variables specified in the CLASS statement are set to their highest levels.

You can specify the following options to control the content, layout, and appearance of a probability plot.

- **ANNOTATE=**SAS-data-set
- **ANNO=**SAS-data-set
  specifies an ANNOTATE data set, as described in *SAS/GRAPH Software: Reference*, that enables you to add features to the probability plot. The ANNOTATE= data set you specify in the PROBPLOT statement is used for all plots created by the statement.

- **CAXIS=**color
- **CAXES=**color
  specifies the color used for the axes and tick marks. This option overrides any COLOR= specifications in an AXIS statement. The default is the first color in the device color list.

- **CCENSOR=**color
  specifies the color for filling the censor plot area. The default is the first color in the device color list.

- **CENBIN**
  plots censored data as frequency counts (rounding-off for non-integer frequency) rather than as individual points.

- **CENCOLOR=**color
  specifies the color for the censor symbol. The default is the first color in the device color list.
CENSYMBOL=\textit{symbol} \mid (\textit{symbol list})
specifies symbols for censored values. The \textit{symbol} is one of the symbol names (plus, star, square, diamond, triangle, hash, paw, point, dot, and circle) or a letter (A–Z). If you do not specify the CENSYMBOL= option, the symbol used for censored values is the same as for failures.

\textbf{CFIT=}\textit{color}
specifies the color for the fitted probability line and confidence curves. The default is the first color in the device color list.

\textbf{CFRAME=}\textit{color}
\textbf{CFR=}\textit{color}
specifies the color for the area enclosed by the axes and frame. This area is not shaded by default.

\textbf{CGRID=}\textit{color}
specifies the color for grid lines. The default is the first color in the device color list.

\textbf{CHREF=}\textit{color}
\textbf{CH=}\textit{color}
specifies the color for lines requested by the HREF= option. The default is the first color in the device color list.

\textbf{CTEXT=}\textit{color}
specifies the color for tick mark values and axis labels. The default is the color specified for the CTEXT= option in the most recent GOPTIONS statement.

\textbf{CVREF=}\textit{color}
\textbf{CV=}\textit{color}
specifies the color for lines requested by the VREF= option. The default is the first color in the device color list.

\textbf{DESCRIPTION=}\textquoteleft\textit{string}\textquoteright
\textbf{DES=}\textquoteleft\textit{string}\textquoteright
specifies a description, up to 40 characters, that appears in the PROC GREPLAY master menu. The default is the variable name.

\textbf{FONT=}\textit{font}
specifies a software font for reference line and axis labels. You can also specify fonts for axis labels in an AXIS statement. The FONT= font takes precedence over the FTEXT= font specified in the most recent GOPTIONS statement. Hardware characters are used by default.

\textbf{HCL}
computes and draws confidence limits for the predicted probabilities in the horizontal direction.

\textbf{HEIGHT=}\textit{value}
specifies the height of text used outside framed areas. The default value is 3.846 (in percentage).
HLOWER=value
  specifies the lower limit on the lifetime axis scale. The HLOWER= option specifies value as the lower lifetime axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

HOFFSET=value
  specifies the offset for the horizontal axis. The default value is 1.

HUPPER=value
  specifies value as the upper lifetime axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

HREF < (INTERSECT) > =value-list
  requests reference lines perpendicular to the horizontal axis. If (INTERSECT) is specified, a second reference line perpendicular to the vertical axis is drawn that intersects the fit line at the same point as the horizontal axis reference line. If a horizontal axis reference line label is specified, the intersecting vertical axis reference line is labeled with the vertical axis value. See also the CHREF=, HREFLABELS=, and LHREF= options.

HREFLABELS=’label1’ . . . ’labeln’
HREFLABEL=’label1’ . . . ’labeln’
HREFLAB=’label1’ . . . ’labeln’
  specifies labels for the lines requested by the HREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

HREFLABPOS=n
  specifies the vertical position of labels for HREF= lines. The following table shows the valid values for n and the corresponding label placements.

<table>
<thead>
<tr>
<th>n</th>
<th>label placement</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>top</td>
</tr>
<tr>
<td>2</td>
<td>staggered from top</td>
</tr>
<tr>

</tr>
<tr>
<td>4</td>
<td>staggered from bottom</td>
</tr>
<tr>
<td>5</td>
<td>alternating from top</td>
</tr>
<tr>
<td>6</td>
<td>alternating from bottom</td>
</tr>
</tbody>
</table>

INBORDER
  requests a border around probability plots.

INTERTILE=value
  specifies the distance between tiles.

ITPRINTEM
  displays the iteration history for the Turnbull algorithm.
**JITTER**=value
specifies the amount to jitter overlaying plot symbols, in units of symbol width.

**LFIT**=linetype
specifies a line style for fitted curves and confidence limits. By default, fitted curves are drawn by connecting solid lines (linetype = 1), and confidence limits are drawn by connecting dashed lines (linetype = 3).

**LGRID**=linetype
specifies a line style for all grid lines. linetype is between 1 and 46. The default is 35.

**LHREF**=linetype
**LH**=linetype
specifies the line type for lines requested by the HREF= option. The default is 2, which produces a dashed line.

**LVREF**=linetype
**LV**=linetype
specifies the line type for lines requested by the VREF= option. The default is 2, which produces a dashed line.

**MAXITEM**=n1 <,n2> n1
specifies the maximum number of iterations allowed for the Turnbull algorithm. Iteration history will be displayed in increments of n2 if requested with the ITPRINTEM option. See the section “Arbitrarily Censored Data” on page 2119 for details.

**NAME**=’string’
specifies a name for the plot, up to eight characters, that appears in the PROC GREPLAY master menu. The default is ’LIFEREG’.

**NOCENPLOT**
suppresses the plotting of censored data points.

**NOCONF**
suppresses the default percentile confidence bands on the probability plot.

**NODATA**
suppresses plotting of the estimated empirical probability plot.

**NOFIT**
suppresses the fitted probability (percentile) line and confidence bands.

**NOFRAME**
suppresses the frame around plotting areas.

**NOGRID**
suppresses grid lines.

**NOHLABEL**
suppresses horizontal labels.
NOHTICK
suppresses horizontal tick marks.

NOPOLISH
suppresses setting small interval probabilities to zero in the Turnbull algorithm.

NOVLABEL
suppresses vertical labels.

NOVTICK
suppresses vertical tick marks.

NPINTERVALS=interval type
specifies one of the two kinds of confidence limits for the estimated cumulative probabilities, pointwise (NPINTERVALS=POINT) or simultaneous (NPINTERVALS=SIMUL), requested by the PPOUT option to be displayed in the tabular output.

PCTLIST=value-list
specifies the list of percentages for which to compute percentile estimates. value-list must be a list of values separated by blanks or commas. Each value in the list must be between 0 and 100.

PLOWER=value
specifies the lower limit on the probability axis scale. The PLOWER= option specifies value as the lower probability axis tick mark. The tick mark interval and the upper axis limit are determined automatically.

PRINTPROBS
displays intervals and associated probabilities for the Turnbull algorithm.

PUPPER=value
specifies the upper limit on the probability axis scale. The PUPPER= option specifies value as the upper probability axis tick mark. The tick mark interval and the lower axis limit are determined automatically.

PPOS=character-list
specifies the plotting position type. See the section “Probability Plotting” on page 2116 for details.

<table>
<thead>
<tr>

</tbody>
</table>

PPOUT
specifies that a table of the cumulative probabilities plotted on the probability plot be displayed. Kaplan-Meier estimates of the cumulative probabilities are also displayed, along with standard errors and confidence limits. The confidence limits can be pointwise or simultaneous, as specified by the NPINTERVALS= option.
PROBPLT Statement ♦ 2107

PROBLIST=value-list
   specifies the list of initial values for the Turnbull algorithm.

ROTATE
   requests probability plots with probability scale on the horizontal axis.

SQUARE
   makes the layout of the probability plots square.

TOLLIKE=value
   specifies the criterion for convergence in the Turnbull algorithm.

TOLPROB=value
   specifies the criterion for setting the interval probability to zero in the Turnbull algorithm.

VAXISLABEL='string'
   specifies a label for the vertical axis.

VREF=value-list
   requests reference lines perpendicular to the vertical axis. If (INTERSECT) is specified, a second reference line perpendicular to the horizontal axis is drawn that intersects the fit line at the same point as the vertical axis reference line. If a vertical axis reference line label is specified, the intersecting horizontal axis reference line is labeled with the horizontal axis value. See also the entries for the CVREF=, LVREF=, and VREFLABELS= options.

VREFLABELS='label1' . . . 'labeln'
VREFLABEL='label1' . . . 'labeln'
VREFLAB='label1' . . . 'labeln'
   specifies labels for the lines requested by the VREF= option. The number of labels must equal the number of lines. Enclose each label in quotes. Labels can be up to 16 characters.

VREFLABPOS=n
   specifies the horizontal position of labels for VREF= lines. The valid values for n and the corresponding label placements are shown in the following table.

<table>
<thead>
<tr>
<th>n</th>
<th>label placement</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>left</td>
</tr>
<tr>
<td>2</td>
<td>right</td>
</tr>
</tbody>
</table>

WAXIS=n
   specifies line thickness for axes and frame. The default value is 1.

WFIT=n
   specifies line thickness for fitted curves. The default value is 1.
WGRID=n
specifies line thickness for grids. The default value is 1.

WREFL=n
specifies line thickness for reference lines. The default value is 1.

**WEIGHT Statement**

```plaintext
WEIGHT variable ;
```

If you want to use weights for each observation in the input data set, place the weights in a variable in the data set and specify the name in a WEIGHT statement. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with nonpositive or missing values for the weight variable do not contribute to the fit of the model. The WEIGHT variable multiplies the contribution to the log likelihood for each observation.

**Details**

**Missing Values**

Any observation with missing values for the dependent variable is not used in the model estimation unless it is one and only one of the values in an interval specification. Also, if one of the explanatory variables or the censoring variable is missing, the observation is not used. For any observation to be used in the estimation of a model, only the variables needed in that model have to be nonmissing. Predicted values are computed for all observations with no missing explanatory variable values. If the censoring variable is missing, the CENSORED= variable in the OUT= SAS data set is also missing.

**Model Specification**

Main effects as well as interaction terms are allowed in the model specification, similar to the GLM procedure. For numeric variables, a main effect is a linear term equal to the value of the variable unless the variable appears in the CLASS statement. For variables listed in the CLASS statement, PROC LIFEREG creates indicator variables (variables taking the values zero or one) for every level of the variable except the last level. If there is no intercept term, the first class variable has indicator variables created for all levels including the last level. The levels are ordered according to the ORDER= option. Estimates of a main effect depend upon other effects in the model and, therefore, are adjusted for the presence of other effects in the model.

**Computational Method**

By default, the LIFEREG Procedure computes initial values for the parameters using ordinary least squares (OLS) ignoring censoring. This might not be the best set of starting values for a given set of data. For example, if there are extreme values in your data the OLS fit may be excessively influenced by the extreme observations, causing
an overflow or convergence problems. See Example 39.3 for one way to deal with convergence problems.

You can specify the INITIAL= option in the MODEL statement to override these starting values. You can also specify the INTERCEPT=, SCALE=, and SHAPE= options to set initial values of the intercept, scale, and shape parameters. For models with multilevel interaction effects, it is a little difficult to use the INITIAL= option to provide starting values for all parameters. In this case, you can use the INEST= data set. See the section “INEST= Data Set” on page 2121 for detail. The INEST= data set overrides all previous specifications for starting values of parameters.

The rank of the design matrix $X$ is estimated before the model is fit. Columns of $X$ that are judged linearly dependent on other columns have the corresponding parameters set to zero. The test for linear dependence is controlled by the SINGULAR= option in the MODEL statement. Variables are included in the model in the order in which they are listed in the MODEL statement with the nonclass variables included in the model before any class variables.

The log-likelihood function is maximized by means of a ridge-stabilized Newton-Raphson algorithm. The maximized value of the log likelihood can take positive or negative values, depending on the specified model and the values of the maximum likelihood estimates of the model parameters.

If convergence of the maximum likelihood estimates is attained, a Type III chi-square test statistic is computed for each effect, testing whether there is any contribution from any of the levels of the effect. This statistic is computed as a quadratic form in the appropriate parameter estimates using the corresponding submatrix of the asymptotic covariance matrix estimate. Refer to Chapter 32, “The GLM Procedure,” and Chapter 11, “The Four Types of Estimable Functions,” for more information about Type III estimable functions.

The asymptotic covariance matrix is computed as the inverse of the observed information matrix. Note that if the NOINT option is specified and class variables are used, the first class variable contains a contribution from an intercept term. The results are displayed in an ODS table named Type3Analysis.

Chi-square tests for individual parameters are Wald tests based on the observed information matrix and the parameter estimates. If an effect has a single degree of freedom in the parameter estimates table, the chi-square test for this parameter is equivalent to the Type III test for this effect.

In releases previous to Version 8.2, a multiple degree of freedom statistic was computed for each effect to test for contribution from any level of the effect. In general, the Type III test statistic in a main effect only model (no interaction terms) will be equal to the previously computed effect statistic, unless there are collinearities among the effects. If there are collinearities, the Type III statistic will adjust for them, and the value of the Type III statistic and the number of degrees of freedom might not be equal to those of the previous effect statistic.

Suppose there are $n$ observations from the model $y = X\beta + \sigma \epsilon$, where $X$ is an $n \times k$ matrix of covariate values (including the intercept), $y$ is a vector of responses, and
\( \epsilon \) is a vector of errors with survival function \( S \), cumulative distribution function \( F \), and probability density function \( f \). That is, \( S(t) = \Pr(\epsilon_i > t) \), \( F(t) = \Pr(\epsilon_i \leq t) \), and \( f(t) = \frac{dF(t)}{dt} \), where \( \epsilon_i \) is a component of the error vector. Then, if all the responses are observed, the log likelihood, \( L \), can be written as

\[
L = \sum \log \left( \frac{f(u_i)}{\sigma} \right)
\]

where \( u_i = \frac{1}{\sigma}(y_i - x_i^T \beta) \).

If some of the responses are left, right, or interval censored, the log likelihood can be written as

\[
L = \sum \log \left( \frac{f(u_i)}{\sigma} \right) + \sum \log (S(u_i)) + \sum \log (F(u_i)) + \sum \log (F(u_i) - F(v_i))
\]

with the first sum over uncensored observations, the second sum over right-censored observations, the third sum over left-censored observations, the last sum over interval-censored observations, and

\[
v_i = \frac{1}{\sigma}(z_i - x_i^T \beta)
\]

where \( z_i \) is the lower end of a censoring interval.

If the response is specified in the binomial format, \( \text{events/trials} \), then the log-likelihood function is

\[
L = \sum r_i \log(P_i) + (n_i - r_i) \log(1 - P_i)
\]

where \( r_i \) is the number of events and \( n_i \) is the number of trials for the \( i \)th observation. In this case, \( P_i = 1 - F(-x_i^T \beta) \). For the symmetric distributions, logistic and normal, this is the same as \( F(x_i^T \beta) \). Additional information on censored and limited dependent variable models can be found in Kalbfleisch and Prentice (1980) and Maddala (1983).

The estimated covariance matrix of the parameter estimates is computed as the negative inverse of \( I \), which is the information matrix of second derivatives of \( L \) with respect to the parameters evaluated at the final parameter estimates. If \( I \) is not positive definite, a positive definite submatrix of \( I \) is inverted, and the remaining rows and columns of the inverse are set to zero. If some of the parameters, such as the scale and intercept, are restricted, the corresponding elements of the estimated covariance matrix are set to zero. The standard error estimates for the parameter estimates are taken as the square roots of the corresponding diagonal elements.

For restrictions placed on the intercept, scale, and shape parameters, one-degree-of-freedom Lagrange multiplier test statistics are computed. These statistics are computed as

\[
\chi^2 = \frac{g^2}{V}
\]
where \( g \) is the derivative of the log likelihood with respect to the restricted parameter at the restricted maximum and

\[
V = I_{11} - I_{12}I_{22}^{-1}I_{21}
\]

where the 1 subscripts refer to the restricted parameter and the 2 subscripts refer to the unrestricted parameters. The information matrix is evaluated at the restricted maximum. These statistics are asymptotically distributed as chi-squares with one degree of freedom under the null hypothesis that the restrictions are valid, provided that some regularity conditions are satisfied. See Rao (1973, p. 418) for a more complete discussion. It is possible for these statistics to be missing if the observed information matrix is not positive definite. Higher degree-of-freedom tests for multiple restrictions are not currently computed.

A Lagrange multiplier test statistic is computed to test this constraint. Notice that this test statistic is comparable to the Wald test statistic for testing that the scale is one. The Wald statistic is the result of squaring the difference of the estimate of the scale parameter from one and dividing this by the square of its estimated standard error.

**Supported Distributions**

For each distribution, the baseline survival function \( S \) and the probability density function \( f \) are listed for the additive random disturbance \( y_0 \) or \( \log(T_0) \) with location parameter \( \mu \) and scale parameter \( \sigma \). See the section “Overview” on page 2083. These distributions apply when the log of the response is modeled (this is the default analysis). The corresponding survival function \( G \) and its density function \( g \) are given for the untransformed baseline distribution \( T_0 \).

For example, for the WEIBULL distribution, \( S(w) \) and \( f(w) \) are the survival function and the probability density function for the extreme value distribution (distribution of the log of the response) while \( G(t) \) and \( g(t) \) are the survival function and the probability density function of a Weibull distribution (using the untransformed response).

The chosen baseline functions define the meaning of the intercept, scale, and shape parameters. Only the gamma distribution has a free shape parameter in the following parameterizations. Notice that some of the distributions do not have mean zero and that \( \sigma \) is not, in general, the standard deviation of the baseline distribution.

Additionally, it is worth mentioning that, for the Weibull distribution, the accelerated failure time model is also a proportional-hazards model. However, the parameterization for the covariates differs by a multiple of the scale parameter from the parameterization commonly used for the proportional hazards model.

The distributions supported in the LIFEREG procedure follow. \( \mu = \text{Intercept} \) and \( \sigma = \text{Scale} \) in the output.
### Exponential

\[ S(w) = \exp(-\exp(w - \mu)) \]
\[ f(w) = \exp(w - \mu) \exp(-\exp(w - \mu)) \]
\[ G(t) = \exp(-\alpha t) \]
\[ g(t) = \alpha \exp(-\alpha t) \]

where \( \exp(-\mu) = \alpha \).

### Generalized Gamma

\[ S(w) = S'(u), \quad f(w) = \sigma^{-1} f'(u), \quad G(t) = G'(v), \quad g(t) = \frac{v}{t\sigma} g'(v). \quad u = \frac{w-\mu}{\sigma}, \quad v = \exp\left(\frac{\log(t)-\mu}{\sigma}\right), \]

and

\[
S'(u) = \begin{cases} 
1 - \frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta > 0 \\
\frac{\Gamma(\delta^{-2}, \delta^{-2} \exp(\delta u))}{\Gamma(\delta^{-2})} & \text{if } \delta < 0
\end{cases}
\]

\[
f'(u) = \frac{|\delta|}{\Gamma(\delta^{-2})} \left(\delta^{-2} \exp(\delta u)\right)^{\delta^{-2}} \exp\left(-\exp(\delta u)\delta^{-2}\right)
\]

\[
G'(v) = \begin{cases} 
1 - \frac{\Gamma(\delta^{-2}, \delta^{-2} v^{\delta})}{\Gamma(\delta^{-2})} & \text{if } \delta > 0 \\
\frac{\Gamma(\delta^{-2}, \delta^{-2} v^{\delta})}{\Gamma(\delta^{-2})} & \text{if } \delta < 0
\end{cases}
\]

\[
g'(v) = \frac{|\delta|}{v\Gamma(\delta^{-2})} \left(\delta^{-2} v^{\delta}\right)^{\delta^{-2}} \exp\left(-v^{\delta} \delta^{-2}\right)
\]

where \( \Gamma(a) \) denotes the complete gamma function, \( \Gamma(a, z) \) denotes the incomplete gamma function, and \( \delta \) is a free shape parameter. The \( \delta \) parameter is referred to as Shape by PROC LIFEREG. Refer to Lawless, 1982, p.240 and Klein and Moeschberger, 1997, p.386 for a description of the generalized gamma distribution.

### Loglogistic

\[ S(w) = \left(1 + \exp\left(\frac{w-\mu}{\sigma}\right)\right)^{-1} \]
\[ f(w) = \frac{\exp(\frac{w-\mu}{\sigma})}{\sigma \left(1 + \exp(\frac{w-\mu}{\sigma})\right)^2} \]
\[ G(t) = \frac{1}{1 + \alpha t^\gamma} \]
where $\gamma = 1/\sigma$ and $\alpha = \exp(-\mu/\sigma)$.

**Lognormal**

\[
S(w) = 1 - \Phi\left(\frac{w - \mu}{\sigma}\right)
\]
\[
f(w) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{1}{2} \left(\frac{w - \mu}{\sigma}\right)^2\right)
\]
\[
G(t) = 1 - \Phi\left(\frac{\log(t) - \mu}{\sigma}\right)
\]
\[
g(t) = \frac{1}{\sqrt{2\pi}\sigma t} \exp\left(-\frac{1}{2} \left(\frac{\log(t) - \mu}{\sigma}\right)^2\right)
\]

where $\Phi$ is the cumulative distribution function for the normal distribution.

**Weibull**

\[
S(w) = \exp\left(-\exp\left(\frac{w - \mu}{\sigma}\right)\right)
\]
\[
f(w) = \frac{1}{\sigma} \exp\left(\frac{w - \mu}{\sigma}\right) \exp\left(-\exp\left(\frac{w - \mu}{\sigma}\right)\right)
\]
\[
G(t) = \exp\left(-\alpha t^\gamma\right)
\]
\[
g(t) = \gamma \alpha t^{\gamma-1} \exp\left(-\alpha t^\gamma\right)
\]

where $\sigma = 1/\gamma$ and $\alpha = \exp(-\mu/\sigma)$.

If your parameterization is different from the ones shown here, you can still use the procedure to fit your model. For example, a common parameterization for the Weibull distribution is

\[
g(t; \lambda, \beta) = \left(\frac{\beta}{\lambda}\right)^\beta \left(\frac{t}{\alpha}\right)^{\beta-1} \exp\left(-\left(\frac{t}{\alpha}\right)^\beta\right)
\]
\[
G(t; \lambda, \beta) = \exp\left(-\left(\frac{t}{\lambda}\right)^\beta\right)
\]
so that \( \lambda = \exp(\mu) \) and \( \beta = 1/\sigma \).

Again note that the expected value of the baseline log response is, in general, not zero and that the distributions are not symmetric in all cases. Thus, for a given set of covariates, \( x \), the expected value of the log response is not always \( x'\beta \).

Some relations among the distributions are as follows:

- The gamma with \( \text{Shape}=1 \) is a Weibull distribution.
- The gamma with \( \text{Shape}=0 \) is a lognormal distribution.
- The Weibull with \( \text{Scale}=1 \) is an exponential distribution.

**Predicted Values**

For a given set of covariates, \( x \) (including the intercept term), the \( p \)th quantile of the log response, \( y_p \), is given by

\[
y_p = x'\beta + \sigma u_p
\]

where \( u_p \) is the \( p \)th quantile of the baseline distribution. The estimated quantile is computed by replacing the unknown parameters with their estimates, including any shape parameters on which the baseline distribution might depend. The estimated quantile of the original response is obtained by taking the exponential of the estimated log quantile unless the NOLOG option is specified in the preceding MODEL statement.

The standard errors of the quantile estimates are computed using the estimated covariance matrix of the parameter estimates and a Taylor series expansion of the quantile estimate. The standard error is computed as

\[
\text{STD} = \sqrt{z'Vz}
\]

where \( V \) is the estimated covariance matrix of the parameter vector \( (\beta', \sigma, \delta)' \), and \( z \) is the vector

\[
z = \begin{bmatrix} x \\ \hat{u}_p \\ \delta \frac{\partial u_p}{\partial \delta} \end{bmatrix}
\]

where \( \delta \) is the vector of the shape parameters. Unless the NOLOG option is specified, this standard error estimate is converted into a standard error estimate for \( \exp(y_p) \) as \( \exp(\hat{y}_p) \text{STD} \). It may be more desirable to compute confidence limits for the log response and convert them back to the original response variable than to use the standard error estimates for \( \exp(y_p) \) directly. See Example 39.1 for a 90% confidence interval of the response constructed by exponentiating a confidence interval for the log response.
The variable, CDF, is computed as

$$CDF_i = F(u_i)$$

where the residual

$$u_i = \left( \frac{y_i - x_i^t b}{\hat{\sigma}} \right)$$

and $F$ is the baseline cumulative distribution function.

**Confidence Intervals**

Confidence intervals are computed for all model parameters and are reported in the “Analysis of Parameter Estimates” table. The confidence coefficient can be specified with the ALPHA=\(\alpha\) MODEL statement option, resulting in a \((1 - \alpha) \times 100\%\) two-sided confidence coefficient. The default confidence coefficient is 95\%, corresponding to \(\alpha = .05\).

**Regression Parameters**

A two-sided \((1 - \alpha) \times 100\%\) confidence interval \([\beta_{iL}, \beta_{iU}]\) for the regression parameter \(\beta_i\) is based on the asymptotic normality of the maximum likelihood estimator \(\hat{\beta}_i\) and is computed by

$$\beta_{iL} = \hat{\beta}_i - z_{1-\alpha/2}(SE_{\hat{\beta}_i})$$
$$\beta_{iU} = \hat{\beta}_i + z_{1-\alpha/2}(SE_{\hat{\beta}_i})$$

where \(SE_{\hat{\beta}_i}\) is the estimated standard error of \(\hat{\beta}_i\), and \(z_p\) is the \(p \times 100\%\) percentile of the standard normal distribution.

**Scale Parameter**

A two-sided \((1 - \alpha) \times 100\%\) confidence interval \([\sigma_L, \sigma_U]\) for the scale parameter \(\sigma\) in the location-scale model is based on the asymptotic normality of the logarithm of the maximum likelihood estimator \(\log(\hat{\sigma})\), and is computed by

$$\sigma_L = \hat{\sigma}/\exp[z_{1-\alpha/2}(SE_{\hat{\sigma}})/\hat{\sigma}]$$
$$\sigma_U = \hat{\sigma} \exp[z_{1-\alpha/2}(SE_{\hat{\sigma}})/\hat{\sigma}]$$

Refer to Meeker and Escobar (1998) for more information.
Weibull Scale and Shape Parameters

The Weibull distribution scale parameter $\eta$ and shape parameter $\beta$ are obtained by transforming the extreme value location parameter $\mu$ and scale parameter $\sigma$:

\[
\eta = \exp(\mu)
\]

\[
\beta = \frac{1}{\sigma}
\]

Consequently, two-sided $(1 - \alpha) \times 100\%$ confidence intervals for the Weibull scale and shape parameters are computed as

\[
[\eta_L, \eta_U] = [\exp(\mu_L), \exp(\mu_U)]
\]

\[
[\beta_L, \beta_U] = \left[\frac{1}{\sigma_U}, \frac{1}{\sigma_L}\right]
\]

Gamma Shape Parameter

A two-sided $(1 - \alpha) \times 100\%$ confidence interval for the 3-parameter gamma shape parameter $\delta$ is computed by

\[
[\delta_L, \delta_U] = \left[\hat{\delta} - z_{1-\alpha/2}(SE_{\hat{\delta}}), \hat{\delta} + z_{1-\alpha/2}(SE_{\hat{\delta}})\right]
\]

Probability Plotting

Probability plots are useful tools for the display and analysis of lifetime data. Probability plots use an inverse distribution scale so that a cumulative distribution function (CDF) plots as a straight line. A nonparametric estimate of the CDF of the lifetime data will plot approximately as a straight line, thus providing a visual assessment of goodness-of-fit.

You can use the PROBPLOT statement in LIFEREG to create probability plots of data that are complete, right-censored, interval-censored, or a combination of censoring types (arbitrarily censored). A line representing the maximum likelihood fit from the MODEL statement and pointwise parametric confidence bands for the cumulative probabilities are also included on the plot.

A random variable $Y$ belongs to a location-scale family of distributions if its CDF $F$ is of the form

\[
Pr\{Y \leq y\} = F(y) = G\left(\frac{y - \mu}{\sigma}\right)
\]

where $\mu$ is the location parameter and $\sigma$ is the scale parameter. Here, $G$ is a CDF that cannot depend on any unknown parameters, and $G$ is the CDF of $Y$ if $\mu = 0$.
and $\sigma = 1$. For example, if $Y$ is a normal random variable with mean $\mu$ and standard deviation $\sigma$,

$$G(u) = \Phi(u) = \int_{-\infty}^{u} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{u^2}{2}\right) du$$

and

$$F(y) = \Phi\left(\frac{y - \mu}{\sigma}\right)$$

The normal, extreme value, and logistic distributions are location-scale models. The 3-parameter gamma distribution is a location-scale model if the shape parameter $\delta$ is fixed. If $T$ has a lognormal, Weibull, or log-logistic distribution, then $\log(T)$ has a distribution that is a location-scale model. Probability plots are constructed for lognormal, Weibull, and log-logistic distributions by using $\log(T)$ instead of $T$ in the plots.

Let $y_{(1)} \leq y_{(2)} \leq \ldots \leq y_{(n)}$ be ordered observations of a random sample with distribution function $F(y)$. A probability plot is a plot of the points $y_{(i)}$ against $m_i = G^{-1}(a_i)$, where $a_i = \hat{F}(y_{(i)})$ is an estimate of the CDF $F(y_{(i)}) = G\left(\frac{y_{(i)} - \mu}{\sigma}\right)$. The nonparametric CDF estimates $a_i$ are sometimes called plotting positions. The axis on which the points $m_i$ are plotted is usually labeled with a probability scale (the scale of $a_i$).

If $F$ is one of the location-scale distributions, then $y$ is the lifetime; otherwise, the log of the lifetime is used to transform the distribution to a location-scale model. If the data actually have the stated distribution, then $\hat{F} \approx F$,

$$m_i = G^{-1}(\hat{F}(y_{(i)})) \approx G^{-1}(G\left(\frac{y_{(i)} - \mu}{\sigma}\right)) = \frac{y_{(i)} - \mu}{\sigma}$$

and points $(y_{(i)}, m_i)$ should fall approximately on a straight line.

There are several ways to compute the nonparametric CDF estimates used in probability plots from lifetime data. These are discussed in the next two sections.

**Complete and Right-Censored Data**

The censoring times must be taken into account when you compute plotting positions for right-censored data. The modified Kaplan-Meier method described in the following section is the default method for computing nonparametric CDF estimates for display on probability plots. Refer to Abernethy (1996), Meeker and Escobar (1998), and Nelson (1982) for discussions of the methods described in the following sections.
Expected Ranks, Kaplan-Meier, and Modified Kaplan-Meier Methods

Let \( y(1) \leq y(2) \leq \ldots \leq y(n) \) be ordered observations of a random sample including failure times and censor times. Order the data in increasing order. Label all the data with reverse ranks \( r_i \), with \( r_1 = n, \ldots, r_n = 1 \). For the lifetime (not censoring time) corresponding to reverse rank \( r_i \), compute the survival function estimate

\[
S_i = \left[ \frac{r_i}{r_i + 1} \right] S_{i-1}
\]

with \( S_0 = 1 \). The expected rank plotting position is computed as \( a_i = 1 - S_i \). The option PPOS=EXPRANK specifies the expected rank plotting position.

For the Kaplan-Meier method,

\[
S_i = \left[ \frac{r_i - 1}{r_i} \right] S_{i-1}
\]

The Kaplan-Meier plotting position is then computed as \( a'_i = 1 - S_i \). The option PPOS=KM specifies the Kaplan-Meier plotting position.

For the modified Kaplan-Meier method, use

\[
S'_i = \frac{S_i + S_{i-1}}{2}
\]

where \( S_i \) is computed from the Kaplan-Meier formula with \( S_0 = 1 \). The plotting position is then computed as \( a''_i = 1 - S'_i \). The option PPOS=MKM specifies the modified Kaplan-Meier plotting position. If the PPOS option is not specified, the modified Kaplan-Meier plotting position is used as the default method.

For complete samples, \( a_i = i/(n+1) \) for the expected rank method, \( a'_i = i/n \) for the Kaplan-Meier method, and \( a''_i = (i - .5)/n \) for the modified Kaplan-Meier method. If the largest observation is a failure for the Kaplan-Meier estimator, then \( F_n = 1 \) and the point is not plotted.

Median Ranks

Let \( y(1) \leq y(2) \leq \ldots \leq y(n) \) be ordered observations of a random sample including failure times and censor times. A failure order number \( j_i \) is assigned to the \( i \)th failure:

\[
j_i = j_{i-1} + \Delta, \quad \text{where} \quad j_0 = 0
\]

The increment \( \Delta \) is initially 1 and is modified when a censoring time is encountered in the ordered sample. The new increment is computed as

\[
\Delta = \frac{(n + 1) - \text{previous failure order number}}{1 + \text{number of items beyond previous censored item}}
\]

The plotting position is computed for the \( i \)th failure time as

\[
a_i = \frac{j_i - .3}{n + .4}
\]
For complete samples, the failure order number \( j_i \) is equal to \( i \), the order of the failure in the sample. In this case, the preceding equation for \( a_i \) is an approximation to the median plotting position computed as the median of the \( i \)th-order statistic from the uniform distribution on \((0, 1)\). In the censored case, \( j_i \) is not necessarily an integer, but the preceding equation still provides an approximation to the median plotting position. The PPOS=MEDRANK option specifies the median rank plotting position.

### Arbitrarily Censored Data

The LIFEREG procedure can create probability plots for data that consists of combinations of exact, left-censored, right-censored, and interval-censored lifetimes, that is, arbitrarily censored data. The LIFEREG procedure uses an iterative algorithm developed by Turnbull (1976) to compute a nonparametric maximum likelihood estimate of the cumulative distribution function for the data. Since the technique is maximum likelihood, standard errors of the cumulative probability estimates are computed from the inverse of the associated Fisher information matrix. This algorithm is an example of the expectation-maximization (EM) algorithm. The default initial estimate assigns equal probabilities to each interval. You can specify different initial values with the PROBLIST= option. Convergence is determined if the change in the log likelihood between two successive iterations is less than delta, where the default value of delta is \(10^{-8}\). You can specify a different value for delta with the TOLLIKE= option. Iterations will be terminated if the algorithm does not converge after a fixed number of iterations. The default maximum number of iterations is 1000. Some data may require more iterations for convergence. You can specify the maximum allowed number of iterations with the MAXITEM= option in the PROBPLOT statement. The iteration history of the log likelihood is displayed if you specify the ITPRINTEM option. The iteration history of the estimated interval probabilities are also displayed if you specify both options ITPRINTEM and PRINTPROBS.

If an interval probability is smaller than a tolerance (\(10^{-6}\) by default) after convergence, the probability is set to zero, the interval probabilities are renormalized so that they add to one, and iterations are restarted. Usually the algorithm converges in just a few more iterations. You can change the default value of the tolerance with the TOLPROB= option. You can specify the NOPOLISH option to avoid setting small probabilities to zero and restarting the algorithm.

If you specify the ITPRINTEM option, a table summarizing the Turnbull estimate of the interval probabilities is displayed. The columns labeled “Reduced Gradient” and “Lagrange Multiplier” are used in checking final convergence of the maximum likelihood estimate. The Lagrange multipliers must all be greater than or equal to zero, or the solution is not maximum likelihood. Refer to Gentleman and Geyer (1994) for more details of the convergence checking. Also refer to Meeker and Escobar (1998, chap. 3) for more information.

See Example 39.6 on page 2142 for an illustration.

### Nonparametric Confidence Intervals

You can use the PPOUT option in the PROBPLOT statement to create a table containing the nonparametric CDF estimates computed by the selected method, Kaplan-Meier CDF estimates, standard errors of the Kaplan-Meier estimator, and nonpara-
metric confidence limits for the CDF. The confidence limits are either pointwise or simultaneous, depending on the value of the NPINTERV ALS= option in the PROBPLOT statement. The method used in the LIFEREG procedure for computation of approximate pointwise and simultaneous confidence intervals for cumulative failure probabilities relies on the Kaplan-Meier estimator of the cumulative distribution function of failure time and approximate standard deviation of the Kaplan-Meier estimator. For the case of arbitrarily censored data, the Turnbull algorithm, discussed previously, provides an extension of the Kaplan-Meier estimator. Both the Kaplan-Meier and the Turnbull estimators provide an estimate of the standard error of the CDF estimator, se, that is used in computing confidence intervals.

**Pointwise Confidence Intervals**

Approximate $(1 - \alpha)100\%$ pointwise confidence intervals are computed as in Meeker and Escobar (1998, section 3.6) as

$$[F_L, F_U] = \left[ \frac{\hat{F}}{\hat{F} + (1 - \hat{F})w}, \frac{\hat{F}}{\hat{F} + (1 - \hat{F})/w} \right]$$

where

$$w = \exp\left( \frac{z_{1-\alpha/2}se_{\hat{F}}}{\hat{F}(1 - \hat{F})} \right)$$

where $z_p$ is the $p$th quantile of the standard normal distribution.

**Simultaneous Confidence Intervals**

Approximate $(1 - \alpha)100\%$ simultaneous confidence bands valid over the lifetime interval $(t_a, t_b)$ are computed as the “Equal Precision” case of Nair (1984) and Meeker and Escobar (1998, section 3.8) as

$$[F_L, F_U] = \left[ \frac{\hat{F}}{\hat{F} + (1 - \hat{F})w}, \frac{\hat{F}}{\hat{F} + (1 - \hat{F})/w} \right]$$

where

$$w = \exp\left( \frac{e_{a,b,1-\alpha/2}se_{\hat{F}}}{\hat{F}(1 - \hat{F})} \right)$$

where the factor $x = e_{a,b,1-\alpha/2}$ is the solution of

$$x \exp(-x^2/2) \log \left( \frac{1 - a}{b} \right) / \sqrt{8\pi} = \alpha / 2$$
The time interval \((t_a, t_b)\) over which the bands are valid depends in a complicated way on the constants \(a\) and \(b\) defined in Nair (1984), \(0 < a < b < 1\). \(a\) and \(b\) are chosen by default so that the confidence bands are valid between the lowest and highest times corresponding to failures in the case of multiply censored data, or, to the lowest and highest intervals for which probabilities are computed for arbitrarily censored data. You can optionally specify \(a\) and \(b\) directly with the \text{NPINTERVALS=SIMULTANEOUS}(a, b)\ option in the \text{PROBPLOT} statement.

\textbf{INEST= Data Set}

If specified, the INEST= data set specifies initial estimates for all the parameters in the model. The INEST= data set must contain the intercept variable (named \texttt{Intercept}) and all independent variables in the \texttt{MODEL} statement.

If BY processing is used, the INEST= data set should also include the BY variables, and there must be at least one observation for each BY group. If there is more than one observation in one BY group, the first one read is used for that BY group.

If the INEST= data set also contains the \_TYPE\_ variable, only observations with \_TYPE\_ value ‘PARMS’ are used as starting values. Combining the INEST= data set and the \texttt{MAXITER=} option in the \texttt{MODEL} statement, partial scoring can be done, such as predicting on a validation data set by using the model built from a training data set.

You can specify starting values for the iterative algorithm in the INEST= data set. This data set overwrites the \texttt{INITIAL=} option in the \texttt{MODEL} statement, which is a little difficult to use for models including multilevel interaction effects. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set. One simple use of the INEST= option is passing the previous OUTEST= data set directly to the next model as an INEST= data set, assuming that the two models have the same parameterization. See Example 39.3 on page 2133 for an illustration.

\textbf{OUTEST= Data Set}

The OUTEST= data set contains parameter estimates and the log likelihood for the model. You can specify a label in the \texttt{MODEL} statement to distinguish between the estimates for different modeling using the \texttt{LIFEREG} procedure. If the \texttt{COVOUT} option is specified, the OUTEST= data set also contains the estimated covariance matrix of the parameter estimates. Note that, if the \texttt{LIFEREG} procedure does not converge, the parameter estimates are set to missing in the OUTEST data set.

The OUTEST= data set contains all variables specified in the \texttt{MODEL} statement and the \texttt{BY} statement. One observation consists of parameter values for the model with the dependent variable having the value \(-1\). If the \texttt{COVOUT} option is specified, there are additional observations containing the rows of the estimated covariance matrix. For these observations, the dependent variable contains the parameter estimate for the corresponding row variable. The following variables are also added to the data set:
Chapter 39. The LIFEREG Procedure

_a character variable containing the label of the MODEL statement, if present. Otherwise, the variable’s value is blank._

_a character variable containing the name of the dependent variable for the parameter estimates observations or the name of the row for the covariance matrix estimates._

_a character variable containing the type of the observation, either PARMS for parameter estimates or COV for covariance estimates._

_a character variable containing the name of the distribution modeled._

_a numeric variable containing the last computed value of the log likelihood._

_a numeric variable containing the intercept parameter estimates and covariances._

_a numeric variable containing the scale parameter estimates and covariances._

_a numeric variable containing the first shape parameter estimates and covariances if the specified distribution has additional shape parameters._

Any BY variables specified are also added to the OUTEST= data set.

**XDATA= Data Set**

The XDATA= data set is used for plotting the predicted probability when there are covariates specified in a MODEL statement and a probability plot is specified with a PROBPLOT statement. See Example 39.4 on page 2136 for an illustration.

The XDATA= data set is an input SAS data set that contains values for all the independent variables in the MODEL statement and variables in the CLASS statement. The XDATA= data set has the same structure as the DATA= data set but is not required to have all the variables or observations that appear in the DATA= data set.

The XDATA= data set must contain all the independent variables in the MODEL statement and variables in the CLASS statement. Even though variables in the CLASS statement may not be used, valid values are required for these variables in the XDATA= data set. Missing values are not allowed. Missing values are not allowed in the XDATA= data set for any of the independent variables either. Missing values are allowed for the dependent variables and other variables if they are included in the XDATA= data set.

If BY processing is used, the XDATA= data set should also include the BY variables, and there must be at least one valid observation for each BY group. If there is more than one valid observation in a BY group, the last one read is used for that BY group.

If there is no XDATA= data set in the PROC LIFEREG statement, by default, the LIFEREG procedure will use the overall mean for effects containing a continuous variable (or variables) and the highest level of a single classification variable as reference level. The rules are summarized as follows:
• If the effect contains a continuous variable (or variables), the overall mean of this effect (not the variables) is used.
• If the effect is a single classification variable, the highest level of the variable is used.

Computational Resources

Let $p$ be the number of parameters estimated in the model. The minimum working space (in bytes) needed is

$$16p^2 + 100p$$

However, if sufficient space is available, the input data set is also kept in memory; otherwise, the input data set is reread for each evaluation of the likelihood function and its derivatives, with the resulting execution time of the procedure substantially increased.

Let $n$ be the number of observations used in the model estimation. Each evaluation of the likelihood function and its first and second derivatives requires $O(np^2)$ multiplications and additions, $n$ individual function evaluations for the log density or log distribution function, and $n$ evaluations of the first and second derivatives of the function. The calculation of each updating step from the gradient and Hessian requires $O(p^3)$ multiplications and additions. The $O(v)$ notation means that, for large values of the argument, $v$, $O(v)$ is approximately a constant times $v$.

Displayed Output

For each model, PROC LIFEREG displays

• the name of the Data Set
• the name of the Dependent Variable
• the name of the Censoring Variable
• the Censoring Value(s) that indicate a censored observation
• the number of Noncensored and Censored Values
• the final estimate of the maximized log likelihood
• the iteration history and the Last Evaluation of the Gradient and Hessian if the ITPRINT option is specified (not shown)

For each explanatory variable in the model, the LIFEREG procedure displays

• the name of the Variable
• the degrees of freedom (DF) associated with the variable in the model
• the Estimate of the parameter
• the standard error (Std Err) estimate from the observed information matrix
• an approximate chi-square statistic for testing that the parameter is zero (the class variables also have an overall chi-square test statistic computed that precedes the individual level parameters)

• the probability of a larger chi-square value (Pr>Chi)

• the Label of the variable or, if the variable is a class level, the Value of the class variable

If there are constrained parameters in the model, such as the scale or intercept, then PROC LIFEREG displays a Lagrange multiplier test for the constraint.

**ODS Table Names**

PROC LIFEREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**Examples**

**Example 39.1. Motorette Failure**

This example fits a Weibull model and a lognormal model to the example given in Kalbfleisch and Prentice (1980, p. 5). An output data set called models is specified to contain the parameter estimates. By default, the natural log of the variable time
is used by the procedure as the response. After this log transformation, the Weibull model is fit using the extreme value baseline distribution, and the lognormal is fit using the normal baseline distribution.

Since the extreme value and normal distributions do not contain any shape parameters, the variable SHAPE1 is missing in the models data set. An additional output data set, out, is created that contains the predicted quantiles and their standard errors for values of the covariate corresponding to temp=130 and temp=150. This is done with the control variable, which is set to 1 for only two observations.

Using the standard error estimates obtained from the output data set, approximate 90% confidence limits for the predicted quantities are then created in a subsequent DATA step for the log response. The logs of the predicted values are obtained because the values of the P= variable in the OUT= data set are in the same units as the original response variable, time. The standard errors of the quantiles of the log(time) are approximated (using a Taylor series approximation) by the standard deviation of time divided by the mean value of time. These confidence limits are then converted back to the original scale by the exponential function. The following statements produce Output 39.1.1 through Output 39.1.5.

Example 39.2. Computing Predicted Values for a Tobit Model

The LIFEREG Procedure can be used to perform a Tobit analysis. The Tobit model, described by Tobin (1958), is a regression model for left-censored data assuming a normally distributed error term. The model parameters are estimated by maximum likelihood. PROC LIFEREG provides estimates of the parameters of the distribution of the uncensored data. Refer to Greene (1993) and Maddala (1983) for a more complete discussion of censored normal data and related distributions. This example shows how you can use PROC LIFEREG and the DATA step to compute two of the three types of predicted values discussed there.

Consider a continuous random variable \( Y \), and a constant \( C \). If you were to sample from the distribution of \( Y \) but discard values less than (greater than) \( C \), the distribution of the remaining observations would be truncated on the left (right). If you were to sample from the distribution of \( Y \) and report values less than (greater than) \( C \) as \( C \), the distribution of the sample would be left (right) censored.

The probability density function of the truncated random variable \( Y' \) is given by

\[
f_{Y'}(y) = \frac{f_Y(y)}{Pr(Y > C)} \text{ for } y > C
\]

where \( f_Y(y) \) is the probability density function of \( Y \). PROC LIFEREG cannot compute the proper likelihood function to estimate parameters or predicted values for a truncated distribution.

Suppose the model being fit is specified as follows:

\[
Y_i^* = x_i' \beta + \epsilon_i
\]

where \( \epsilon_i \) is a normal error term with zero mean and standard deviation \( \sigma \).

Define the censored random variable \( Y_i \) as

\[
Y_i = \begin{cases} 
0 & \text{if } Y_i^* \leq 0 \\
Y_i^* & \text{if } Y_i^* > 0 
\end{cases}
\]

This is the Tobit model for left-censored normal data. \( Y_i^* \) is sometimes called the latent variable. PROC LIFEREG estimates parameters of the distribution of \( Y_i^* \) by maximum likelihood.

You can use the LIFEREG procedure to compute predicted values based on the mean functions of the latent and observed variables. The mean of the latent variable \( Y_i^* \) is \( x_i' \beta \) and you can compute values of the mean for different settings of \( x_i \) by specifying XBETA=variable-name in an OUTPUT statement. Estimates of \( x_i' \beta \) for each observation will be written to the OUT= data set. Predicted values of the observed variable \( Y_i \) can be computed based on the mean

\[
E(Y_i) = \Phi \left( \frac{x_i' \beta}{\sigma} \right) \left( x_i' \beta + \sigma \lambda_i \right)
\]
Chapter 39. The LIFEREG Procedure

where

\[ \lambda_i = \frac{\phi(x'_i \beta/\sigma)}{\Phi(x'_i \beta/\sigma)} \]

\( \phi \) and \( \Phi \) represent the normal probability density and cumulative distribution functions.

Although the distribution of \( \epsilon_i \) in the Tobit model is often assumed normal, you can use other distributions for the Tobit model in the LIFEREG procedure by specifying a distribution with the DISTRIBUTION= option in the MODEL statement. One distribution should be mentioned is the logistic distribution. For this distribution, the MLE has bounded influence function with respect to the response variable, but not the design variables. If you believe your data has outliers in the response direction, you might try this distribution for some robust estimation of the Tobit model.

With the logistic distribution the predicted values of the observed variable \( Y_i \) can be computed based on the mean of \( Y_i^* \)

\[ E(Y_i) = \sigma \ln(1 + \exp(x'_i \beta/\sigma)) \]

The following table shows a subset of the Mroz (1987) data set. In this data, \texttt{Hours} is the number of hours the wife worked outside the household in a given year, \texttt{Yrs._Ed} is the years of education, and \texttt{Yrs._Exp} is the years of work experience. A Tobit model will be fit to the hours worked with years of education and experience as covariates.

Example 39.2. Computing Predicted Values for a Tobit Model

If the wife was not employed (worked 0 hours), her hours worked will be left-censored at zero. In order to accommodate left censoring in PROC LIFEREG, you need two variables to indicate censoring status of observations. You can think of these variables as lower and upper endpoints of interval censoring. If there is no censoring, set both variables to the observed value of Hours. To indicate left censoring, set the lower endpoint to missing and the upper endpoint to the censored value, zero in this case.

The following statements create a SAS data set with the variables Hours, Yrs_Ed, and Yrs_Exp from the preceding data. A new variable, Lower is created such that Lower=. if Hours=0 and Lower=Hours if Hours>0.

```sas
data subset;
  input Hours Yrs_Ed Yrs_Exp @@;
  if Hours eq 0
    then Lower=.;
  else Lower=Hours;
datalines;
0 8 9 0 8 12 0 9 10 0 10 15 0 11 4 0 11 6
1000 12 1 1960 12 29 0 13 3 2100 13 36
3686 14 11 1920 14 38 0 15 14 1728 16 3
1568 16 19 1316 17 7 0 17 15
;
```

The following statements fit a normal regression model to the left-censored Hours data using Yrs_Ed and Yrs_Exp as covariates. You will need the estimated standard deviation of the normal distribution to compute the predicted values of the censored distribution from the preceding formulas. The data set OUTEST contains the standard deviation estimate in a variable named _SCALE_. You also need estimates of $x_i^T \beta$. These are contained in the data set OUT as the variable Xbeta.

```sas
proc lifereg data=subset outest=OUTEST(keep=_scale_);
  model (lower, hours) = yrs_ed yrs_exp / d=normal;
  output out=OUT xbeta=Xbeta;
run;
```

Output 39.2.1 shows the results of the model fit. These tables show parameter estimates for the uncensored, or latent variable, distribution.
**Output 39.2.1.** Parameter Estimates from PROC LIFEREG

</tbody>
</table>

The following statements combine the two data sets created by PROC LIFEREG to compute predicted values for the censored distribution. The OUTEST= data set contains the estimate of the standard deviation from the uncensored distribution, and the OUT= data set contains estimates of $x_i^\prime \beta$.

```plaintext
data predict;
drop lambda _scale_ _prob_
set out;
if _n_ eq 1 then set outest;
lambda = pdf('NORMAL',Xbeta/_scale_)
/ cdf('NORMAL',Xbeta/_scale_);
Predict = cdf('NORMAL', Xbeta/_scale_)
* (Xbeta + _scale_*lambda);
label Xbeta='MEAN OF UNCENSORED VARIABLE'
Predict = 'MEAN OF CENSORED VARIABLE';
run;

proc print data=predict noobs label;
var hours lower yrs: xbeta predict;
run;
```

**Output 39.2.2** shows the original variables, the predicted means of the uncensored distribution, and the predicted means of the censored distribution.

The following statements combine the two data sets created by PROC LIFEREG to compute predicted values for the censored distribution. The OUTEST= data set contains the estimate of the standard deviation from the uncensored distribution, and the OUT= data set contains estimates of $x_i^\prime \beta$. 

```plaintext
data predict;
drop lambda _scale_ _prob_
set out;
if _n_ eq 1 then set outest;
lambda = pdf('NORMAL',Xbeta/_scale_)
/ cdf('NORMAL',Xbeta/_scale_);
Predict = cdf('NORMAL', Xbeta/_scale_)
* (Xbeta + _scale_*lambda);
label Xbeta='MEAN OF UNCENSORED VARIABLE'
Predict = 'MEAN OF CENSORED VARIABLE';
run;

proc print data=predict noobs label;
var hours lower yrs: xbeta predict;
run;
```
Example 39.3. Overcoming Convergence Problems by Specifying Initial Values

This example illustrates the use of parameter initial value specification to help overcome convergence difficulties.

The following statements create a data set and request a Weibull regression model be fit to the data.

```sas
data raw;
  input censor x c1 @@;
datalines;
0 16 0.00 0 17 0.00 0 18 0.00
0 17 0.04 0 18 0.04 0 18 0.04
0 23 0.40 0 22 0.40 0 22 0.40
0 33 4.00 0 34 4.00 0 35 4.00
1 54 40.00 1 54 40.00 1 54 40.00
1 54 400.00 1 54 400.00 1 54 400.00
;
run;

proc print;
run;

title 'OLS (default) initial values';
proc lifereg data=raw;
  model x*censor(1) = c1 / distribution = weibull itprint;
run;
```

Output 39.3.1 shows the data set contents.
Convergence was not attained in 50 iterations for this model, as the messages to the log indicate:

**WARNING:** Convergence was not attained in 50 iterations. You may want to increase the maximum number of iterations (**MAXITER=** option) or change the convergence criteria (**CONVERGE =** value) in the **MODEL** statement.

**WARNING:** The procedure is continuing in spite of the above warning. Results shown are based on the last maximum likelihood iteration. Validity of the model fit is questionable.

The first line (**iter=0**) of the iteration history table, in Output 39.3.2, shows the default initial ordinary least squares (OLS) estimates of the parameters.

**Output 39.3.2.** Initial Least Squares

<table>
<thead>
<tr>
<th>OLS (default) initial values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Iter</td>
</tr>
<tr>
<td>------</td>
</tr>
<tr>
<td>0</td>
</tr>
</tbody>
</table>

The log logistic distribution is more robust to large values of the response than the Weibull, so one approach to improving the convergence performance is to fit a log logistic distribution, and if this converges, use the resulting parameter estimates as initial values in a subsequent fit of a model with the Weibull distribution.

The following statements fit a log logistic distribution to the data.

```
proc lifereg data=raw;
    model x*censor(1) = c1 / distribution = llogistic;
run;
```

The algorithm converges, and the maximum likelihood estimates for the log logistic distribution are shown in Output 39.3.3.
Example 39.3. Overcoming Convergence Problems by Specifying Initial Values

Output 39.3.3. Estimates from the Log Logistic Distribution

The LIFEREG Procedure

- Number of Observations: 18
- Noncensored Values: 12
- Right Censored Values: 6
- Left Censored Values: 0
- Interval Censored Values: 0
- Name of Distribution: LLogistic
- Log Likelihood: 12.093136846

Analysis of Parameter Estimates

<table>
<thead>
<tr>
<th>Parameter</th>
<th>DF</th>
<th>Estimate</th>
<th>Standard Error</th>
<th>95% Confidence Limits</th>
<th>Chi-Square</th>
<th>Pr &gt; ChiSq</th>
</tr>
</thead>
<tbody>
<tr>
<td>Intercept</td>
<td>1</td>
<td>2.8983</td>
<td>0.0318</td>
<td>2.8360 - 2.9606</td>
<td>8309.43</td>
<td>&lt;.0001</td>
</tr>
<tr>
<td>c1</td>
<td>1</td>
<td>0.1592</td>
<td>0.0133</td>
<td>0.1332 - 0.1852</td>
<td>143.85</td>
<td>&lt;.0001</td>
</tr>
<tr>
<td>Scale</td>
<td>1</td>
<td>0.0498</td>
<td>0.0122</td>
<td>0.0308 - 0.0804</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The following statements re-fit the Weibull model using the maximum likelihood estimates from the log logistic fit as initial values.

```latex
proc lifereg data=raw outest=outest;
  model x*censor(1) = c1 / itprint distribution = weibull
                   intercept=2.898 initial=0.16 scale=0.05;
  output out=out xbeta=xbeta;
run;
```

Examination of the resulting output in Output 39.3.4 shows that the convergence problem has been solved by specifying different initial values.

As an example, the following invocation of PROC LIFEREG, using the INEST= data set providing starting values for the three parameters, is equivalent to the previous invocation.

```latex
data in;
  input intercept c1 scale;
datalines;
  2.898 0.16 0.05 ;
proc lifereg data=raw inest=in outest=outest;
  model x*censor(1) = c1 / itprint distribution = weibull;
  output out=out xbeta=xbeta;
run;
```

</table>

Algorithm converged.

Example 39.4. Analysis of Arbitrarily Censored Data with Interaction Effects

The following artificial data are for a study of the natural recovery time of mice after injection of a certain toxin. 20 mice were grouped by sex (SEX: 1 = Male, 2 = Female) with equal sizes. Their ages (in days) were recorded at the injection. Their recovery times (in minutes) were also recorded. Toxin density in blood was used to decide whether a mouse recovered. Mice were checked at two times for recovery. If a mouse had recovered at the first time, the observation is left-censored, and no further measurement is made. The variable time1 is set to missing and time2 is set to the measurement time to indicate left-censoring. If a mouse had not recovered at the first time, it was checked later at a second time. If it had recovered by the second measurement time, the observation is interval-censored and the variable time1 is set to the first measurement time and time2 is set to the second measurement time. If there was no recovery at the second measurement, the observation is right-censored, and time1 is set to the second measurement time and time2 is set to missing to indicate right-censoring.

The following statements create a SAS data set containing the data from the experiment and fit a Weibull model with age, sex, and age and sex interaction as covariates.

title 'Natural Recovery Time';
data mice;
  input sex age time1 time2 ;
datalines;
  1 57 631 631
  1 45 . 170
  1 54 227 227
  1 43 143 143
Example 39.4. Analysis of Arbitrarily Censored Data with Interaction Effects

```
data xrow1;
  input sex age time1 time2 ;
  datalines;
1 50 . . ;
```

```
data xrow2;
  input sex age time1 time2 ;
  datalines;
2 60.6 . . ;
```

```
proc lifereg data=mice xdata=xrow1;
  class sex ;
  model (time1, time2) = age sex age*sex / dist=Weibull;
  probplot / nodata
    font = swiss
    plower=.5
    vref(intersect) = 75
    vreflab = '75 Percent'
    vreflabpos = 2
    cfit=blue
    cframe=ligr
    ;
  inset / cfill = white
    ctext = blue;
run;
```

Standard output is shown in Output 39.4.1. Tables containing general model information, Type III tests for the main effects and interaction terms, and parameter estimates are created.

The following two plots display the predicted probability against the recovery time for two different populations. **Output 39.4.2** is created with the PROBPLOT statement with the option XDATA= xrow1, which specifies the population with sex = 1, age = 50. Although the SAS statements are not shown, **Output 39.4.3** is created with the PROBPLOT statement with the option XDATA= xrow2, which specifies the population with sex = 2, age = 60.6. These are the default values that the LIFEREG procedure would use for the probability plot if the XDATA= option had not been specified. Reference lines are used to display specified predicted probability points and their relative locations on the plot.
Output 39.4.2. Probability Plot for Recovery Time with sex = 1, age = 50

Output 39.4.3. Probability Plot for Recovery Time with sex = 2, age = 60.6
Example 39.5. Probability Plotting–Right Censoring

The following statements create a SAS data set containing observed and right-censored lifetimes of 70 diesel engine fans (Nelson 1982, p. 318).

```sas
title 'Engine Fan Lifetime Study';
data fan;
  input lifetime censor@@;
  lifetime = lifetime / 1000;
  label lifetime = 'Lifetime';
datalines;
  450 0  460 1  1150 0  1150 0  1560 1
  1600 0  1660 1  1850 1  1850 1  1850 1
  1850 1  1850 1  2030 1  2030 1  2030 1
  2070 0  2070 0  2080 0  2200 1  3000 1
  3000 1  3000 1  3000 1  3100 0  3200 1
  3450 0  3750 1  3750 1  4150 1  4150 1
  4150 1  4150 1  4300 1  4300 1  4300 1
  4300 1  4600 0  4850 1  4850 1  4850 1
  4850 1  5000 1  5000 1  5000 1  6100 1
  6100 0  6100 1  6100 1  6300 1  6450 1
  6450 1  6700 1  7450 1  7800 1  7800 1
  8100 1  8100 1  8200 1  8500 1  8500 1
  8500 1  8750 1  8750 0  8750 1  9400 1
  9900 0  10100 1  10100 1  10100 1  11500 1;
run;
```

Some of the fans had not failed at the time the data were collected, and the unfailed units have right-censored lifetimes. The variable LIFETIME represents either a failure time or a censoring time in thousands of hours. The variable CENSOR is equal to 0 if the value of LIFETIME is a failure time, and it is equal to 1 if the value is a censoring time. The following statements use the LIFEREG procedure to produce the probability plot with an inset for the engine lifetimes.

```sas
symbol v=dot c=white;
proc lifereg;
  model lifetime*censor( 1 ) = / d = weibull;
  probplot
    cencolor = red
    cframe   = ligr
    cfit     = blue
    ppout
    npintervals=simul;
  inset /
    cfill = white
    ctext = blue;
run;
```

The resulting graphical output is shown in Output 39.5.1. The estimated CDF, a line representing the maximum likelihood fit, and pointwise parametric confidence bands
are plotted in the body of Output 39.5.1. The values of right-censored observations are plotted along the top of the graph. The “Cumulative Probability Estimates” table is also created in Output 39.5.2.

Example 39.6. Probability Plotting–Arbitrarily Censoring

Table 39.3 contains microprocessor failure data from Nelson (1990). Units were inspected at predetermined time intervals. The data consist of inspection interval endpoints (in hours) and the number of units failing in each interval. A missing (.) lower endpoint indicates left censoring, and a missing upper endpoint indicates right censoring. These can be thought of as semi-infinite intervals with a lower (upper) endpoint of negative (positive) infinity for left (right) censoring.

  model ( t1 t2 ) = / d=lognormal intercept=25 scale=5;
  weight f;
```
The two initial values INTERCEPT= 25 and SCALE= 5 in the MODEL statement are used to aid convergence in the model-fitting algorithm. The following tables are created by the PROBPLOT statement in addition to the standard tabular output from the MODEL statement. Output 39.6.1 shows the iteration history for the Turnbull estimate of the CDF for the microprocessor data. With both options ITPRINTEM and PRINTPROBS specified in the PROBPLOT statement, this table contains the log likelihoods and interval probabilities for every 25th iteration and the last iteration. It would only contain the log likelihoods if the option PRINTPROBS were not specified.

**Output 39.6.1.** Iteration History for the Turnbull Estimate

Output 39.6.2. Summary for the Turnbull Algorithm

The table in Output 39.6.2 summarizes the Turnbull estimates of the interval probabilities, the reduced gradients, and Lagrange multipliers as described in the section “Arbitrarily Censored Data” on page 2119.

Output 39.6.3. Final CDF Estimates for Turnbull Algorithm

Output 39.6.3 shows the final estimate of the CDF, along with standard errors and nonparametric confidence limits. Two kinds of nonparametric confidence limits, pointwise or simultaneous, are available. The default is the pointwise nonparametric confidence limits. You can specify the simultaneous nonparametric confidence limits by the NPINTERVALS= SIMUL option.

Output 39.6.4 shows the CDF estimates, the maximum likelihood fit, and the pointwise parametric confidence limits plotted on a lognormal probability plot.

Chapter 40. The LIFETEST Procedure
Chapter 40
The LIFETEST Procedure

Overview

A common feature of lifetime or survival data is the presence of right-censored observations due either to withdrawal of experimental units or to termination of the experiment. For such observations, you know only that the lifetime exceeded a given value; the exact lifetime remains unknown. Such data cannot be analyzed by ignoring the censored observations because, among other considerations, the longer-lived units are generally more likely to be censored. The analysis methodology must correctly use the censored observations as well as the uncensored observations.

Usually, a first step in the analysis of survival data is the estimation of the distribution of the survival times. Survival times are often called failure times, and event times are uncensored survival times. The survival distribution function (SDF), also known as the survivor function, is used to describe the lifetimes of the population of interest. The SDF evaluated at $t$ is the probability that an experimental unit from the population will have a lifetime exceeding $t$, that is

$$S(t) = \Pr(T > t)$$

where $S(t)$ denotes the survivor function and $T$ is the lifetime of a randomly selected experimental unit. The LIFETEST procedure can be used to compute nonparametric estimates of the survivor function either by the product-limit method (also called the Kaplan-Meier method) or by the life-table method (also called the actuarial method).

Some functions closely related to the SDF are the cumulative distribution function (CDF), the probability density function (PDF), and the hazard function. The CDF, denoted $F(t)$, is defined as $1 - S(t)$ and is the probability that a lifetime does not exceed $t$. The PDF, denoted $f(t)$, is defined as the derivative of $F(t)$, and the hazard function, denoted $h(t)$, is defined as $f(t)/S(t)$. If the life-table method is chosen, the estimates of the probability density function and the hazard function can also be computed. Plots of these estimates can be produced by a graphical or line printer device, or by launching the experimental graphics based on the output delivery system (ODS). For specific information about the experimental graphics that is available in PROC LIFETEST, see the section “ODS Graphics” on page 2190.

An important task in the analysis of survival data is the comparison of survival curves. It is of interest to determine whether the underlying populations of $k$ ($k \geq 2$) samples have identical survivor functions. PROC LIFETEST provides nonparametic
Chapter 40. The LIFETEST Procedure

*k*-sample tests based on weighted comparisons of the estimated hazard rate of the individual population under the null and alternative hypotheses. Corresponding to various weight functions, a variety of tests can be specified, which include the log-rank test, Wilcoxon test, Tarone-Ware test, Peto-Peto test, modified Peto-Peto test, and the Fleming-Harrington $G_p$ family of tests. PROC LIFETEST also provides corresponding trend tests to detect ordered alternatives. Stratified tests can be specified to adjust for prognostic factors that affect the events rates in the various populations. A likelihood ratio test, based on an underlying exponential model, is also included to compare the survival curves of the samples.

There are other prognostic variables called covariates that are thought to be related to the failure time. These covariates can also be used to construct statistics to test for association between the covariates and the lifetime variable. PROC LIFETEST can compute two such test statistics: censored data linear rank statistics based on the exponential scores and the Wilcoxon scores. The corresponding tests are known as the log-rank test and the Wilcoxon test, respectively. These tests are computed by pooling over any defined strata, thus adjusting for the stratum variables.

### Getting Started

You can use the LIFETEST procedure to compute nonparametric estimates of the survivor functions, to compare survival curves, and to compute rank tests for association of the failure time variable with covariates.

For simple analyses, only the PROC LIFETEST and TIME statements are required. Consider a sample of survival data. Suppose that the time variable is $T$ and the censoring variable is $C$ with value 1 indicating censored observations. The following statements compute the product-limit estimate for the sample:

```latex
proc lifetest;
  time t*c(1);
run;
```

You can use the STRATA statement to divide the data into various strata. A separate survivor function is then estimated for each stratum, and tests of the homogeneity of strata are performed. However, if the GROUP= option is also specified in the STRATA statement, the GROUP= variable is used to identify the samples whose survivor functions are to be compared and the STRATA variables are used to define the strata for the stratified tests. You can specify covariates in the TEST statement. PROC LIFETEST computes linear rank statistics to test the effects of these covariates on survival.

For example, consider the results of a small randomized trial on rats. Suppose you randomize 40 rats that have been exposed to a carcinogen into two treatment groups (Drug X and Placebo). The event of interest is death from cancer induced by the carcinogen. The response is the time from randomization to death. Four rats died of other causes; their survival times are regarded as censored observations. Interest lies in whether the survival distributions differ between the two treatments.
The data set Exposed contains four variables: Days (survival time in days from treatment to death), Status (censoring indicator variable: 0 if censored and 1 if not censored), Treatment (treatment indicator), and Sex (gender: F if female and M if male).

```
proc format;
  value Rx 1='Drug X' 0='Placebo';
data exposed;
  input Days Status Treatment Sex $ @@;
  format Treatment Rx.;
datalines;
179 1 1 F  378 0 1 M
256 1 1 F  355 1 1 M
262 1 1 M  319 1 1 M
256 1 1 F  256 1 1 M
255 1 1 M  171 1 1 F
224 0 1 F  325 1 1 M
225 1 1 F  325 1 1 M
287 1 1 M  217 1 1 F
319 1 1 M  255 1 1 F
264 1 1 M  256 1 1 F
237 0 0 F  291 1 0 M
156 1 0 F  323 1 0 M
270 1 0 M  253 1 0 M
257 1 0 M  206 1 0 F
242 1 0 M  206 1 0 F
157 1 0 F  237 1 0 M
249 1 0 M  211 1 0 F
180 1 0 F  229 1 0 F
226 1 0 F  234 1 0 F
268 0 0 M  209 1 0 F
```

PROC LIFETEST is invoked to compute the product-limit estimate of the survivor function for each treatment and to compare the survivor functions between the two treatments.

```
ods html;
ods graphics on;

proc lifetest data=Exposed;
  time Days*Status(0);
  strata Treatment;
run;

ods graphics off;
ods html close;
```

In the TIME statement, the survival time variable, Days, is crossed with the censoring variable, Status, with the value 0 indicating censoring. That is, the values of Days are considered censored if the corresponding values of Status are 0; otherwise, they
are considered as event times. In the STRATA statement, the variable Treatment is specified, which indicates that the data are to be divided into strata based on the values of Treatment. PROC LIFETEST computes the product-limit estimate for each stratum and tests whether the survivor functions are identical across strata. The experimental ODS GRAPHICS statement is specified to display the estimated survivor functions.

The results of the analysis are displayed in the following figures.

**Figure 40.1** displays the product-limit survival estimate for the Drug X group (Treatment=1). The figure lists, for each observed time, the survival estimate, failure rate, standard error of the estimate, number of failures, and number of subjects remaining in the study.

**NOTE**: The marked survival times are censored observations.

**Figure 40.1**. Survivor Function Estimate for the Drug X-Treated Rats

**Figure 40.2** displays summary statistics of survival times for the Drug X group. It contains estimates of the 25th, 50th, and 75th percentiles and the corresponding 95% confidence limits.

The median survival time for rats in this treatment is 256 days. The mean and standard error are also displayed; however, it is noted that these values are underestimated because the largest observed time is censored and the estimation is restricted to the largest event time.

**Figure 40.5.** Number of Event and Censored Observations

Results of the comparison of survival curves between the two treatments are shown in Figure 40.6. The rank tests for homogeneity indicate a significant difference between the treatments ($p=0.0175$ for the log-rank test and $p=0.0249$ for the Wilcoxon test). Rats treated with Drug X live significantly longer than those treated with Placebo. The log-rank test, which places more weight on larger survival times, is more significant than the Wilcoxon test, which places more weight on early survival times. As noted earlier, the exponential model is not appropriate for the given survival data; consequently, the result of the likelihood ratio test should be ignored.

**Figure 40.7.** Plot of Estimated Survivor Functions (Experimental)

This graphical display is requested by specifying the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the LIFETEST procedure, see the section “ODS Graphics” on page 2190.

Next, suppose male rats and female rats are thought to have different survival rates, and you want to assess the treatment effect while adjusting for the gender differences. By specifying the variable Sex in the STRATA statement as a stratifying variable and by specifying the variable Treatment in the GROUP= option, you can carry out a stratified test to test Treatment while adjusting for Sex. The test statistics are computed by pooling over the strata defined by the values of Sex, thus controlling for the effect of Sex. The NOTABLE option is added to the PROC LIFETEST statement to avoid estimating a survival curve for each gender.

```plaintext
proc lifetest data=Exposed notable;
  time Days*Status(0);
  strata Sex / group=Treatment;
run;
```
Results of the stratified tests are shown in Figure 40.8. The treatment effect is statistically significant for both the log-rank test ($p=0.0071$) and the Wilcoxon test ($p=0.0150$). As compared to the results of the unstratified tests in Figure 40.6, the significance of the treatment effect has been sharpened by controlling for the effect of the gender of the subjects.

**Figure 40.8.** Results of the Stratified 2-sample Tests

Since Treatment is a binary variable, another way to study the effect of Treatment is to carry out a censored linear rank test with Treatment as an independent variable. Although this test is less popular than the 2-sample test, nevertheless, in situations where the independent variables are continuous and are difficult to discretize, it may be infeasible to perform the $k$-sample test. To compute the censored linear rank statistics to test the Treatment effect, Treatment is specified in the TEST statement.

```plaintext
proc lifetest data=Exposed notable;
  time Days*Status(0);
  test Treatment;
run;
```

**Figure 40.9.** Results of Linear Rank Tests of Treatment

Results of the linear rank tests are shown Figure 40.9. The $p$-values are very similar to those of the 2-sample tests in Figure 40.6.
With Sex as a prognostic factor that you want to control, you can compute a stratified linear rank statistic to test the effect of Treatment by specifying Sex in the STRATA statement and Treatment in the TEST statement. The NOTEST option is specified in the STRATA statement to suppress the \( k \)-sample tests for Sex.

```
proc lifetest data=Exposed notable;
  time Days*Status(0);
  strata Sex / notest;
  test Treatment;
run;
```

**Figure 40.10.** Result of Stratified Linear Rank Tests of Treatment

Results of the stratified linear rank tests are shown in Figure 40.10. The \( p \)-values are very similar to those of the stratified 2-sample tests in Figure 40.8.

**Syntax**

The following statements are available in PROC LIFETEST:

```
PROC LIFETEST < options >;
  TIME variable < *censor(list) >;
  BY variables;
  FREQ variable;
  ID variables;
  STRATA variable < (list) > < ... variable < (list) > >;
  SURVIVAL options;
  TEST variables;
```

The simplest use of PROC LIFETEST is to request the nonparametric estimates of the survivor function for a sample of survival times. In such a case, only the PROC LIFETEST statement and the TIME statement are required. You can use the STRATA statement to divide the data into various strata. A separate survivor function is then
estimated for each stratum, and tests of the homogeneity of strata are performed. However, if the GROUP= option is also specify in the STRATA statement, stratified tests are carried out to test the $k$ samples defined by the GROUP= variable while controlling for the effect of the STRATA variables. You can use the SURVIVAL statement to output the estimates of the survivor function into a SAS data set. You can specify covariates in the TEST statement. PROC LIFETEST computes linear rank statistics to test the effects of these covariates on survival.

The PROC LIFETEST statement invokes the procedure. All statements except the TIME statement are optional, and there is no required order for the statements following the PROC LIFETEST statement. The TIME statement is used to specify the variables that define the survival time and censoring indicator. The STRATA statement specifies a variable or set of variables defining the strata for the analysis. The SURVIVAL statement enables you to specify a transformation to be used in the computation of the confidence intervals; it also enables you to output simultaneous confidence intervals. The TEST statement specifies a list of numeric covariates to be tested for their association with the response survival time. Each variable is tested individually, and a joint test statistic is also computed. The ID statement provides a list of variables whose values are used to identify observations in the product-limit estimates of the survival function. When only the TIME statement appears, no strata are defined and no tests of homogeneity are performed.

### PROC LIFETEST Statement

```sas
PROC LIFETEST <options> ;
```

The PROC LIFETEST statement invokes the procedure. The following options can appear in the PROC LIFETEST statement and are described in alphabetic order. If no options are requested, PROC LIFETEST computes and displays product-limit estimates of the survival distribution within each stratum and tests the equality of the survival functions across strata.

</tbody>
</table>
**ALPHA=** value

specifies a number between 0.0001 and 0.9999 that sets the confidence level for the confidence intervals for the survivor function. The confidence level for the interval is 1 - ALPHA. For example, the option ALPHA=0.05 requests a 95% confidence interval for the SDF at each time point. The default value is 0.05.

**ALPHAQT=** value

specifies a number between 0.0001 and 0.9999 that sets the level for the confidence intervals for the quartiles of the survival time. The confidence level for the interval is 1 - ALPHAQT. For example, the option ALPHAQT=0.05 requests a 95% confidence interval for the quantiles of the survival time. The default value is 0.05.

**ANNOTATE=** SAS-data-set

specifies an input data set that contains appropriate variables for annotation of the traditional high-resolution graphics. The ANNOTATE= option enables you to add features (for example, labels explaining extreme observations) to plots produced on graphics devices. The ANNOTATE= option cannot be used if the **LINEPRINTER** option or the experimental ODS GRAPHICS statement is specified. The data set specified must be an ANNOTATE= type data set, as described in SAS/GRAPH Software: Reference.

The data set specified with the ANNOTATE= option in the PROC LIFETEST statement is “global” in the sense that the information in this data set is displayed on every plot produced by a single invocation of PROC LIFETEST.

**CENSOREDSYMBOL=** name | 'string'

**CS=** name | 'string'

specifies the symbol value for the censored observations in the traditional high-resolution graphics. The value, name or 'string', is the symbol value specification allowed in SAS/GRAPH software. The default is CS=CIRCLE. If you want to omit plotting the censored observations, specify CS=NONE. The CENSOREDSYMBOL= option cannot be used if the **LINEPRINTER** option or the experimental ODS GRAPHICS statement is specified.

**DATA=** SAS-data-set

names the SAS data set used by PROC LIFETEST. By default, the most recently created SAS data set is used.

**DESCRIPTION=** 'string'

**DES=** 'string'

specifies a descriptive string of up to 40 characters that appears in the “Description” field of the traditional high-resolution graphics catalog. The description does not appear on the plots. By default, PROC LIFETEST assigns a description of the form PLOT OF vname vs hname, where vname and hname are the names of the y variable and the x variable, respectively. The DESCRIPTION= option cannot be used if the **LINEPRINTER** option or the experimental ODS GRAPHICS is specified.
EVENTSYMBOL=\textit{name} | \'\textit{string}'

\textit{ES}=\textit{name} | \'\textit{string}'

specifies the symbol value for the event observations in the traditional high-resolution graphics. The value, \textit{name} or \'\textit{string}', is the symbol value specification allowed in SAS/GRAPH software. The default is ES=NONE. The EVENTSYMBOL= option cannot be used if the \textsc{lineprinter} option or the experimental ODS GRAPHICS statement is specified.

\textbf{FORMCHAR(1,2,7,9)=\textit{string}}

defines the characters used for constructing the vertical and horizontal axes of the line printer plots. The string should be four characters. The first and second characters define the vertical and horizontal bars, respectively, which are also used in drawing the \textit{steps} of the product-limit survival function. The third character defines the tick mark for the axes, and the fourth character defines the lower left corner of the plot. If the FORMCHAR option in PROC LIFETEST is not specified, the value supplied, if any, with the system option FORMCHAR= is used. The default is FORMCHAR(1,2,7,9)=\textquoteleft+\textquoteleft. Any character or hexadecimal string can be used to customize the plot appearance. To send the plot output to a printer with the IBM graphics character set (1 or 2) or display it directly on your PC screen, you can use the following hexadecimal representation

\begin{verbatim}
formchar(1,2,7,9)='B3C4C5C0'x
\end{verbatim}

or system option

\begin{verbatim}
formchar='B3C4DAC2BFC3C5B4C0C1D9'x
\end{verbatim}

\textbf{GOUT=\textit{graphics-catalog}}

specifies the graphics catalog for saving traditional high-resolution graphics output from PROC LIFETEST. The default is WORK.GSEG. The GOUT= option cannot be used if the \textsc{lineprinter} option or the experimental ODS GRAPHICS statement is specified. For more information, refer to the chapter titled “The GREPLAY Procedure” in \textit{SAS/GRAPH Software: Reference}.

\textbf{INTERVALS=\textit{values}}

specifies a list of interval endpoints for the life-table method. These endpoints must all be nonnegative numbers. The initial interval is assumed to start at zero whether or not zero is specified in the list. Each interval contains its lower endpoint but does not contain its upper endpoint. When this option is used with the product-limit method, it reduces the number of survival estimates displayed by displaying only the estimates for the smallest time within each specified interval. The INTERV ALS= option can be specified in any of the following ways:
list separated by blanks  \( \text{intervals}=1\ 3\ 5\ 7 \)
list separated by commas  \( \text{intervals}=1,3,5,7 \)
x to y  \( \text{intervals}=1\ to\ 7 \)
x to y by z  \( \text{intervals}=1\ to\ 7\ by\ 1 \)
combination of the above  \( \text{intervals}=1,3\ to\ 5,7 \)

For example, the specification

\[ \text{intervals}=5,10\ to\ 30\ by\ 10 \]

produces the set of intervals

\[ \{[0,5),[5,10),[10,20),[20,30),[30,\infty)\} \]

\text{LANNOTATE=}SAS-data-set

\text{LANN=}SAS-data-set

specifies an input data set that contains variables for local annotation of traditional high-resolution graphics. You can use the \text{LANNOTATE=} option to specify a different annotation for each \text{BY} group, in which case the \text{BY} variables must be included in the \text{LANNOTATE=} data set. The \text{LANNOTATE=} option cannot be used if the \text{LINEPRINTER} option or the experimental ODS GRAPHICS statement is specified. The data set specified must be an \text{ANNOTATE=} type data set, as described in \text{SAS/GRAPH Software: Reference}.

If there is no \text{BY}-group processing, the \text{ANNOTATE=} and \text{LANNOTATE=} options have the same effects.

\text{LINEPRINTER}

\text{LS}

specifies that plots are produced by a line printer instead of by a graphical device. This option cannot be used if the experimental ODS GRAPHICS statement is specified.

\text{MAXTIME=}value

specifies the maximum value of the time variable allowed on the plots so that outlying points do not determine the scale of the time axis of the plots. This parameter only affects the displayed plots and has no effect on the calculations.

\text{METHOD=}type

specifies the method used to compute the survival function estimates. Valid values for \text{type} are as follows.

\text{PL | KM} specifies that product-limit (PL) or Kaplan-Meier (KM) estimates are computed.

\text{ACT | LIFE | LT} specifies that life-table (or actuarial) estimates are computed.
PROC LIFETEST Statement

By default, METHOD=PL.

MISSING
allows missing values for numeric variables and blank values for character variables as valid stratum levels. See the section “Missing Values” on page 2171 for details.

By default, PROC LIFETEST does not use observations with missing values for any stratum variables.

NINTERVAL=value
specifies the number of intervals used to compute the life-table estimates of the survivor function. This parameter is overridden by the WIDTH= option or the INTERVALS= option. When you specify the NINTERVAL= option, PROC LIFETEST tries to find an interval that results in round numbers for the endpoints. Consequently, the number of intervals may be different from the number requested. Use the INTERVALS= option to control the interval endpoints. The default is NINTERVAL=10.

NOCENSPLOT
requests that the plot of censored observations be suppressed when the PLOTS= option is specified. This option is not needed when the life-table method is used to compute the survival estimates, since the plot of censored observations is not produced.

NOPRINT
suppresses the display of output. This option is useful when only an output data set is needed. Note that this option temporarily disables the Output Delivery System (ODS).

For more information, see Chapter 14, “Using the Output Delivery System.”

NOTABLE
suppresses the display of survival function estimates. Only the number of censored and event times, plots, and test results are displayed.

OUTSURV=SAS-data-set
OUTS=SAS-data-set
creates an output SAS data set to contain the estimates of the survival function and corresponding confidence limits for all strata. See the section “Output Data Sets” on page 2183 for more information on the contents of the OUTSURV=SAS data set.

OUTTEST=SAS-data-set
OUTT=SAS-data-set
creates an output SAS data set to contain the overall chi-square test statistic for association with failure time for the variables in the TEST statement, the values of the univariate rank test statistics for each variable in the TEST statement, and the estimated covariance matrix of the univariate rank test statistics. See the section “Output Data Sets” on page 2183 for more information on the contents of the OUTTEST=SAS data set.
Chapter 40. The LIFETEST Procedure

**PLOTS=** *(type <(NAME=name)>, ..., type <(NAME=name)>)*
creates plots of survival estimates or censored observations, where *type* is the type of plot and *name* is a catalog entry name of up to eight characters. Valid values of *type* are as follows:

- **CENSORED | C** specifies a plot of censored observations by strata (product-limit method only).
- **SURVIVAL | S** specifies a plot of the estimated SDF versus time.
- **LOGSURV | LS** specifies a plot of the $-\log(\text{estimated SDF})$ versus time.
- **LOGLOGS | LLS** specifies a plot of the $\log(-\log(\text{estimated SDF}))$ versus $\log(\text{time})$.
- **HAZARD | H** specifies a plot of the estimated hazard function versus time (life-table method only).
- **PDF | P** specifies a plot of the estimated probability density function versus time (life-table method only).

Parentheses are required in specifying the plots. For example,

```plaintext
plots = (s)
```
requests a plot of the estimated survivor function versus time, and

```plaintext
plots = (s(name=Surv2), h(name=Haz2))
```
requests a plot of the estimated survivor function versus time and a plot of the estimated hazard function versus time, with *Surv2* and *Haz2* as their catalog names, respectively.

**REDUCEOUT**
specifies that the OUTSURV= data set contains only those observations that are included in the INTERVALS= or TIMELIST= option. This option has no effect if the OUTSURV= option is not specified. It also has no effect if neither the INTERVALS= option nor the TIMELIST= option is specified.

**SINGULAR=** *value*
specifies the tolerance for testing singularity of the covariance matrix for the rank test statistics. The test requires that a pivot for sweeping a covariance matrix be at least this number times a norm of the matrix. The default value is 1E-12.

**TIMELIM=** *time-limit*
specifies the time limit used in the estimation of the mean survival time and its standard error. The mean survival time can be shown to be the area under the Kaplan-Meier survival curve. However, if the largest observed time in the data is censored, the area under the survival curve is not a closed area. In such a situation, you can choose a time limit $L$ and estimate the mean survival curve limited to a time $L$ (Lee 1992, pp. 72–76). This option is ignored if the largest observed time is an event time. Valid *time-limit* values are as follows:
EVENT | LET specifies that the time limit \( L \) is the largest event time in the data. TIMELIM=EVENT is the default.

OBSERVED | LOT specifies that the time limit \( L \) is the largest observed time in the data.

\( \text{number} \) specifies that the time limit \( L \) is the given \( \text{number} \). The \( \text{number} \) must be positive and at least as large as the largest event time in the data.

\( \text{TIMELIST=}\text{number-list} \)

specifies a list of time points at which the Kaplan-Meier estimates are displayed. The time points are listed in the column labeled as Timelist. Since the Kaplan-Meier survival curve is a decreasing step function, each given time point falls in an interval that has a constant survival estimate. The event time that corresponds to the beginning of the time interval is displayed along with its survival estimate.

\( \text{WIDTH=}\text{value} \)

sets the width of the intervals used in the life-table calculation of the survival function. This parameter is overridden by the INTERVALS= option.

**BY Statement**

\textbf{BY variables ;}

You can specify a BY statement with PROC LIFETEST to obtain separate analyses on observations in groups defined by the BY variables.

The BY statement is more efficient than the STRATA statement for defining strata in large data sets. However, if you use the BY statement to define strata, PROC LIFETEST does not pool over strata for testing the association of survival time with covariates nor does it test for homogeneity across the BY groups.

Interval size is computed separately for each BY group. When intervals are determined by default, they may be different for each BY group. To make intervals the same for each BY group, use the INTERVALS= option in the PROC LIFETEST statement.

When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the LIFETEST procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.
For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

**FREQ Statement**

```
FREQ variable;
```

The `variable` in the FREQ statement identifies a variable containing the frequency of occurrence of each observation. PROC LIFETEST treats each observation as if it appeared `n` times, where `n` is the value of the FREQ variable for the observation. The FREQ statement is useful for producing life tables when the data are already in the form of a summary data set. If not an integer, the frequency value is truncated to an integer. If the frequency value is less than one, the observation is not used.

**ID Statement**

```
ID variables;
```

The ID variable values are used to label the observations of the product-limit survival function estimates. SAS format statements can be used to format the values of the ID variables.

**STRATA Statement**

```
STRATA variable < (list) > < . . . variable < (list) > > < /options >;
```

The STRATA statement indicates which variables determine strata levels for the computations. The strata are formed according to the nonmissing values of the designated strata variables. The MISSING option can be used to allow missing values as a valid stratum level. Other options enable you to specify various $k$-sample tests, trend tests and stratified tests.

In the preceding syntax, `variable` is a variable whose values determine the stratum levels and `list` is a list of endpoints for a numeric variable. The values for `variable` can be formatted or unformatted. If the variable is a character variable, or if the variable is numeric and no list appears, then the strata are defined by the unique values of the strata variable. More than one variable can be specified in the STRATA statement, and each numeric variable can be followed by a list. Each interval contains its lower endpoint but does not contain its upper endpoint. The corresponding strata are formed by the combination of levels. If a variable is numeric and is followed by a list, then the levels for that variable correspond to the intervals defined by the list. The initial interval is assumed to start at $-\infty$ and the final interval is assumed to end at $\infty$.

The specification of STRATA variables can have any of the following forms:
list separated by blanks  strata age(5 10 20 30)
list separated by commas strata age(5,10,20,30)
x to y        strata age(5 to 10)
x to y by z  strata age(5 to 30 by 10)
combination of the above strata age(5,10 to 50 by 10)

For example, the specification

strata age(5,20 to 50 by 10) sex;

indicates the following levels for the Age variable

\{(\(\infty\), 5), [5, 20), [20, 30), [30, 40), [40, 50), [50, \(\infty\))\}

This statement also specifies that the age strata is further subdivided by values of the variable Sex. In this example, there are 6 age groups by 2 sex groups, forming a total of 12 strata.

The specification of several variables (for example, A B C) is equivalent to the A*B*C... syntax of the TABLES statement in the FREQ procedure. The number of strata levels usually grows very rapidly with the number of STRATA variables, so you must be cautious when specifying the list of STRATA variables.

The following options can appear in the STRATA statement after a slash (“/”). Other than the MISSING option, these options are dedicated to the tests of the two or more samples of survival data.

GROUP=variable
specifies the variable whose formatted values identify the various samples whose underlying survival curves are to be compared. The tests are stratified on the levels of the STRATA variables. For instance, in a multicenter trial in which two forms of therapy are to be compared, you specify the variable identifying therapies as the GROUP= variable and the variable identifying centers as the STRATA variable, in order to perform a stratified 2-sample test to compare the therapies while controlling the effect of the centers.

MISSING
allows missing values to be a stratum level or a valid value of the GROUP= variable.

NODETAIL
suppresses the display of the rank statistics and the corresponding covariance matrices for various strata. If the TREND option is specified, the display of the scores for computing the trend tests is suppressed.

NOTEST
suppresses the \(k\)-sample tests, stratified tests, and trend tests
TREND computes the trend tests for testing the null hypothesis that the k population hazards rate are the same versus an ordered alternatives. If there is only one STRATA variable and the variable is numeric, the unformatted values of the variable are used as the scores; otherwise, the scores are 1, 2, . . . , in the given order of the strata.

TEST=(list)

enables you to select the weight functions for the k-sample tests, stratified tests, or trend tests. You can specify a list containing one or more of the following keywords.

- LOGRANK specifies the log-rank test
- WILCOXON specifies the Wilcoxon test. The test is also referred to as the Gehan test or the Breslow test.
- TARONE specifies the Tarone-Ware test
- PETO specifies the Peto-Peto test. The test is also referred to as the Peto-Peto-Prentice test.
- MODPETO specifies the modified Peto-Peto test
- FLEMING(ρ1, ρ2) specifies the family of tests in Harrington and Fleming (1982), where ρ1 and ρ2 are nonegative numbers. FLEMING(ρ1,ρ2) reduces to the Fleming-Harrington Gρ family (Fleming and Harrington 1981) when ρ2=0, which you can specify FLEMING(ρ) with one argument. When ρ=0, the test becomes the log-rank test. When ρ=1, the test should be very close to the Peto-Peto test.
- LR specifies the likelihood ratio test based on the exponential model.
- ALL specifies all the nonparametric tests with ρ1=1 and ρ2=0 for the FLEMING( , ) test.

By default, TEST=(LOGRANK WILCOXON LR) for the k-sample tests, and TEST=(LOGRANK WILCOXON) for stratified and trend tests.

SURVIVAL Statement

SURVIVAL options;

The SURVIVAL statement creates an output SAS data set containing the results of the estimation of the survivor function. Although you can use the OUTSURV= option in the PROC LIFETEST statement to produce the output data set, the SURVIVAL statement enables you to output confidence bands and to specify a transformation of survival time in the computation of the pointwise confidence intervals and the confidence bands. Options in the PROC LIFETEST statements (ALPHA=, INTERVALS=, REDUCEOUT, and TIMELIST=) that applies to the OUTSURV= data can also be specified in the SURVIVAL statements. You can plot these survival estimates using the experimental ODS graphics (see the section “ODS Graphics” on page 2190).
Table 40.2. Summary of SURVIVAL Statement Options

<table>
<thead>
<tr>
<th>Task Options Description</th>

</tr>
</tbody>
</table>

\begin{align*}
\text{BANDMAXTIME} &= \text{value} \\
\text{BANDMAX} &= \text{value} \\
\text{BANDMINTIME} &= \text{value} \\
\text{BANDMIN} &= \text{value} \\
\text{CONFBAND} &= \text{keyword} \\
\text{CONFTYPE} &= \text{keyword}
\end{align*}

specifies the maximum time for the confidence bands. The default is the largest observed event time. If the specified BANDMAX= time exceeds the largest observed event time, it is truncated to the largest observed event time.

specifies the minimum time for the confidence bands. The default is the smallest observed event time. For the equal precision band, if the BANDMIN= value is less than the smallest observed event time, it is defaulted to the smallest observed event time.

specifies the confidence bands to output. Confidence bands are available only for the product-limit method. You can use the following keywords:

- ALL outputs both the Hall-Wellner and the equal precision confidence bands.
- EP outputs the equal precision confidence band.
- HW outputs the Hall and Wellner confidence band.

specifies the transformation applied to $S(t)$ to obtain the pointwise confidence intervals as well as the confidence bands. The following keywords can be used and the default is CONFTYPE=LOGLOG.

- ASINSQRT the arcsine-square root transformation

$$g(x) = \sin^{-1}(\sqrt{x})$$
LOGLOG the log-log transformation

\[ g(x) = \log(-\log(x)) \]

This is also referred to as the log cumulative hazard transformation since it is applying the logarithmic function \( \log(.) \) to the cumulative hazard function. Collett (1994) and Lachin (2000) refer it as the complementary log-log transformation.

LINEAR the identity transformation

\[ g(x) = x \]

LOG the logarithmic transformation

\[ g(x) = \log(x) \]

LOGIT the logit transformation

\[ g(x) = \log\left(\frac{x}{1-x}\right) \]

\( \text{OUT} = \text{SAS-Data-Set} \)

names the SAS data set that contains the survival estimates. If the OUT= option is omitted, PROC LIFETEST creates an output SAS data set with the default name DATA\( n \). If you do not want to create this output SAS data set, set OUT=\_NULL\_.

\( \text{STDERR} \)

specifies that the standard error of the survivor function (SDF\_STDERR) be output. If the life-table method is used, the standard error of the density function (PDF\_STDERR) and the standard error of the hazard function (HAZ\_STDERR) are also output.

**TEST Statement**

```
TEST variables ;
```

The TEST statement specifies a list of numeric (continuous) covariates that you want tested for association with the failure time.

Two sets of rank statistics are computed. These rank statistics and their variances are pooled over all strata. Univariate (marginal) test statistics are displayed for each of the covariates.

Additionally, a sequence of test statistics for joint effects of covariates is displayed. The first element of the sequence is the largest univariate test statistic. Other variables are then added on the basis of the largest increase in the joint test statistic. The process continues until all the variables have been added or until the remaining variables are linearly dependent on the previously added variables.

See the section “Rank Tests for the Association of Survival Time with Covariates” on page 2180 for more information.
TIME Statement

```
TIME variable < *censor(list) > ;
```

The TIME statement is required. It is used to indicate the failure time variable, where `variable` is the name of the failure time variable that can be optionally followed by an asterisk, the name of the censoring variable, and a parenthetical list of values that correspond to right censoring. The censoring values should be numeric, nonmissing values. For example, the statement

```
time T*Flag(1,2);
```

identifies the variable T as containing the values of the event or censored time. If the variable Flag has value 1 or 2, the corresponding value of T is a right-censored value.

Details

Missing Values

Observations with a missing value for either the failure time or the censoring variable are not used in the analysis. If a stratum variable value is missing, survival function estimates are computed for the strata labeled by the missing value, but these data are not used in any rank tests. However, the MISSING option can be used to request that missing values be treated as valid stratum values. If any variable specified in the TEST statement has a missing value, that observation is not used in the calculation of the rank statistics.

Computational Formulas

**Product-Limit Method**

Let \( t_1 < t_2 < \cdots < t_k \) represent the distinct event times. For each \( i = 1, \ldots, k \), let \( n_i \) be the number of surviving units, the size of the risk set, just prior to \( t_i \). Let \( d_i \) be the number of units that fail at \( t_i \), and let \( s_i = n_i - d_i \).

The product-limit estimate of the SDF at \( t_i \) is the cumulative product

\[
\hat{S}(t_i) = \prod_{j=1}^{i} \left( 1 - \frac{d_j}{n_j} \right)
\]

Notice that the estimator is defined to be right continuous; that is, the events at \( t_i \) are included in the estimate of \( S(t_i) \). The corresponding estimate of the standard error is computed using Greenwood’s formula (Kalbfleisch and Prentice 1980) as

\[
\hat{\sigma} \left( \hat{S}(t_i) \right) = \hat{S}(t_i) \sqrt{\sum_{j=1}^{i} \frac{d_j}{n_j s_j}}
\]
The first sample quartile of the survival time distribution is given by

\[ q_{0.25} = \frac{1}{2} (\inf \{ t : 1 - \hat{S}(t) \geq 0.25 \} + \sup \{ t : 1 - \hat{S}(t) \leq 0.25 \} ) \]

Confidence intervals for the quartiles are based on the sign test (Brookmeyer and Crowley 1982). The 100(1 - \( \alpha \))% confidence interval for the first quartile is given by

\[ I_{0.25} = \{ t : (1 - \hat{S}(t) - 0.25)^2 \leq c_\alpha \hat{\sigma}^2 (\hat{S}(t)) \} \]

where \( c_\alpha \) is the upper \( \alpha \) percentile of a central chi-squared distribution with 1 degree of freedom. The second and third sample quartiles and the corresponding confidence intervals are calculated by replacing the 0.25 in the last two equations by 0.50 and 0.75, respectively.

The estimated mean survival time is

\[ \hat{\mu} = \sum_{i=1}^{k} \hat{S}(t_{i-1})(t_i - t_{i-1}) \]

where \( t_0 \) is defined to be zero. When the largest observed time is censored, this sum underestimates the mean. The standard error of \( \hat{\mu} \) is estimated as

\[ \hat{\sigma}(\hat{\mu}) = \sqrt{\frac{m}{m-1} \sum_{i=1}^{k} \frac{A_i^2}{n_i s_i}} \]

where

\[ A_i = \sum_{j=i}^{k-1} \hat{S}(t_j)(t_{j+1} - t_j) \]

\[ m = \sum_{j=1}^{k} d_j \]

If the largest observed time is not an event, you can use the TIMELEIM= option to specify a time limit \( L \) and estimate the mean survival time limited to the time \( L \) and its standard error by replacing \( k \) by \( k + 1 \) with \( t_{k+1} = L \).

**Life-Table Method**

The life-table estimates are computed by counting the numbers of censored and uncensored observations that fall into each of the time intervals \([t_{i-1}, t_i)\), \( i = 1, 2, \ldots, k + 1 \), where \( t_0 = 0 \) and \( t_{k+1} = \infty \). Let \( n_i \) be the number of units entering the interval \([t_{i-1}, t_i]\), and let \( d_i \) be the number of events occurring in the interval. Let \( b_i = t_i - t_{i-1} \), and let \( n'_i = n_i - w_i / 2 \), where \( w_i \) is the number of units censored in
the interval. The effective sample size of the interval \([t_{i-1}, t_i)\) is denoted by \(n_i'\). Let \(t_{mi}\) denote the midpoint of \([t_{i-1}, t_i)\).

The conditional probability of an event in \([t_{i-1}, t_i)\) is estimated by

\[
\hat{q}_i = \frac{d_i}{n_i'}
\]

and its estimated standard error is

\[
\hat{\sigma}(\hat{q}_i) = \sqrt{\frac{\hat{q}_i\hat{p}_i}{n_i'}}
\]

where \(\hat{p}_i = 1 - \hat{q}_i\).

The estimate of the survival function at \(t_i\) is

\[
\hat{S}(t_i) = \begin{cases} 
1 & i = 0 \\
\hat{S}(t_{i-1})\hat{p}_{i-1} & i > 0
\end{cases}
\]

and its estimated standard error is

\[
\hat{\sigma}\left(\hat{S}(t_i)\right) = \hat{S}(t_i)\sqrt{\sum_{j=1}^{i-1} \frac{\hat{q}_j}{n_j'\hat{p}_j}}
\]

The density function at \(t_{mi}\) is estimated by

\[
\hat{f}(t_{mi}) = \frac{\hat{S}(t_i)\hat{q}_i}{b_i}
\]

and its estimated standard error is

\[
\hat{\sigma}\left(\hat{f}(t_{mi})\right) = \hat{f}(t_{mi})\sqrt{\sum_{j=1}^{i-1} \frac{\hat{q}_j}{n_j'\hat{p}_j} + \frac{\hat{p}_i}{n_i'\hat{q}_i}}
\]

The estimated hazard function at \(t_{mi}\) is

\[
\hat{h}(t_{mi}) = \frac{2\hat{q}_i}{b_i(1 + \hat{p}_i)}
\]

and its estimated standard error is

\[
\hat{\sigma}\left(\hat{h}(t_{mi})\right) = \hat{h}(t_{mi})\sqrt{\frac{1 - (b_i\hat{h}(t_{mi})/2)^2}{n_i'\hat{q}_i}}
\]
Let \( [t_{j-1}, t_j) \) be the interval in which \( \hat{S}(t_{j-1}) \geq \hat{S}(t_i)/2 > \hat{S}(t_j) \). The median residual lifetime at \( t_i \) is estimated by

\[
\hat{M}_i = t_{j-1} - t_i + b_j \frac{\hat{S}(t_{j-1}) - \hat{S}(t_i)/2}{\hat{S}(t_{j-1}) - \hat{S}(t_j)}
\]

and the corresponding standard error is estimated by

\[
\hat{\sigma}(\hat{M}_i) = \frac{\hat{S}(t_i)}{2 \hat{f}(t_{mj}) \sqrt{n_i}}
\]

### Interval Determination

If you want to determine the intervals exactly, use the `INTERVALS=` option in the `PROC LIFETEST` statement to specify the interval endpoints. Use the `WIDTH=` option to specify the width of the intervals, thus indirectly determining the number of intervals. If neither the `INTERVALS=` option nor the `WIDTH=` option is specified in the life-table estimation, the number of intervals is determined by the `NINTERVAL=` option. The width of the time intervals is 2, 5, or 10 times an integer (possibly a negative integer) power of 10. Let \( c = \log_{10}(\text{maximum observed time/number of intervals}) \), and let \( b \) be the largest integer not exceeding \( c \). Let \( d = 10^c \times b \) and let

\[
a = 2 \times I(d \leq 2) + 5 \times I(2 < d \leq 5) + 10 \times I(d > 5)
\]

with \( I \) being the indicator function. The width is then given by

\[
\text{width} = a \times 10^b
\]

By default, `NINTERVAL=10`.

### Pointwise Confidence Limits Added to the Output Data Set

Pointwise confidence limits are computed for the survivor function, and for the density function and hazard function when the life-table method is used. Let \( \alpha \) be specified by the `ALPHA=` option. Let \( z_{\alpha/2} \) be the critical value for the standard normal distribution. That is, \( \Phi(-z_{\alpha/2}) = \alpha/2 \), where \( \Phi \) is the cumulative distribution function of the standard normal random variable.

### Survival Function

When the computation of confidence limits for the survivor function \( S(t) \) is based on the asymptotic normality of the survival estimator \( \hat{S}(t) \), the approximate confidence interval may include impossible values outside the range \([0,1]\) at extreme values of \( t \). This problem can be avoided by applying the asymptotic normality to a transformation of \( S(t) \) for which the range is unrestricted. In addition, certain transformed confidence intervals for \( S(t) \) perform better than the usual linear confidence intervals (Borgan and Liestøl 1990). The `CONFTYPE=` option enables you to pick one of the following transformations: the log-log function (Kalbfleisch and Prentice 1980),
the arcsine-square root function (Nair 1984), the logit function (Meeker and Escobar 1998), the log function, and the linear function.

Let \( g \) be the transformation that is being applied to the survivor function \( S(t) \). By the delta method, the standard error of \( g(\hat{S}(t)) \) is estimated by

\[
\tau(t) = \hat{\sigma}(\hat{S}(t)) = g'(\hat{S}(t))\hat{\sigma}(\hat{S}(t))
\]

where \( g' \) is the first derivative of the function \( g \). The 100(1-\( \alpha \))% confidence interval for \( S(t) \) is given by

\[
g^{-1}\left(g(\hat{S}(t)) \pm z_{\alpha/2} g'(\hat{S}(t))\hat{\sigma}(\hat{S}(t))\right)
\]

where \( g^{-1} \) is the inverse function of \( g \).

**Arcsine-Square Root Transformation**

The estimated variance of \( \sin^{-1}(\sqrt{\hat{S}(t)}) \) is \( \hat{\tau}^2(t) = \frac{\hat{\sigma}^2[\hat{S}(t)]}{4\hat{S}(t)[1-\hat{S}(t)]} \). The 100(1-\( \alpha \))% confidence interval for \( S(t) \) is given by

\[
\sin^2\{\max[0, \sin^{-1}(\sqrt{\hat{S}(t)}) - z_{\alpha/2} \hat{\tau}(t)]\} \leq S(t) \leq \sin^2\{\min[\pi/2, \sin^{-1}(\sqrt{\hat{S}(t)}) + z_{\alpha/2} \hat{\tau}(t)]\}
\]

**Linear Transformation**

This is the same as having no transformation in which \( g \) is the identity. The 100(1-\( \alpha \))% confidence interval for \( S(t) \) is given by

\[
\hat{S}(t) - z_{\alpha/2} \hat{\sigma}(S(t))) \leq S(t) \leq \hat{S}(t) + z_{\alpha/2} \hat{\sigma}(S(t)))
\]

**Log Transformation**

The estimated variance of \( \log(\hat{S}(t)) \) is \( \hat{\tau}^2(t) = \frac{\hat{\sigma}^2(\hat{S}(t))}{S^2(t)} \). The 100(1-\( \alpha \))% confidence interval for \( S(t) \) is given by

\[
\hat{S}(t) \exp(z_{\alpha/2} \hat{\tau}(t)) \leq S(t) \leq \hat{S}(t) \exp(-z_{\alpha/2} \hat{\tau}(t))
\]

**Log-log Transformation**

The estimated variance of \( \log(-\log(\hat{S}(t))) \) is \( \hat{\tau}^2(t) = \frac{\hat{\sigma}^2[\hat{S}(t)]}{[\hat{S}(t) \log(\hat{S}(t))]^2} \). The 100(1-\( \alpha \))% confidence interval for \( S(t) \) is given by

\[
[\hat{S}(t)]^{\exp(z_{\alpha/2} \hat{\tau}(t))} \leq S(t) \leq [\hat{S}(t)]^{\exp(-z_{\alpha/2} \hat{\tau}(t))}
\]
Logit Transformation

The estimated variance of \( \log(\hat{S}(t)) \) is \( \hat{\tau}^2(t) = \frac{\hat{\sigma}^2(\hat{S}(t))}{S^2(t)[1-S(t)]^2} \). The 100(1-\( \alpha \))% confidence limits for \( S(t) \) are given by

\[
\frac{\hat{S}(t)}{S(t) + (1 - S(t)) \exp(z_{\frac{\alpha}{2}} \hat{\tau}(t))} \leq S(t) \leq \frac{\hat{S}(t)}{S(t) + (1 - \hat{S}(t)) \exp(-z_{\frac{\alpha}{2}} \hat{\tau}(t))}
\]

Density and Hazard Functions

For the life-table method, a 100(1-\( \alpha \))% confidence interval for hazard function or density function at time \( t \) is computed as

\[
\hat{g}(t) \pm z_{\frac{\alpha}{2}} \hat{\sigma}[\hat{g}(t)]
\]

where \( \hat{g}(t) \) is the estimate of either the hazard function or the density function at time \( t \), and \( \hat{\sigma}[\hat{g}(t)] \) is the corresponding standard error estimate.

Simultaneous Confidence Intervals for Kaplan-Meier Curve

The pointwise confidence interval for the survivor function \( S(t) \) is valid for a single fixed time at which the inference is to be made. In some applications, it is of interest to find the upper and lower confidence bands that guarantee, with a given confidence level, that the survivor function falls within the band for all \( t \) in some interval. Hall and Wellner (1980) and Nair (1984) provide two different approaches for deriving the confidence bands. An excellent review can be found in Klein and Moeschberger (1997). You can use CONFBAND= option in the SURVIVAL statement to select the confidence bands. The EP confidence band provides confidence bounds that are proportional to the pointwise confidence interval, while those of the HW band are not proportional to the pointwise confidence bounds. The maximum time, \( t_U \), for the bands can be specified by the BANDMAX= option; the minimum time, \( t_L \), can be specified by the BANDMIN= option. Transformations that are used to improve the pointwise confidence intervals can be applied to improve the confidence bands. It may turn out that the upper and lower bounds of the confidence bands are not decreasing in \( t_L < t < t_U \), which is contrary to the nonincreasing characteristic of survivor function. Meeker and Escobar (1998) suggest making an adjustment so that the bounds do not increase: if the upper bound is increasing on the right, it is made flat from the minimum to \( t_U \); if the lower bound is increasing from the right, it is made flat from \( t_L \) to the maximum. PROC LIFETEST does not make any adjustment for the nondecreasing behavior of the confidence bands in the OUT= data set. However, the adjustment was made in the display of the confidence bands using ODS graphics.

For Kaplan-Meier estimation, let \( t_1 < t_2 < \ldots < t_D \) be the \( D \) distinct events times, and that at time \( t_i \), there are \( d_i \) events. Let \( Y_i \) be the number of individuals who are at risk at time \( t_i \). The variance of \( \hat{S}(t) \), given by the Greenwood formula, is \( \hat{\sigma}^2[\hat{S}(t)] = \sigma^2_{S}(t)\hat{S}^2(t) \) where

\[
\sigma^2_{S}(t) = \sum_{t_i \leq t} \frac{d_i}{Y_i(Y_i - d_i)}
\]
Let $t_L < t_U$ be the time range for the confidence band so that $t_U$ is less than or equal to the largest event time. For the Hall-Wellner band, $t_L$ can be zero, but for the equal precision band, $t_L$ is greater than or equal to the smallest event time. Let

$$a_L = \frac{n \sigma_S^2(t_L)}{1 + n \sigma_S^2(t_L)} \quad \text{and} \quad a_U = \frac{n \sigma_S^2(t_U)}{1 + n \sigma_S^2(t_U)}$$

Let \(\{W^0(u), 0 \leq u \leq 1\}\) be a Brownian bridge.

**Hall-Wellner Band**

The 100(1-$\alpha$)% HW band of Hall and Wellner (1980) is

$$\hat{S}(t) - h_\alpha(a_L, a_U) n^{-\frac{1}{2}} [1 + n \sigma_S^2(t)] \hat{S}(t) \leq S(t) \leq \hat{S}(t) + h_\alpha(a_L, a_U) n^{-\frac{1}{2}} [1 + n \sigma_S^2(t)] \hat{S}(t)$$

for all $t_L \leq t \leq t_U$, where $h_\alpha(a_L, a_U)$ is given by

$$\alpha = \Pr\{ \sup_{a_L \leq u \leq a_U} |W^0(u)| > h_\alpha(a_L, a_U) \}$$

The critical values are computed from the results in Chung (1986).

Note that the given confidence band has a formula similar to that of the (linear) pointwise confidence interval where $h_\alpha(a_L, a_U)$ and $n^{-\frac{1}{2}} [1 + n \sigma_S^2(t)] \hat{S}(t)$ in the former correspond to $z_\frac{\alpha}{2}$ and $\hat{\sigma}(\hat{S}(t))$ in the latter, respectively. You can obtain the other transformations (arcsine-square root, log-log, log, and logit) for the confidence bands by replacing $z_\frac{\alpha}{2}$ and $\hat{\tau}(t)$ in the corresponding pointwise confidence interval formula by $h_\alpha(a_L, a_U)$ and the following $\hat{\tau}(t)$, respectively.

**Arcsine-Square Root Transformation**

$$\hat{\tau}(t) = \frac{1 + n \sigma_S^2(t)}{2} \sqrt{\frac{S(t)}{n[1 - S(t)]}}$$

**Log Transformation**

$$\hat{\tau}(t) = \frac{1 + n \sigma_S^2(t)}{\sqrt{n}}$$

**Log-log Transformation**

$$\hat{\tau}(t) = \frac{1 + n \sigma_S^2(t)}{\sqrt{n} \log[|S(t)|]}$$

**Logit Transformation**

$$\hat{\tau}(t) = \frac{1 + n \sigma_S^2(t)}{\sqrt{n}[1 - S(t)]}$$
Equal Precision Band

The 100(1-α)% EP band of Nair (1984) is

\[ \hat{S}(t) - e_\alpha(a_L, a_U)\hat{S}(t)\sigma_S(t) \leq S(t) \leq \hat{S}(t) + e_\alpha(a_L, a_U)\hat{S}(t)\sigma_S(t) \]

for all \( t_L \leq t \leq t_U \), where \( e_\alpha(a_L, a_U) \) is given by

\[ \alpha = \Pr\{ \sup_{a_L \leq u \leq a_U} \frac{|W^0(u)|}{u(1-u)}^{\frac{1}{2}} > e_\alpha(a_L, a_U) \} \]

PROC LIFETEST uses the approximation of Miller and Siegmund (1982, Equation 8) to approximate the tail probability in which \( e_\alpha(a_L, a_U) \) is obtained by solving \( x \) in

\[ \frac{4x\phi(x)}{x} + \phi(x) \left( x - \frac{1}{x} \right) \log \left[ \frac{a_U(1-a_L)}{a_L(1-a_U)} \right] = \alpha \]

where \( \phi() \) is the standard normal density. Note that the given confidence bounds are proportional to the pointwise confidence intervals. As a matter of fact, this confidence band and the (linear) pointwise confidence interval have the same formula except for the critical values (\( z^2_\alpha \) for the pointwise confidence interval and \( e_\alpha(a_L, a_U) \) for the band). You can obtain the other transformations (arcsine-square root, log-log, log, and logit) for the confidence bands by replacing \( z^2_\alpha \) by \( e_\alpha(a_L, a_U) \) in the formulae of the pointwise confidence intervals.

Comparison of Two or More Groups of Survival Data

Let \( k \) be the number of groups. Let \( S_i(t) \) be the underlying survivor function \( i \)th group, \( i = 1, \ldots, k \). The null and alternative hypotheses to be tested are

\[ H_0 : S_1(t) = S_2(t) = \ldots = S_k(t) \text{ for all } t \leq \tau \]

versus

\[ H_1 : \text{at least one of the } S_i(t) \text{’s is different for some } t \leq \tau \]

respectively, where \( \tau \) is the largest observed time. Let \( t_1 < t_2 < \ldots < t_D \) be the distinct event times in the pooled sample. At time \( t_i \), let \( W(t_i) \) be a positive weight function, and let \( n_{ij} \) and \( d_{ij} \) be the size of the risk set and the number of events in the \( j \)th sample, respectively. Let \( n_i = \sum_{j=1}^{k} n_{ij}, d_i = \sum_{j=1}^{k} d_{ij} \text{ and } s_i = n_i - d_i \).

Nonparametric tests

The rank statistics (Klein and Moeschberger 1997, Section 7.3) for testing \( H_0 \) versus \( H_1 \) have the form of a \( k \)-vector \( v = (v_1, v_2, \ldots, v_k)' \) with

\[ v_j = \sum_{i=1}^{D} W(t_i) \left\{ d_{ij} - \frac{n_{ij}d_i}{n_i} \right\} \]
and the estimated covariance matrix, \( V = (V_{jl}) \), is given by

\[
V_{jl} = \sum_{i=1}^{D} W^2(t_i) \left\{ \frac{d_i s_i (n_i n_d \delta_{jl} - n_{ij} n_{id})}{n_i^2 (n_i - 1)} \right\}
\]

where \( \delta_{jl} \) is 1 if \( j = l \) and 0 otherwise. The term \( v_j \) can be interpreted as a weighted sum of observed minus expected numbers of failure under the null hypothesis of identical survival curves. The overall test statistic for homogeneity is \( \mathbf{v}^\top \mathbf{V}^\top \mathbf{v} \), where \( \mathbf{V}^\top \) denotes a generalized inverse of \( \mathbf{V} \). This statistic is treated as having a chi-square distribution with degrees of freedom equal to the rank of \( \mathbf{V} \) for the purposes of computing an approximate probability level. The choices of the weight function \( W(t_i) \) are given in the following table:

<table>
<thead>
<tr>
<th>Test</th>
<th>( W(t_i) )</th>
</tr>
</thead>
<tbody>
<tr>
<td>log-rank</td>
<td>1.0</td>
</tr>
<tr>
<td>Wilcoxon</td>
<td>( n_i )</td>
</tr>
<tr>
<td>Tarone-Ware</td>
<td>( \sqrt{n_i} )</td>
</tr>
<tr>
<td>Peto-Peto</td>
<td>( \hat{S}(t_i) )</td>
</tr>
<tr>
<td>modified Peto-Peto</td>
<td>( \hat{S}(t_i) \frac{n_i}{n_i+1} )</td>
</tr>
<tr>
<td>Harrington-Fleming ((p,q))</td>
<td>( [\hat{S}(t_i)]^p [1 - \hat{S}(t_i)]^q ), ( p \geq 0, q \geq 0 )</td>
</tr>
</tbody>
</table>

where \( \hat{S}(t) \) is the product-limit estimate at \( t \) for the pooled sample, and \( \tilde{S}(t) \) is a survivor function estimate close to \( \hat{S}(t) \) given by

\[
\tilde{S}(t) = \prod_{t_i \leq t} \left( 1 - \frac{d_i}{n_i+1} \right)
\]

**Likelihood Ratio Test**

The likelihood ratio test statistic (Lawless 1982) for test \( H_0 \) versus \( H_1 \) assumes that the data in the various samples are exponentially distributed and tests that the scale parameters are equal. The test statistic is computed as

\[
Z = 2N \log \left( \frac{T}{N} \right) - 2 \sum_{j=1}^{k} N_j \log \left( \frac{T_j}{N_j} \right)
\]

where \( N_j \) is the total number of events in the \( j \)th stratum, \( N = \sum_{j=1}^{k} N_j \), \( T_j \) is the total time on test in the \( j \)th stratum, and \( T = \sum_{j=1}^{k} T_j \). The approximate probability value is computed by treating \( Z \) as having a chi-square distribution with \( c - 1 \) degrees of freedom.

**Trend Tests**

Trend tests (Klein and Moeschberger 1997, Section 7.4) have more power to detect ordered alternatives as
Let $a_1 < a_2 < \ldots < a_k$ be a sequence of scores associated with the $k$ samples. The test statistic and its standard error are given by

$$\sum_{j=1}^{k} a_j v_j \quad \text{and} \quad \sum_{j=1}^{k} \sum_{l=1}^{k} a_j a_l V_{jl}$$

respectively. Under $H_0$, the $z$–score

$$Z = \frac{\sum_{j=1}^{k} a_j v_j}{\sqrt{\sum_{j=1}^{k} \sum_{l=1}^{k} a_j a_l V_{jl}}}$$

has, asymptotically, a standard normal distribution.

**Stratified Tests**

Suppose the test is to be stratified on $M$ levels of a set of STRATA variables. Based only on the data of the $s$th stratum ($s = 1 \ldots M$), let $v_s$ be the test statistic (Klein and Moeschberger 1997, Section 7.5) for the $s$th stratum, and let $V_s$ be its covariance matrix. A global test statistic is constructed as

$$\chi^2 = \left( \sum_{i=1}^{M} v_s \right)' \left( \sum_{i=1}^{M} V_s \right)^{-1} \left( \sum_{i=1}^{M} v_s \right)$$

Under the null hypothesis, the test statistic has a $\chi^2$ distribution with the same df as the individual test for each stratum.

**Rank Tests for the Association of Survival Time with Covariates**

The rank tests for the association of covariates (Kalbfleisch and Prentice 1980, Chapter 6) are more general cases of the rank tests for homogeneity. In this section, the index $\alpha$ is used to label all observations, $\alpha = 1, 2, \ldots, n$, and the indices $i, j$ range only over the observations that correspond to events, $i, j = 1, 2, \ldots, k$. The ordered event times are denoted as $t_{(i)}$, the corresponding vectors of covariates are denoted as $z_{(i)}$, and the ordered times, both censored and event times, are denoted as $t_{\alpha}$.

The rank test statistics have the form

$$v = \sum_{\alpha=1}^{n} c_{\alpha, \delta_{\alpha}} z_{\alpha}$$

where $n$ is the total number of observations, $c_{\alpha, \delta_{\alpha}}$ are rank scores, which can be either log-rank or Wilcoxon rank scores, $\delta_{\alpha}$ is 1 if the observation is an event and 0 if the observation is censored, and $z_{\alpha}$ is the vector of covariates in the TEST statement for the $\alpha$th observation. Notice that the scores, $c_{\alpha, \delta_{\alpha}}$, depend on the censoring pattern and that the terms are summed up over all observations.
The log-rank scores are
\[ c_{\alpha,\delta} = \sum_{(j:t(j) \leq t_\alpha)} \left( \frac{1}{n_j} - \delta_\alpha \right) \]
and the Wilcoxon scores are
\[ c_{\alpha,\delta} = 1 - (1 + \delta_\alpha) \prod_{(j:t(j) \leq t_\alpha)} \frac{n_j}{n_j + 1} \]
where \( n_j \) is the number at risk just prior to \( t(j) \).

The estimates used for the covariance matrix of the log-rank statistics are
\[ V = \sum_{i=1}^{k} \frac{V_i}{n_i} \]
where \( V_i \) is the corrected sum of squares and crossproducts matrix for the risk set at time \( t(i) \); that is,
\[ V_i = \sum_{(\alpha:t_\alpha \geq t(i))} (z_\alpha - \bar{z}_i)'(z_\alpha - \bar{z}_i) \]
where
\[ \bar{z}_i = \sum_{(\alpha:t_\alpha \geq t(i))} \frac{z_\alpha}{n_i} \]

The estimate used for the covariance matrix of the Wilcoxon statistics is
\[ V = \sum_{i=1}^{k} \left[ a_i(1 - a_i^*) (2z_{(i)} x_i' + S_i) - (a_i^* - a_i) \left( a_i x_i x_i' + \sum_{j=i+1}^{k} a_j (x_i x_j' + x_j x_i') \right) \right] \]
where
\[ a_i = \prod_{j=1}^{i} \frac{n_j}{n_j + 1} \]
\[ a_i^* = \prod_{j=1}^{i} \frac{n_j + 1}{n_j + 2} \]
\[ S_i = \sum_{(\alpha:t_\alpha > t_{i+1})} z_\alpha z_\alpha' \]
\[ x_i = 2z_{(i)} + \sum_{(\alpha:t_\alpha > t_{i+1})} z_\alpha \]
In the case of tied failure times, the statistics $v$ are averaged over the possible orderings of the tied failure times. The covariance matrices are also averaged over the tied failure times. Averaging the covariance matrices over the tied orderings produces functions with appropriate symmetries for the tied observations; however, the actual variances of the $v$ statistics would be smaller than the preceding estimates. Unless the proportion of ties is large, it is unlikely that this will be a problem.

The univariate tests for each covariate are formed from each component of $v$ and the corresponding diagonal element of $V$ as $v^2_i/V_{ii}$. These statistics are treated as coming from a chi-square distribution for calculation of probability values.

The statistic $v'V^{-1}v$ is computed by sweeping each pivot of the $V$ matrix in the order of greatest increase to the statistic. The corresponding sequence of partial statistics is tabulated. Sequential increments for including a given covariate and the corresponding probabilities are also included in the same table. These probabilities are calculated as the tail probabilities of a chi-square distribution with one degree of freedom. Because of the selection process, these probabilities should not be interpreted as $p$-values.

If desired for data screening purposes, the output data set requested by the OUTTEST= option can be treated as a sum of squares and crossproducts matrix and processed by the REG procedure using the option METHOD=RSQUARE. Then the sets of variables of a given size can be found that give the largest test statistics. Example 40.1 illustrates this process.

**Computer Resources**

The data are first read and sorted into strata. If the data are originally sorted by failure time and censoring state, with smaller failure times coming first and event values preceding censored values in cases of ties, the data can be processed by strata without additional sorting. Otherwise, the data are read into memory by strata and sorted.

**Memory Requirements**

For a given BY group, define

- $N$ the total number of observations
- $V$ the number of STRATA variables
- $C$ the number of covariates listed on the TEST statement
- $L$ total length of the ID variables in bytes
- $S$ number of strata
- $n$ maximum number of observations within strata
- $b$ $12 + 8C + L$
- $m1$ $(112 + 16V) \times S$
- $m2$ $50 \times b \times S$
The memory, in bytes, required to process the BY-group is at least

\[ m_1 + \max(m_2, m_3) + m_4 \]

The test of equality of survival functions across strata requires additional memory (\(m_5\) bytes). However, if this additional memory is not available, PROC LIFETEST skips the test for equality of survival functions and finishes the other computations. Additional memory is required for the PLOTS= option. Temporary storage of 16\(n\) bytes is required to store the product-limit estimates for plotting.

### Output Data Sets

#### OUTSURV= Data Set

You can specify either the OUTSURV= option in the PROC LIFETEST statement to create an output data set containing the following columns:

- any specified BY variables
- any specified STRATA variables, their values coming from either their original values or the midpoints of the stratum intervals if endpoints are used to define strata (semi-infinite intervals are labeled by their finite endpoint)
- STRATUM, a numeric variable that numbers the strata
- the time variable as given in the TIME statement. In the case of the product-limit estimates, it contains the observed failure or censored times. For the life-table estimates, it contains the lower endpoints of the time intervals.
- SURVIVAL, a variable containing the survivor function estimates
- CONFTYPE, a variable containing the name of the transformation applied to the survival time in the computation of confidence intervals (if the OUT= option is specified in the SURVIVAL statement)
- SDF_LCL, a variable containing the lower limits of the pointwise confidence intervals for the survivor function
- SDF_UCL, a variable containing the upper limits of the pointwise confidence intervals for the survivor function

If the estimation uses the product-limit method, then the data set also contains

- _CENSOR_, an indicator variable that has a value 1 for a censored observation and a value 0 for an event observation
If the estimation uses the life-table method, then the data set also contains

- **MIDPOINT**, a variable containing the value of the midpoint of the time interval
- **PDF**, a variable containing the density function estimates
- **PDF_LCL**, a variable containing the lower endpoint of the PDF confidence interval
- **PDF_UCL**, a variable containing the upper endpoint of the PDF confidence interval
- **HAZARD**, a variable containing the hazard estimates
- **HAZ_LCL**, a variable containing the lower endpoint of the hazard confidence interval
- **HAZ_UCL**, a variable containing the upper endpoint of the hazard confidence interval

Each survival function contains an initial observation with the value 1 for the SDF and the value 0 for the time. The output data set contains an observation for each distinct failure time if the product-limit method is used or an observation for each time interval if the life-table method is used. The product-limit survival estimates are defined to be right continuous; that is, the estimates at a given time include the factor for the failure events that occur at that time.

Labels are assigned to all the variables in the output data set except the BY variable and the STRATA variable.

**OUT= Data Set**

The OUT= option in the SURVIVAL statement creates an output data set containing all the variables listed in the OUTSURV= data set specified in the PROC LIFETEST statement with the additional variable

- **CONFTYPE**, a variable containing the type of transform used in the computation of the confidence intervals and bands for the survivor function

If the product-limit method is used, the OUT= data set also contains

- **SDF_STDERR**, a variable containing the standard error of the survivor function estimator (if the STDERR option is specified in the SURVIVAL statement)
- **HW_LCL**, a variable containing the lower limits of the Hall-Wellner confidence bands (if the CONFBAND=HW or CONFBAND=ALL is specified in the SURVIVAL statement)
- **HW_UCL**, a variable containing the upper limits of the Hall-Wellner confidence bands (if the CONFBAND=HW or CONFBAND=ALL is specified in the SURVIVAL statement)
- **EP_LCL**, a variable containing the lower limits of the equal precision confidence bands (if the CONFBAND=EP or CONFBAND=ALL is specified in the SURVIVAL statement)
- EP_UCL, a variable containing the upper limits of the equal precision confidence bands (if the CONFBAND=EP or CONFBAND=ALL is specified in the SURVIVAL statement)

In this release, the OUTSURV= data set is not created if you specify both the OUTSURV= option in the PROC LIFETEST statement and the OUT= option in the PROC statement.

**OUTTEST= Data Set**

The OUTTEST= option in the LIFETEST statement creates an output data set containing the rank statistics for testing the association of failure time with covariates. It contains

- any specified BY variables
- _TYPE_, a character variable of length 8 that labels the type of rank test, either “LOG-RANK” or “WILCOXON”
- _NAME_, a character variable of length 8 that labels the rows of the covariance matrix and the test statistics
- the TIME variable, containing the overall test statistic in the observation that has _NAME_ equal to the name of the time variable and the univariate test statistics under their respective covariates.
- all variables listed in the TEST statement

The output is in the form of a symmetric matrix formed by the covariance matrix of the rank statistics bordered by the rank statistics and the overall chi-square statistic. If the value of _NAME_ is the name of a variable in the TEST statement, the observation contains a row of the covariance matrix and the value of the rank statistic in the time variable. If the value of _NAME_ is the name of the TIME variable, the observation contains the values of the rank statistics in the variables from the TEST list and the value of the overall chi-square test statistic in the TIME variable.

Two complete sets of statistics labeled by the _TYPE_ variable are produced, one for the log-rank test and one for the Wilcoxon test.

**Displayed Output**

If you use the NOPRINT option in the PROC LIFETEST statement, the procedure does not display any output.

For each stratum, the LIFETEST procedure displays the following unless the NOTABLE option is specified.

- if you specify the STRATA statement, the values of the stratum variables
- if you request the product-limit estimate, the “Product-Limit Survival Estimates” table, which displays
  - the observed (event or censored) time
the estimate of the survivor function
the estimate of the cumulative distribution function of the failure time
the standard error estimate of the estimated survivor function
the number of event times that have been observed
the number of event or censored times that remain to be observed
if you specify the FREQ statement, the frequency of the observed event or censored times
if you specify the ID statement, the values of the ID variables

• if you request the product-limit estimate, the “Quartile Estimates” table, which contains
  – point estimates of the quartiles of the failure times
  – lower and upper confidence limits for the quartiles

• if you requested the product-limit estimate, the estimated mean survival time and its estimated standard error

• if you requested the life-table estimate, the “Life Table Survival Estimates” table, which displays
  – time intervals into which the failure and censored times are distributed; each interval is from the lower limit, up to but not including the upper limit. If the upper limit is infinity, the missing value is printed.
  – the number of events that occur in the interval
  – the number of censored observations that fall into the interval
  – the effective sample size for the interval
  – the estimate of conditional probability of events (failures) in the interval
  – the standard error of the estimated conditional probability of events
  – the estimate of the survival function at the beginning of the interval
  – the estimate of the cumulative distribution function of the failure time at the beginning of the interval
  – the standard error estimate of the estimated survival function
  – the estimate of the median residual lifetime, which is the amount of time elapsed before reducing the number of at-risk units to one-half. This is also known as the median future lifetime in Elandt-Johnson and Johnson (1980).
  – the estimated standard error of the estimated median residual lifetime
  – the density function estimated at the midpoint of the interval
  – the standard error estimate of the estimated density
  – the hazard rate estimated at the midpoint of the interval
  – the standard error estimate of the estimated hazard

The following results, processed across all strata, are displayed:

• the “Summary of the Number of Censored and Uncensored Values” table, which contains
— if the STRATA statement is specified, the stratum identification
— the total number of observations
— the number of event observations
— the number of censored observations
— the percentage of censored observations

• the “Rank Statistics” table that contains the test statistics of the nonparametric $k$-sample tests or stratified $k$-sample tests
• the covariance matrix for the LOGRANK $k$-sample statistics
• the covariance matrix for the WILCOXON $k$-sample statistics
• the covariance matrix for the TARONE $k$-sample statistics (if requested)
• the covariance matrix for the PETO $k$-sample statistics (if requested)
• the covariance matrix for the MODPETO $k$-sample statistics (if requested)
• the covariance matrix for the FLEMING $k$-sample statistics (if requested)
• the “Test of Equality over Strata” table, which displays the results of the nonparametric $k$-sample test and the likelihood ratio test that is based on the exponential distribution (if the GROUP= option is not specified in the STRATA statement)
• the “Stratified Test of Equality over Group” table, which displays the results of the stratified $k$-sample tests for the GROUP= variable (if the GROUP= option in the STRATA statement is specified)
• the “Scores for Trend Test” tables, which displays the set of scores used to construct the trend tests (if the TREND option is specified in the STRATA statement)
• the “Trend Tests” tables, which displays the results of the trend tests (if the TREND option is specified in the STRATA statement)
• the line printer plot or traditional high resolution graph of the estimated survivor function against failure time (if requested)
• the line printer plot or traditional high resolution graph of the negative log of the estimated survivor function against failure time (if requested)
• the line printer plot or traditional high resolution graph of the log of the negative log of the estimated survivor function against the log of the failure time (if requested)
• the line printer plot or traditional high resolution graph of the estimated hazard function against failure time (if requested and only for life-table method)
• the line printer plot or traditional high resolution graph of the estimated density function against failure time (if requested and only for life-table method)

If you specify the TEST statement, the PROC LIFETEST also displays

• the “Univariate Chi-Squares for the Log-Rank Test” table, which contains the log-rank test results for individual variables in the TEST statement
• the “Covariance Matrix for the Log-Rank Statistics” table
• the “Forward Stepwise Sequence of Chi-Squares for the Log-Rank Test” table, which contains
  – the sequence of partial chi-square statistics for the log-rank test in the order of the greatest increase to the overall test statistic
  – the degrees of freedom of the partial chi-square statistics
  – the approximate probability values of the partial chi-square statistics
  – the chi-square increments for including the given variables
  – the probability values of the chi-square increments

• the “Univariate Chi-Squares for the Wilcoxon Test” table, which contains the log-rank test results for individual variables in the TEST statement
• the “Covariance Matrix for the Wilcoxon Statistics” table
• the “Forward Stepwise Sequence of Chi-Squares for the Wilcoxon Test” table, which contains
  – the sequence of partial chi-square statistics for the Wilcoxon test in the order of the greatest increase to the overall test statistic
  – the degrees of freedom of the partial chi-square statistics
  – the approximate probability values of the partial chi-square statistics
  – the chi-square increments for including the given variables
  – the probability values of the chi-square increments

**ODS Table Names**

PROC LIFETEST assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**Table 40.3. ODS Tables Produced in PROC LIFETEST**

**ODS Graphics** *(Experimental)*

This section describes the use of ODS for creating statistical graphs with the LIFETEST procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the PLOTS= option. For general information about ODS GRAPHICS, see Chapter 15, “Statistical Graphics Using ODS.”

You can specify the PLOTS= option in the SURVIVAL statement to request graphical displays of survival distribution and related function estimates:

```
PLOTS=(type < type, .... , type>)
```

requests one or more plots of the survival estimates, where `type` is the type of plot. The following table shows the valid values of `type`.

<table>
<thead>
<tr>
<th>Type</th>
<th>Plot Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>CL</td>
<td>PCL</td>

For the product-limit method, the panel contains a plot of the product-limit estimates, a plot of the Hall-Wellner band, and a plot of the equal precision band. Pointwise confidence limits and the product-limit estimates are also plotted along with the confidence bands. For the life-table method, the panel contains a plot of life-table estimates, a plot of the estimated hazard function, and a plot of the estimated density. Corresponding pointwise confidence limits are also plotted along with the survival estimates.</td>
</tr>
<tr>
<td>SURVIVAL</td>
<td>S</td>
</tr>
</tbody>
</table>

*Note: The table may contain typographical errors and should be regarded as illustrative.*
You can use the ALPHA=, BANDMIN=, BANDMAX=, and CONFTYPE= options in the SURVIVAL statement to modify the confidence limits and confidence bands. To restrict the display of the plots up to a certain limit on the time scale, specify the following option in the SURVIVAL statement.

**MAXTIME=value**

specifies the maximum value of the time variable allowed on the plots so that outlying points do not determine the scale of the time axis of the plots.

### ODS Graph Names

PROC LIFETEST assigns a name to each graph it creates using the Output Delivery System (ODS). You can use these names to reference the graphs when using ODS. The names are listed in Table 40.4.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 40.4. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

### Examples

**Example 40.1. Product-Limit Estimates and Tests of Association for the VA Lung Cancer Data**

This example uses the data presented in Appendix I of Kalbfleisch and Prentice (1980). The response variable, SurvTime, is the survival time in days of a lung cancer patient. Negative values of SurvTime are censored values. The covariates are Cell (type of cancer cell), Therapy (type of therapy: standard or test), Prior (prior therapy: 0=no, 10=yes), Age (age in years), DiagTime (time in months from diagnosis to entry into the trial), and Kps (performance status). A censoring indicator
variable *Censor* is created from the data, with value 1 indicating a censored time and value 0 an event time. Since there are only two types of therapy, an indicator variable, *Treatment*, is constructed for therapy type, with value 0 for standard therapy and value 1 for test therapy.

```plaintext
data VALung;
  drop check m;
  retain Therapy Cell;
  infile cards column=column;
  length Check $ 1;
  label SurvTime='failure or censoring time'
    Kps='karnofsky index'
    DiagTime='months till randomization'
    Age='age in years'
    Prior='prior treatment?'
    Cell='cell type'
    Therapy='type of treatment'
    Treatment='treatment indicator';
  M=Column;
  input Check $ @@;
  if M>Column then M=1;
  if Check='s'|Check='t' then input @M Therapy $ Cell $ ;
  else input @M SurvTime Kps DiagTime Age Prior @@;
  if SurvTime > .;
  censor=(SurvTime<0);
  SurvTime=abs(SurvTime);
  Treatment=(Therapy='test');
cards;
```

test small
PROC LIFETEST is invoked to compute the product-limit estimate of the survivor function for each type of cancer cell and to analyze the effects of the variables Age, Prior, DiagTime, Kps, and Treatment on the survival of the patients. These prognostic factors are specified in the TEST statement, and the variable Cell is specified in the STRATA statement. Traditional high-resolution graphs of the product-limit estimates, the log estimates, and the negative log-log estimates are requested through the PLOTS= option in the PROC LIFETEST statement. Because of a few large survival times, a MAXTIME of 600 is used to set the scale of the time axis; that is, the time scale extends from 0 to a maximum of 600 days in the plots. The variable Therapy is specified in the ID statement to identify the type of therapy for each observation in the product-limit estimates. The OUTTEST option specifies the creation of an output data set named Test to contain the rank test matrices for the covariates.

time SurvTime*Censor(1);
   id Therapy;
   strata Cell;
   test Age Prior DiagTime Kps Treatment;
run;

Output 40.1.1 through Output 40.1.4 display the product-limit estimates of the survivor functions for the four cell types. Summary statistics of the survival times are also shown. The median survival times are 51 days, 156 days, 51 days, and 118 days for patients with adeno cells, large cells, small cells, and squamous cells, respectively.
### Output 40.1.1. Estimation Results for Cell = adeno

**Stratum 1: Cell = adeno**

</tbody>
</table>

The graph of the estimated survivor functions is shown in Output 40.1.6. The adeno cell curve and the small cell curve are much closer to each other than to the large cell curve or the squamous cell curve. The survival rates of the adeno cell patients and the small cell patients decrease rapidly to approximately 29% in 90 days. Shapes of the large cell curve and the squamous cell curve are quite different, although both decrease less rapidly than those of the adeno and small cells. The squamous cell curve decreases more rapidly initially than the large cell curve, but the role is reversed in the later period.

**Output 40.1.6.** Graph of the Estimated Survivor Functions
Output 40.1.7.  Graph of Negative Log of the Estimated Survivor Functions

Output 40.1.8.  Graph of Log of the Negative Log of the Estimated Survivor Functions
The graph of the negative log of the estimated survivor functions is displayed in Output 40.1.7. Output 40.1.8 displays the log of the negative log of the estimated survivor functions against the log of time.

Results of the homogeneity tests across cell types are given in Output 40.1.9. The log-rank and Wilcoxon statistics and their corresponding covariance matrices are displayed. Also given is a table that consists of the approximate chi-square statistics, degrees of freedom, and \( p \)-values for the log-rank, Wilcoxon, and likelihood ratio tests. All three tests indicate strong evidence of a significant difference among the survival curves for the four types of cancer cells \( (p < 0.001) \).

Results of the log-rank test of the prognostic variables are shown in Output 40.1.10. The univariate test results correspond to testing each prognostic factor marginally. The joint covariance matrix of these univariate test statistics is also displayed. In computing the overall chi-square statistic, the partial chi-square statistics following a forward stepwise entry approach are tabulated.
Consider the log-rank test in Output 40.1.10. Since the univariate test for Kps has the largest chi-square (43.4747) among all the covariates, Kps is entered first. At this stage, the partial chi-square and the chi-square increment for Kps are the same as the univariate chi-square. Among all the covariates not in the model (Age, Prior, DiagTime, Treatment), Treatment has the largest approximate chi-square increment (1.7261) and is entered next. The approximate chi-square for the model containing Kps and Treatment is 43.4747 + 1.7261 = 45.2008 with 2 degrees of freedom. The third covariate entered is Age. The fourth is Prior, and the fifth is DiagTime. The overall chi-square statistic on the last line of output is the partial chi-square for including all the covariates. It has a value of 46.4200 with 5 degrees of freedom, which is highly significant ($p < 0.0001$).

You can establish this forward stepwise entry of prognostic factors by passing the matrix corresponding to the log-rank test to the RSQUARE method in the REG procedure. PROC REG finds the sets of variables that yield the largest chi-square statistics.

```sas
data RSq;
  set Test;
  if _type_='LOG RANK';
  _type_='cov';

proc print data=RSq;
proc reg data=RSq(type=COV);
  model SurvTime=Age Prior DiagTime Kps Treatment /
           selection=rsquare;
  title 'All Possible Subsets of Covariates for the log-rank Test';
run;
```

Output 40.1.11 displays the univariate statistics and their covariance matrix for the log-rank test.

</tbody>
</table>

Results of the best subset regression are shown in Output 40.1.12. The variable Kps generates the largest univariate test statistic among all the covariates, the pair Kps and Age generate the largest test statistic among any other pairs of covariates, and so on. The entry order of covariates is identical to that of PROC LIFETEST.

Example 40.2. Confidence Bands for Survival of Bone Marrow Transplant Patients (Experimental)

This example uses the data of 137 bone marrow transplant patients extracted from Klein and Moeschberger (1997). At the time of transplant, each patient is classified into one of three risk categories: ALL (Acute Lymphoblastic Leukemia), low-risk AML (Acute Myelocytic Leukemia), and high-risk AML. The endpoint of interest is the disease-free survival, which is the time to death or relapse or the end of the study in days. The data are saved in the SAS data set BMT. In this data set, the variable Group represents the Patient’s risk category, the variable T represents the disease-free survival time, and the variable Status is the censoring indicator with value 1 indicating an event time and value 0 a censored time.

```sas
proc format;

;
Klein and Moeschberger (1997, Section 4.4) describe in detail how to compute the Hall and Wellner (HW) and equal precision (EP) confidence bands. Now you can use the SURVIVAL statement in PROC LIFETEST to obtain these confidence bands. In the following code, PROC LIFETEST is invoked to compute the product-limit estimates of the disease-free survival. The SURVIVAL statement is included to create an output SAS data set (named Out1) that contains the survival function estimates and to plot them with the experimental graphics using the ODS. To obtain both the HW and EP confidence bands in the OUT= data set, you specify the CONFBAND=ALL option. The BANDMIN=100 and BANDMAX=600 options restrict the confidence bands for the survivor function $S(t)$ over the range $100 \leq t \leq 600$. The CONFTYPE=ASINSQRT option is specified to apply the arcsine-square root transform to the survivor function in computing the pointwise confidence intervals and the confidence bands. The experimental ODS graphics statement is specified to display the graphics using ODS. The specific plots to be displayed are specified by the PLOTS=(STRATUM, SURVIVAL, HWB) option, which includes a panel of plots for each stratum, a plot of the survivor functions estimates for all strata, and a plot of the Hall-Wellner bands for all strata. Since most of the events occur within 800 days, MAXTIME=800 is specified to restrict the display to such time.

```sas
ods html;
ods graphics on;

proc lifetest data=BMT noprint;
   time T * Status(0);
   survival out=Out1
      confband=all bandmin=100 bandmax=600 maxtime=800
      conftype=asinsqrt
      plots=(stratum, survival, hwb);
   strata Group;
   run;

ods graphics off;
ods html close;

proc contents data=Out1;
   run;
```

The HW confidence bands for disease-free survival are represented by the variables HW_LCL and HW_UCL in the Out1 data set, and the EP confidence bands are represented by the variables EP_LCL and EP_UCL. Other variables in the Out1 data set are shown in the printed output of PROC CONTENTS in Output 40.2.1.

### Output 40.2.2. Panel Plot for ALL Patients (Experimental)

#### Stratum 1: Group = ALL

![Survival curve](image)

- **No of Subjects**: 39
- **Event**: 63% (24)
- **Censored**: 37% (14)
- **Percentile**: Survival Time (95%CL)
  - 25: 122.0 (107.0 276.0)
  - 50: 418.0 (164.0 NA)
  - 75: NA (699.0 NA)

#### 95% HW Band with Pointwise Limits

![Kaplan-Meier plot with HW bands](image)

#### 95% EP Band with Pointwise Limits

![Kaplan-Meier plot with EP bands](image)
The panel plot for the ALL patients is shown in Output 40.2.2. The upper left cell in this $2 \times 2$ matrix plot displays the estimated survival curve, the upper right cell shows a table of summary statistics, the lower left cell displays the Hall-Wellner band, and the lower right cell displays the equal precision band. Pointwise confidence limits are plotted along with the confidence bands. As expected, the confidence bands are much wider than the set of the pointwise confidence intervals. The EP confidence band appears to be slightly wider than the HW confidence band for survival time over 200 days. The panel plots for the low-risk and high-risk AML patients are not shown here.

**Output 40.2.3.** Product-Limit Estimates of Survival of Bone Marrow Transplant Patients (Experimental)

![Product-Limit Survival Function Estimates](image)

Output 40.2.3 shows a plot of the estimated survival curves for the three leukemia groups. Censored observations are plotted as a plus sign. It appears that the low-risk AML patients have the best prognosis while the high-risk AML patients have the worse prognosis, with the ALL patients in between. Output 40.2.4 shows a plot of
the Hall-Wellner bands for the three leukemia groups. The band for the ALL patients overlaps with those of the low-risk and high-risk AML patients, but there is very little overlapping between the band for the low-risk AML patients and the band for the high-risk patients. One would expect the low-risk AML patients to live much longer than the high-risk AML patients.

**Output 40.2.4.** Hall-Wellner Bands for the Survival of Bone Marrow Transplant Patients (Experimental)

The graphical display in **Output 40.2.2** as well as those shown in **Output 40.2.3** and **Output 40.2.4** are requested by specifying the experimental ODS GRAPHICS statement and the experimental PLOTS= option in the SURVIVAL statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the LIFETEST procedure, see the section “ODS Graphics” on page 2190.
Example 40.3. Life-Table Estimates for Males with Angina Pectoris

The data in this example come from Lee (1992, p. 91) and represent the survival rate of males with angina pectoris. Survival time is measured as years from the time of diagnosis. The data are read as number of events and number of withdrawals in each one-year time interval for 16 intervals. Three variables are constructed from the data: Years (an artificial time variable with values that are the midpoints of the time intervals), Censored (a censoring indicator variable with value 1 indicating censored observations and value 0 indicating event observations), and Freq (the frequency variable). Two observations are created for each interval, one representing the event observations and the other representing the censored observations.

```
title 'Survival of Males with Angina Pectoris';
data males;
  keep Freq Years Censored;
  retain Years -.5;
  input fail withdraw @@;
  Years + 1;
  Censored=0;
  Freq=fail;
  output;
  Censored=1;
  Freq=withdraw;
  output;
  datalines;
  456 0 226 39 152 22 171 23 135 24 125 107 83 133 74 102 51 68 42 64 43 45 34 53 18 33 9 27 6 23 0 30;
```

PROC LIFETEST is invoked to compute the various life-table survival estimates, the median residual time, and their standard errors. The life-table method of computing estimates is requested by specifying METHOD=LT. The intervals are specified by the INTERVAL= option. Traditional high-resolution graphs of the life-table estimate, negative log of the estimate, negative log-log of the estimate, estimated density function, and estimated hazard function are requested by the PLOTS= option. No tests for homogeneity are carried out because the data are not stratified.

```
symbol1 c=blue;
  proc lifetest data=males method=lt intervals=(0 to 15 by 1) plots=(s,ls,lls,h,p);
    time Years*Censored(1);
    freq Freq;
  run;
```
Results of the life-table estimation are shown in Output 40.3.1. The five-year survival rate is 0.5193 with a standard error of 0.0103. The estimated median residual lifetime, which is 5.33 years initially, has reached a maximum of 6.34 years at the beginning of the second year and decreases gradually to a value lower than the initial 5.33 years at the beginning of the seventh year.

</tr>
<tr>
<td>2418 1625 793 32.80</td>
</tr>
</tbody>
</table>

*NOTE: There were 2 observations with missing values, negative time values or frequency values less than 1.*

**Output 40.3.3** displays the graph of the life-table survivor function estimate. The median survival time, read from the survivor function curve, is 5.33 years, and the 25th and 75th percentiles are 1.04 and 11.13 years, respectively.

**Output 40.3.3.** Life-Table Survivor Function Estimate
An exponential model may be appropriate for the survival of these male patients with angina pectoris since the curve of the negative log of the survivor function estimate versus the survival time (Output 40.3.4) approximates a straight line through the origin. Note that the graph of the log of the negative log of the survivor function estimate versus the log of time (Output 40.3.5) is practically a straight line.

**Output 40.3.4.** Negative Log of Survivor Function Estimate

As discussed in Lee (1992), the graph of the estimated hazard function (Output 40.3.6) shows that the death rate is highest in the first year of diagnosis. From the end of the first year to the end of the tenth year, the death rate remains relatively constant, fluctuating between 0.09 and 0.12. The death rate is generally higher after the tenth year. This could indicate that a patient who has survived the first year has a better chance than a patient who has just been diagnosed. The profile of the median residual lifetimes also supports this interpretation.
Output 40.3.5.  Log of Negative Log of Survivor Function Estimate

Output 40.3.6.  Hazard Function Estimate
The density estimate is shown in (Output 40.3.7). Visually, it resembles that of an exponential distribution.

**Output 40.3.7.** Density Function Estimate

Chapter 41
The LOESS Procedure

Overview

The LOESS procedure implements a nonparametric method for estimating regression surfaces pioneered by Cleveland, Devlin, and Grosse (1988), Cleveland and Grosse (1991), and Cleveland, Grosse, and Shyu (1992). The LOESS procedure allows great flexibility because no assumptions about the parametric form of the regression surface are needed.

The SAS System provides many regression procedures such as the GLM, REG, and NLIN procedures for situations in which you can specify a reasonable parametric model for the regression surface. You can use the LOESS procedure for situations in which you do not know a suitable parametric form of the regression surface. Furthermore, the LOESS procedure is suitable when there are outliers in the data and a robust fitting method is necessary.

The main features of the LOESS procedure are as follows:

- fits nonparametric models
- supports the use of multidimensional data
- supports multiple dependent variables
- supports both direct and interpolated fitting using kd trees
- performs statistical inference
- performs automatic smoothing parameter selection
- performs iterative reweighting to provide robust fitting when there are outliers in the data
- supports multiple SCORE statements

Experimental graphics are now available with the LOESS procedure. For more information, refer to the “ODS Graphics” section on page 2248.

Local Regression and the Loess Method

Assume that for \( i = 1 \) to \( n \), the \( i \)th measurement \( y_i \) of the response \( y \) and the corresponding measurement \( x_i \) of the vector \( x \) of \( p \) predictors are related by

\[
y_i = g(x_i) + \epsilon_i
\]

where \( g \) is the regression function and \( \epsilon_i \) is a random error. The idea of local regression is that at a predictor \( x \), the regression function \( g(x) \) can be locally approximated
by the value of a function in some specified parametric class. Such a local approxi-
mation is obtained by fitting a regression surface to the data points within a chosen 
neighborhood of the point \( x \).

In the loess method, weighted least squares is used to fit linear or quadratic functions 
of the predictors at the centers of neighborhoods. The radius of each neighborhood 
is chosen so that the neighborhood contains a specified percentage of the data points. 
The fraction of the data, called the smoothing parameter, in each local neighborhood 
controls the smoothness of the estimated surface. Data points in a given local neigh-
borhood are weighted by a smooth decreasing function of their distance from the 
center of the neighborhood.

In a direct implementation, such fitting is done at each point at which the regression 
surface is to be estimated. A much faster computational procedure is to perform such 
local fitting at a selected sample of points in predictor space and then to blend these 
local polynomials to obtain a regression surface.

You can use the LOESS procedure to perform statistical inference provided the error 
distribution satisfies some basic assumptions. In particular, such analysis is appropri-
ate when the \( e_i \) are i.i.d. normal random variables with mean 0. By using the iterative 
reweighting, the LOESS procedure can also provide statistical inference when the 
error distribution is symmetric but not necessarily normal. Furthermore, by doing 
itervative reweighting, you can use the LOESS procedure to perform robust fitting in 
the presence of outliers in the data.

While all output of the LOESS procedure can be optionally displayed, most often the 
LOESS procedure is used to produce output data sets that will be viewed and ma-
nipulated by other SAS procedures. PROC LOESS uses the Output Delivery System 
(ODS) to place results in output data sets. This is a departure from older SAS proce-
dures that provide OUTPUT statements to create SAS data sets from analysis results.

**Getting Started**

**Scatter Plot Smoothing**

The following data from the Connecticut Tumor Registry presents age-adjusted num-
ers of melanoma incidences per 100,000 people for 37 years from 1936 to 1972 
(Houghton, Flannery, and Viola 1980).

```plaintext
  data Melanoma;
      input Year Incidences @@;
      format Year d4.0;
      format DepVar d4.1;
  datalines;
  1936  0.9  1937  0.8  1938  0.8  1939  1.3
  1940  1.4  1941  1.2  1942  1.7  1943  1.8
  1944  1.6  1945  1.5  1946  1.5  1947  2.0
  1948  2.5  1949  2.7  1950  2.9  1951  2.5
  1952  3.1  1953  2.4  1954  2.2  1955  2.9
  1956  2.5  1957  2.6  1958  3.2  1959  3.8
```
The following PROC GPLOT statements produce the simple scatter plot of these data displayed in Figure 41.1.

```plaintext
symbol1 color=black value=dot;
proc gplot data=Melanoma;
title1 'Scatter Plot of Melanoma Data';
plot Incidences*Year;
run;
```

Suppose that you want to smooth the response variable Incidences as a function of the variable Year. The following PROC LOESS statements request this analysis:

```plaintext
proc loess data=Melanoma;
    model Incidences=Year/details(OutputStatistics);
run;
```

You use the PROC LOESS statement to invoke the procedure and specify the data set. The MODEL statement names the dependent and independent variables. You use options in the MODEL statement to specify fitting parameters and control the displayed...
output. For example, the MODEL statement option DETAILS(OutputStatistics) requests that the “Output Statistics” table be included in the displayed output. By default, this table is not displayed.

The results are displayed in Figure 41.2 and Figure 41.3.

Figure 41.3. Output from PROC LOESS continued

Usually, such displayed results are of limited use. Most frequently the results are needed in an output data set so that they can be displayed graphically and analyzed further. For example, to place the “Output Statistics” table shown in Figure 41.3 in an output data set, you use the ODS OUTPUT statement as follows:

```plaintext
proc loess data=Melanoma;
    model Incidences=Year;
    ods output OutputStatistics=Results;
run;
```
The statement

\[
\text{ods output OutputStatistics=Results;}
\]
requests that the “Output Statistics” table that appears in Figure 41.2 be placed in a SAS data set named \texttt{Results}. Note also that the DETAILS(OutputStatistics) option that caused this table to be included in the displayed output need not be specified.

The PRINT procedure displays the first five observations of this data set:

\[
title1 'First 5 Observations of the Results Data Set';
proc print data=Results(obs=5);
  id obs;
run;
\]

<table>
<thead>
<tr>
<th>Obs</th>
<th>Year</th>
<th>Var</th>
<th>Pred</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1936</td>
<td>0.9</td>
<td>0.76235</td>
</tr>
<tr>
<td>2</td>
<td>1937</td>
<td>0.8</td>
<td>0.88992</td>
</tr>
<tr>
<td>3</td>
<td>1938</td>
<td>0.8</td>
<td>1.01764</td>
</tr>
<tr>
<td>4</td>
<td>1939</td>
<td>1.3</td>

<td>1940</td>
<td>1.4</td>
<td>1.28654</td>
</tr>
</tbody>
</table>

\textbf{Figure 41.4.} PROC PRINT Output of the Results Data Set

You can now produce a scatter plot including the fitted loess curve as follows:

\[
symbol1 color=black value=dot;
symbol2 color=black interpol=join value=none;

/* macro used in subsequent examples */
%let opts=vaxis=axis1 hm=3 vm=3 overlay;

axis1 label=(angle=90 rotate=0);

proc gplot data=Results;
  title1 'Melanoma Data with Default LOESS Fit';
  plot DepVar*Year Pred*Year/ &opts;
run;
\]
The smoothing parameter value used in the loess fit shown in Figure 41.5 was obtained with a default method of selecting this value. This method minimizes a bias corrected AIC criterion (Hurvich, Simonoff, and Tsai 1998), which balances the residual sum of squares against the smoothness of the fit.

You can find the selected smoothing parameter value in the “Smoothing Criterion” table shown in Figure 41.2. Note that with this smoothing parameter value, the loess fit captures the increasing trend in the data as well the periodic pattern in the data, which is related to an 11-year sunspot activity cycle.

You can obtain a summary of all the models that PROC LOESS evaluated in choosing this smoothing parameter value in the “Model Summary” table. You request this optionally displayed table by adding the choice, ModelSummary, in the DETAILS option in the model statement as follows:

```plaintext
proc loess data=Melanoma;
  model Incidences=Year/details(OutputStatistics ModelSummary);
  ods output OutputStatistics=Results;
run;
```

Note that this example shows that you can request more than one optional table using the DETAILS option. The requested “Model Summary” table is shown in Figure 41.6.

Figure 41.6. Model Summary Table

Rather than use an automatic method for selecting the smoothing parameter value, you may want to examine loess fits for a range of values. You do this by using the SMOOTH= option in the MODEL statement as follows:

```plaintext
proc loess data=Melanoma;
  model Incidences=Year/smooth=0.1 0.2 0.3 0.4 residual;
  ods output OutputStatistics=Results;
run;
```

The RESIDUAL option causes the residuals to be added to the “Output Statistics” table. PROC PRINT displays the first five observations of this data set:

```plaintext
proc print data=Results(obs=5);
  id obs;
run;
```

Figure 41.7. PROC PRINT Output of the Results Data Set
Note that the fits for all the smoothing parameters are placed in single data set and that ODS has added a SmoothingParameter variable to this data set that you can use to distinguish each fit.

The following statements display the loess fits obtained in a 2 by 2 plot grid:

```sas
options nodisplay;
proc gplot data=Results;
   by SmoothingParameter;
   plot DepVar*Year=1 Pred*Year/ &opts name='fit';
run; quit;

options display;
proc greplay nofs tc=sashelp.templt template=l2r2;
   igout gseg;
   treplay 1:fit 2:fit2 3:fit1 4:fit3;
run; quit;
```

![Figure 41.8. Loess Fits with a Range of Smoothing Parameters]

If you examine the plots in Figure 41.8, you see that a good fit is obtained with smoothing parameter value 0.2. You can gain further insight in how to choose the smoothing parameter value by examining scatter plots of the fit residuals versus the year. To aid the interpretation of these scatter plots, you can again use PROC LOESS to smooth the response Residual as a function of Year.
proc loess data=Results;
   by SmoothingParameter;
   ods output OutputStatistics=residout;
   model Residual=Year / smooth=0.3;
run;

axis1 label = (angle=90 rotate=0)
   order = (-0.8 to 0.8 by 0.4);
goptions nodisplay;
proc gplot data=residout;
   by SmoothingParameter;
   format DepVar 3.1;
   plot DepVar*Year Pred*Year / &opts vref=0 lv=2 vm=1
      name='resids';
run; quit;

   goptions display;
   proc gplay nofs tc=sashelp.templt template=l2r2;
   igout gseg;
   treplay 1:resids 2:resids2 3:resids1 4:resids3;
run; quit;

Figure 41.9. Scatter Plots of Residuals versus Year

Looking at the scatter plots in Figure 41.9 confirms that the choice 0.2 is reasonable. With smoothing parameter value 0.1, there is gross overfitting in the sense that the original data are exactly interpolated. The loess fits on the Residual versus Year scatter plots for smoothing parameter values 0.3 and 0.4 reveal that there is a periodic trend in the residuals that is much weaker when the value 0.2. This suggests that
when the smoothing parameter value is above 0.3, an overly smooth fit is obtained that misses essential features in the original data.

Having now decided on a loess fit, you may want to obtain confidence limits for your model predictions. This is done by adding the CLM option in the MODEL statement. By default 95% limits are produced, but this can be changed by using the ALPHA= option in the MODEL statement. The following statements add 90% confidence limits to the Results data set and display the results graphically:

```plaintext
proc loess data=Melanoma;
   model Incidences=Year/smooth=0.2 residual clm
                  alpha=0.1;
   ods output OutputStatistics=Results;
run;

symbol3 color=green interpol=join value=none;
symbol4 color=green interpol=join value=none;
axis1 label = (angle=90 rotate=0)
            order = (0 to 6);
title1 'Age-adjusted Melanoma Incidences for 37 Years';
proc gplot data=Results;
  plot DepVar*Year Pred*Year LowerCl*Year UpperCL*Year
      / &opts;
run;
```

![Figure 41.10. Loess fit of Melanoma Data with 90% Confidence Bands](image)
Syntax

The following statements are available in PROC LOESS:

```plaintext
PROC LOESS <DATA=SAS-data-set> ;
   MODEL dependents=regressors < / options > ;
   ID variables ;
   BY variables ;
   WEIGHT variable ;
   SCORE DATA=SAS-data-set < ID=(variable list) > < / options > ;
```

The PROC LOESS and MODEL statements are required. The BY, WEIGHT, and ID statements are optional. The SCORE statement is optional, and more than one SCORE statement can be used.

The statements used with the LOESS procedure, in addition to the PROC LOESS statement, are as follows.

- **BY**: specifies variables to define subgroups for the analysis.
- **ID**: names variables to identify observations in the displayed output.
- **MODEL**: specifies the dependent and independent variables in the loess model, details and parameters for the computational algorithm, and the required output.
- **SCORE**: specifies a data set containing observations to be scored.
- **WEIGHT**: declares a variable to weight observations.

**PROC LOESS Statement**

```plaintext
PROC LOESS <DATA=SAS-data-set> ;
```

The PROC LOESS statement is required. The only option in this statement is the DATA= option, which names a data set to use for the loess model.

**BY Statement**

```plaintext
BY variables ;
```

You can specify a BY statement with PROC LOESS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables. The variables are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
• Specify the BY statement option NOTSORTED. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

• Create an index on the BY variables using the DATASETS procedure (in Base SAS software).

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

### ID Statement

```
ID variables;
```

The ID statement is optional, and more than one ID statement can be used. The variables listed in any of the ID statements are displayed in the “Output Statistics” table beside each observation. Any variables specified as a regressor or dependent variable in the MODEL statement already appear in the “Output Statistics” table and are not treated as ID variables, even if they appear in the variable list of an ID statement.

### MODEL Statement

```
MODEL dependents=independent variables < / options >;
```

The MODEL statement names the dependent variables and the independent variables. Variables specified in the MODEL statement must be numeric variables in the data set being analyzed.

</table>

The following options are available in the MODEL statement after a slash (/).

ALL
requests all these options: CLM, RESIDUAL, SCALEDINDEP, STD, and T.

ALPHA=number
sets the significance level used for the construction of confidence intervals for the current MODEL statement. The value must be between 0 and 1; the default value of 0.05 results in 95% intervals.

BUCKET=number
specifies the maximum number of points in the leaf nodes of the kd tree. The default value used is \( s \times n/5 \), where \( s \) is a smoothing parameter value specified using the SMOOTH= option and \( n \) is the number of observations being used in the current BY group. The BUCKET= option is ignored if the DIRECT option is specified.

CLM
requests that \( 100(1 - \alpha) \) confidence limits on the mean predicted value be added to the “Output Statistics” table. By default, 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the \( \alpha \)-level. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

DEGREE= 1 | 2
sets the degree of the local polynomials to use for each local regression. The valid values are 1 for local linear fitting or 2 for local quadratic fitting, with 1 being the default.

DETAILS < ( tables ) >
selects which tables to display, where tables is one or more of KDTREE, MODELSUMMARY, OUTPUTSTATISTICS, and PREDATVERTICES:

- KDTREE displays the kd tree structure.
- MODELSUMMARY displays the fit criteria for all smoothing parameter values that are specified in the SMOOTH= option in the MODEL statement, or which are fit with automatic smoothing parameter selection.
• OUTPUTSTATISTICS displays the predicted values and other requested statistics at the points in the input data set.

• PREDATVERTICES displays fitted values and coordinates of the kd tree vertices where the local least squares fitting is done.

The KDTREE and PREDATVERTICES specifications are ignored if the DIRECT option is specified in the MODEL statement. Specifying the option DETAILS with no qualifying list outputs all tables.

DFMETHOD= NONE | EXACT | APPROX < (approx-options) >
specifies the method used to calculate the “lookup” degrees of freedom used in performing statistical inference. The default is DFMETHOD=NONE, unless you specify any of the MODEL statement options ALL, CLM, or T, or any SCORE statement CLM option, in which case the default is DFMETHOD=EXACT.

You can specify the following approx-options in parentheses after the DFMETHOD=APPROX option:

QUANTILE=number   specifies that the smallest 100(number)% of the nonzero coefficients in the smoothing matrix is set to zero in computing the approximate lookup degrees of freedom. The default value is QUANTILE=0.9.

CUTOFF=number     specifies that coefficients in the smoothing matrix whose magnitude is less than the specified value are set to zero in computing the approximate lookup degrees of freedom. Using the CUTOFF= option overrides the QUANTILE= option.

See the “Sparse and Approximate Degrees of Freedom Computation” section on page 2246 for a description of the method used when the DFMETHOD=APPROX option is specified.

DIRECT
specifies that local least squares fits are to be done at every point in the input data set. When the direct option is not specified, a computationally faster method is used. This faster method performs local fitting at vertices of a kd tree decomposition of the predictor space followed by blending of the local polynomials to obtain a regression surface.

DROPSQUARE=(variables)
specifies the quadratic monomials to exclude from the local quadratic fits. This option is ignored unless the DEGREE=2 option has been specified. For example,

    model z=x y / degree=2 dropsquare=(y)

uses the monomials 1, x, y, x^2, and xy in performing the local fitting.
**INTERP= LINEAR | CUBIC**
specifies the degree of the interpolating polynomials used for blending local polynomial fits at the kd tree vertices. This option is ignored if the DIRECT option is specified in the model statement. INTERP=CUBIC is not supported for models with more than two regressors. The default is INTERP=LINEAR.

**ITERATIONS=number**
specifies the number of iterative reweighting steps to be done. Such iterations are appropriate when there are outliers in the data or when the error distribution is a symmetric long-tailed distribution. The default number of iterations is 1.

**RESIDUAL | R**
specifies that residuals are to be included in the “Output Statistics” table.

**SCALE= NONE | SD <(number)>**
specifies the scaling method to be applied to scale the regressors. The default is NONE, in which case no scaling is applied. A specification of SD(number) indicates that a trimmed standard deviation is to be used as a measure of scale, where number is the trimming fraction. A specification of SD with no qualification defaults to 10% trimmed standard deviation.

**SCALEDINDEP**
specifies that scaled regressor coordinates be included in the output tables. This option is ignored if the SCALE= model option is not used or if SCALE=None is specified.

**SELECT=criterion < ( <GLOBAL> <STEPS> <RANGE(lower,upper)> )>**
**SELECT=DFCriterion ( target <GLOBAL> <STEPS> <RANGE(lower,upper)> )**
specifies that automatic smoothing parameter selection be done using the named criterion or DFCriterion. Valid values for the criterion are

- AICC specifies the $AIC_C$ criterion (Hurvich, Simonoff, and Tsai 1998).
- AICC1 specifies the $AIC_C^1$ criterion (Hurvich, Simonoff, and Tsai 1998).
- GCV specifies the generalized cross-validation criterion (Craven and Wahba 1979).

The *DFCriterion* specifies the measure used to estimate the model degrees of freedom. The measures implemented in PROC LOESS all depend on prediction matrix $L$ relating the observed and predicted values of the dependent variable. Valid values are

- DF1 specifies $\text{Trace}(L)$.
- DF2 specifies $\text{Trace}(L^T L)$.
- DF3 specifies $2\text{Trace}(L) - \text{Trace}(L^T L)$.

For both types of selection, the smoothing parameter value is selected to yield a minimum of an optimization criterion. If you specify criterion as one of AICC, AICC1, or GCV, the optimization criterion is the specified criterion. If you specify *DFCriterion*
as one of DF1, DF2, or DF3, the optimization criterion is \(|DFCriterion - target|\), where \(target\) is a specified target degree of freedom value. Note that if you specify a \(DFCriterion\), then you must also specify a target value. See the section “Automatic Smoothing Parameter Selection” on page 2243 for definitions and properties of the selection criteria.

The selection is done as follows:

- If you specify the \texttt{SMOOTH=value-list} option, then PROC LOESS selects the largest value in this list that yields the global minimum of the specified optimization criterion.
- If you do not specify the \texttt{SMOOTH=} option, then PROC LOESS finds a local minimum of the specified optimization criterion using a golden section search of values less than or equal to one.

You can specify the following modifiers in parentheses after the specified criterion to alter the behavior of the \texttt{SELECT=} option:

- \texttt{GLOBAL} specifies that a global minimum be found within the range of smoothing parameter values examined. This modifier has no effect if you also specify the \texttt{SMOOTH=} option in the \texttt{MODEL} statement.
- \texttt{STEPS} specifies that all models evaluated in the selection process be displayed.
- \texttt{RANGE(lower,upper)} specifies that only smoothing parameter values greater than or equal to \texttt{lower} and less than or equal to \texttt{upper} be examined.

For models with one dependent variable, if you specify neither the \texttt{SELECT=} nor the \texttt{SMOOTH=} options in the \texttt{MODEL} statement, then PROC LOESS uses \texttt{SELECT=AICC}.

The following table summarizes how the smoothing parameter values are chosen for various combinations of the \texttt{SMOOTH=} option, the \texttt{SELECT=} option, and the \texttt{SELECT=} option modifiers.

**Table 41.2.** Smoothing Parameter Value(s) Used for Combinations of SMOOTH= and SELECT= OPTIONS for Models with One Dependent Variable

</tr>
</tbody>
</table>
Some examples of using the SELECT= option are

- SELECT=GCV specifies selection using the GCV criterion.
- SELECT=DF1(6.3) specifies selection using the DF1 DFCriterion with target value 6.3.
- SELECT=AICC(STEPS) specifies selection using the AICC criterion showing all step details.
- SELECT=DF2(7 GLOBAL) specifies selection using the DF2 DFCriterion with target value 7 using a global search algorithm.

**Note:** The SELECT= option cannot be used for models with more than one dependent variable.

**SMOOTH=** value-list

specifies a list of positive smoothing parameter values. If you do not SELECT= option in the MODEL statement, then a separate fit is obtained for each SMOOTH= value specified. If you do specify the SELECT= option, then models with all values specified in the SMOOTH= list are examined, and PROC LOESS selects the value that minimizes the criterion specified in the SELECT= option.

For models with two or more dependent variables, if the SMOOTH= option is not specified in the MODEL statement, then SMOOTH=0.5 is used as a default.

**STD**

specifies that standardized errors are to be included in the “Output Statistics” table.

**T**

specifies that t statistics are to be included in the “Output Statistics” table.

**TRACEL**

specifies that the trace of the prediction matrix as well as the GCV and AICC statistics are to be included in the “FIT Summary” table. The use of any of the MODEL statement options ALL, CLM, DFMETHOD=EXACT, DIRECT, SELECT=, or T implicitly selects the TRACEL option.

**SCORE Statement**

```
SCORE <DATA=SAS-data-set> < ID=(variable list) > < / options > ;
```

The fitted loess model is used to score the data in the specified SAS data set. This data set must contain all the regressor variables specified in the MODEL statement. Furthermore, when a BY statement is used, the score data set must also contain all the BY variables sorted in the order of the BY variables. A SCORE statement is optional, and more than one SCORE statement can be used. SCORE statements cannot be used if the DIRECT option is specified in the MODEL statement. The optional ID= (variable list) specifies ID variables to be included in the “Score Results” table.
You find the results of the SCORE statement in the “Score Results” table. This table contains all the data in the data set named in the SCORE statement, including observations with missing values. However, only those observations with nonmissing regressor variables are scored. If no data set is named in the SCORE statement, the data set named in the PROC LOESS statement is scored. You use the PRINT option in the SCORE statement to request that the “Score Results” table be displayed. You can place the “Score Results” table in an output data set using an ODS OUTPUT statement even if this table is not displayed.

The following options are available in the SCORE statement after a slash (/).

**CLM** requests that \(100(1 - \alpha)\) confidence limits on the mean predicted value be added to the “Score Results” table. By default the 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the \(\alpha\)-level. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

**PRINT < (variables) >** specifies that the “Score Results” table is to be displayed. By default only the variables named in the MODEL statement, the variables listed in the ID list in the SCORE statement, and the scored dependent variables are displayed. The optional list in the PRINT option specifies additional variables in the score data set that are to be included in the displayed output. Note however that all columns in the SCORE data set are placed in the SCORE results table, even if you do not request that they be included in the displayed output.

**SCALEINDEP** specifies that scaled regressor coordinates be included in the SCORE results table. This option is ignored if the SCALE= model option is not used or if SCALE=NONE is specified.

**STEPS** requests that all models evaluated during smoothing parameter value selection be scored, provided that the SELECT= option together with the STEPS modifier is specified in the MODEL statement. By default only the selected model is scored.

**WEIGHT Statement**

```
WEIGHT variable ;
```

The WEIGHT statement specifies a variable in the input data set that contains values to be used as a priori weights for a loess fit.

The values of the weight variable must be nonnegative. If an observation’s weight is zero, negative, or missing, the observation is deleted from the analysis.
**Details**

**Missing Values**

PROC LOESS deletes any observation with missing values for any variable specified in the MODEL statement. This enables the procedure to reuse the kd tree for all the dependent variables that appear in the MODEL statement. If you have multiple dependent variables with different missing value structures for the same set of independent variables, you may want to use separate PROC LOESS steps for each dependent variable.

**Output Data Sets**

PROC LOESS assigns a name to each table it creates. You can use the ODS OUTPUT statement to place one or more of these tables in output data sets. See the section “ODS Table Names” on page 2248 for a list of the table names created by PROC LOESS. For detailed information on ODS, see Chapter 14, “Using the Output Delivery System.”

For example, the following statements create an output data set named MyOutStats containing the OutputStatistics table and an output data set named MySummary containing the FitSummary table.

```sas
proc loess data=Melanoma;
   model Incidences=Year;
   ods output OutputStatistics = MyOutStats
         FitSummary = MySummary;
run;
```

Often, a single MODEL statement describes more than one model. For example, the following statements fit eight different models (4 smoothing parameter values for each dependent variable).

```sas
proc loess data=notReal;
   model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
   ods output OutputStatistics = MyOutStats;
run;
```

The eight OutputStatistics tables for these models are stacked in a single data set called MyOutStats. The data set contains a column named DepVarName and a column named SmoothingParameter that distinguish each model (see Figure 41.4 on page 2224 for an example). If you want the OutputStatistics table for each model to be in its own data set, you can do so by using the MATCH_ALL option in the ODS OUTPUT statement. The following statements create eight data sets named MyOutStats, MyOutStats1, ... , MyOutStats7.

```sas
proc loess data=notReal;
   model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
   ods output OutputStatistics(match_all) = MyOutStats;
run;
```
For further options available in the ODS OUTPUT statement, see Chapter 14, “Using the Output Delivery System.”

Only the ScaleDetails and FitSummary tables are displayed by default. The other tables are optionally displayed by using the DETAILS option in the MODEL statement and the PRINT option in the SCORE statement. Note that it is not necessary to display a table in order for that table to be used in an ODS OUTPUT statement. For example, the following statements display the OutputStatistics and kdTree tables but place the OutputStatistics and PredAtVertices tables in output data sets.

```sql
proc loess data=Melanoma;
  model Incidences=Year/details(OutputStatistics kdTree);
  ods output OutputStatistics = MyOutStats
       PredAtVertices = MyVerticesOut;
run;
```

Using the DETAILS option alone causes all tables to be displayed.

The MODEL statement options CLM, RESIDUAL, STD, SCALEDINDEP, and T control which optional columns are added to the OutputStatistics table. For example, to obtain an OutputStatistics output data set containing residuals and confidence limits in addition to the model variables and predicted value, you need to specify the RESIDUAL and CLM options in the MODEL statement as in the following example:

```sql
proc loess data=Melanoma;
  model Incidences=Year/residual clm;
  ods output OutputStatistics = MyOutStats;
run;
```

Finally, note that the ALL option in the MODEL statement includes all optional columns in the output. Also, ID columns can be added to the OutputStatistics table by using the ID statement.

### Data Scaling

The loess algorithm to obtain a predicted value at a given point in the predictor space proceeds by doing a least squares fit using all data points that are close to the given point. Thus the algorithm depends critically on the metric used to define closeness. This has the consequence that if you have more than one predictor variable and these predictor variables have significantly different scales, then closeness depends almost entirely on the variable with the largest scaling. It also means that merely changing the units of one of your predictors can significantly change the loess model fit.

To circumvent this problem, it is necessary to standardize the scale of the independent variables in the loess model. The SCALE= option in the MODEL statement is provided for this purpose. PROC LOESS uses a symmetrically trimmed standard deviation as the scale estimate for each independent variable of the loess model. This is a robust scale estimator in that extreme values of a variable are discarded before
estimating the data scaling. For example, to compute a 10% trimmed standard deviation of a sample, you discard the smallest and largest 5% of the data and compute the standard deviation of the remaining 90% of the data points. In this case, the trimming fraction is 0.1.

For example, the following statements specify that the variables Temperature and Catalyst are scaled before performing the loess fitting. In this case, because the trimming fraction is 0.1, the scale estimate used for each of these variables is a 10% trimmed standard deviation.

```
model Yield=Temperature Catalyst / scale = SD(0.1);
```

The default trimming fraction used by PROC LOESS is 0.1 and need not be specified by the SCALE= option. Thus the following MODEL statement is equivalent to the previous MODEL statement.

```
model Yield=Temperature Catalyst / scale = SD;
```

If the SCALE= option is not specified, no scaling of the independent variables is done. This is appropriate when there is only a single independent variable or when all the independent variables are a priori scaled similarly.

When the SCALE= option is specified, the scaling details for each independent variable are added to the ScaleDetails table (see Output 41.3.2 on page 2265 for an example). By default, this table contains only the minimum and maximum values of each independent variable in the model. Finally, note that when the SCALE= option is used, specifying the SCALEDIINDEP option in the MODEL statement adds the scaled values of the independent variables to the OutputStatistics and PredAtVertices tables. If the SCALEDIINDEP option is specified in the SCORE statement then scaled values of the independent variables are included in the ScoreResults table. By default, only the unscaled values are placed in these tables.

## Direct versus Interpolated Fitting

Local regression to obtain a predicted value at a given point in the predictor space is done by doing a least squares fit using all data points in a local neighborhood of the given point. This method is computationally expensive because a local neighborhood must be determined and a least squares problem solved for each point at which a fitted value is required. A faster method is to obtain such fits at a representative sample of points in the predictor space and to obtain fitted values at all other points by interpolation.

PROC LOESS can fit models using either of these two paradigms. By default, PROC LOESS uses fitting at a sample of points and interpolation. The method fitting a local model at every data point is selected by specifying the DIRECT option in the MODEL statement.
PROC LOESS uses a kd tree to divide the box (also called the initial cell or bucket) enclosing all the predictor data points into rectangular cells. The vertices of these cells are the points at which local least squares fitting is done.

Starting from the initial cell, the direction of the longest cell edge is selected as the split direction. The median of this coordinate of the data in the cell is the split value. The data in the starting cell are partitioned into two child cells. The left child consists of all data from the parent cell whose coordinate in the split direction is less than the split value. The above procedure is repeated for each child cell that has more than a prespecified number of points, called the bucket size of the kd tree.

You can specify the bucket size with the BUCKET= option in the MODEL statement. If you do not specify the BUCKET= option, the default value used is the largest integer less than or equal to \( ns/5 \), where \( n \) is the number of observations and \( s \) is the value of the smoothing parameter. Note that if fitting is being done for a range of smoothing parameter values, the bucket size may change for each value.

The set of vertices of all the cells of the kd tree are the points at which PROC LOESS performs its local fitting. The fitted value at an original data point (or at any other point within the original data cell) is obtained by blending the fitted values at the vertices of the kd tree cell that contains that data point.

The univariate blending methods available in PROC LOESS are linear and cubic polynomial interpolation, with linear interpolation being the default. You can request cubic interpolation by specifying the INTERP=CUBIC option in the MODEL statement. In this case, PROC LOESS uses the unique cubic polynomial whose values and first derivatives match those of the fitted local polynomials evaluated at the two endpoints of the kd tree cell edge.

In the multivariate case, such univariate interpolating polynomials are computed on each edge of the kd-tree cells, and are combined using blending functions (Gordon 1971). In the case of two regressors, if you specify INTERP=CUBIC in the MODEL statement, PROC LOESS uses Hermite cubic polynomials as blending functions. If you do not specify INTERP=CUBIC, or if you specify a model with more than two regressors, then PROC LOESS uses linear polynomials as blending functions. In these cases, the blending method reduces to tensor product interpolation from the \( 2^p \) vertices of each kd tree cell, where \( p \) is the number of regressors.

While the details of the kd tree and the fitted values at the vertices of the kd tree are implementation details that seldom need to be examined, PROC LOESS does provide options for their display. Each kd tree subdivision of the data used by PROC LOESS is placed in the “kdTree” table. The predicted values at the vertices of each kd tree are placed in the “PredAtVertices” table. You can request these tables using the DETAILS option in the MODEL statement.
Local Weighting

The size of the local neighborhoods that PROC LOESS uses in performing local fitting is determined by the smoothing parameter value $s$. When $s < 1$, the local neighborhood used at a point $x$ contains the $s$ fraction of the data points closest to the point $x$. When $s \geq 1$, all data points are used.

Suppose $q$ denotes the number of points in the local neighborhoods and $d_1, d_2, \ldots, d_q$ denote the distances in increasing order of the $q$ points closest to $x$. The point at distance $d_i$ from $x$ is given a weight $w_i$ in the local regression that decreases as the distance from $x$ increases. PROC LOESS uses a tricube weight function to define

$$w_i = \frac{32}{5} \left( 1 - \left( \frac{d_i}{d_q} \right)^3 \right)^3$$

If $s > 1$, then $d_q$ is replaced by $d_q s^{1/p}$ in the previous formula, where $p$ is the number of predictors in the model.

Finally, note that if a weight variable has been specified using a WEIGHT statement, then $w_i$ is multiplied by the corresponding value of the specified weight variable.

Iterative Reweighting

PROC LOESS can do iterative reweighting to improve the robustness of the fit in the presence of outliers in the data. Iterative reweighting is also appropriate when statistical inference is requested and the error distribution is symmetric but not Gaussian.

The number of iterations is specified by the ITERATIONS= option in the MODEL statement. The default is ITERATIONS=1, which corresponds to no reweighting.

At iterations beyond the first iteration, the local weights $w_i$ of the previous section are replaced by $r_i w_i$ where $r_i$ is a weight that decreases as the residual of the fitted value at the previous iteration at the point corresponding to $d_i$ increases. Refer to Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) for details.

Specifying the Local Polynomials

PROC LOESS uses linear or quadratic polynomials in doing the local least squares fitting. The option DEGREE = in the MODEL statement is used to specify the degree of the local polynomials used by PROC LOESS, with DEGREE = 1 being the default. In addition, when DEGREE = 2 is specified, the MODEL statement DROPSQUARE= option can be used to exclude specific monomials during the least squares fitting.

For example, the following statements use the monomials 1, $x_1$, $x_2$, $x_1^2 x_2$, and $x_2^2 x_2$ for the local least squares fitting.

```plaintext
proc loess data=notReal;
   model y= x1 x2/ degree=2 dropsquare=(x1);
run;
```
**Statistical Inference**

If you denote the $i$th measurement of the response by $y_i$ and the corresponding measurement of predictors by $x_i$, then

$$y_i = g(x_i) + \epsilon_i$$

where $g$ is the regression function and $\epsilon_i$ are independent random errors with mean zero. If the errors are normally distributed with constant variance, then you can obtain confidence intervals for the predictions from PROC LOESS. You can also obtain confidence limits in the case where $\epsilon_i$ is heteroscedastic but $a_i \epsilon_i$ has constant variance and $a_i$ are a priori weights that are specified using the WEIGHT statement of PROC LOESS. You can do inference in the case in which the error distribution is symmetric by using iterative reweighting.

Formulae for doing statistical inference under the preceding conditions can be found in Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992). The main result of their analysis is that a standardized residual for a loess model follows a $t$ distribution with $\rho$ degrees of freedom, where $\rho$ is called the “lookup degrees of freedom.” $\rho$ is a function of the smoothing matrix $L$, which defines the linear relationship between the fitted and observed dependent variable values of a loess model.

The determination of $\rho$ is computationally expensive and is not done by default. It is computed if you specify the DFMETHOD=EXACT or DFMETHOD=APPROX option in the MODEL statement. It is also computed if you specify any of the options CLM, STD, or T in the MODEL statement.

If you specify the CLM option in the MODEL statement, confidence limits are added to the OutputStatistics table. By default, 95% limits are computed, but you can change this by using the ALPHA= option in the MODEL statement.

**Automatic Smoothing Parameter Selection**

There are several methodologies for automatic smoothing parameter selection. One class of methods chooses the smoothing parameter value to minimize a criterion that incorporates both the tightness of the fit and model complexity. Such a criterion can usually be written as a function of the error mean square, $\hat{\sigma}^2$, and a penalty function designed to decrease with increasing smoothness of the fit. This penalty function is usually defined in terms of the matrix $L$ such that

$$\hat{y} = Ly$$

where $y$ is the vector of observed values and $\hat{y}$ is the corresponding vector of predicted values of the dependent variable. Examples of specific criteria are generalized cross-validation (Craven and Wahba 1979) and the Akaike information criterion (Akaike 1973). These classical selectors have two undesirable properties when used with local polynomial and kernel estimators: they tend to undersmooth and tend to be non-robust in the sense that small variations of the input data can change the choice
of smoothing parameter value significantly. Hurvich, Simonoff, and Tsai (1998) obtained several bias-corrected AIC criteria that limit these unfavorable properties and perform comparably with the plug-in selectors (Ruppert, Sheather, and Wand 1995). PROC LOESS provides automatic smoothing parameter selection using two of these bias-corrected AIC criteria, named AICC1 and AICC in Hurvich, Simonoff, and Tsai (1998), and generalized cross-validation, denoted by the acronym GCV.

The relevant formulae are

\[
AIC_{C_1} = n \log(\hat{\sigma}^2) + n \frac{\delta_1/\delta_2 (n + \nu_1)}{\delta_1/\delta_2 - 2}
\]

\[
AIC_C = \log(\hat{\sigma}^2) + 1 + \frac{2 (\text{Trace}(L) + 1)}{n \text{Trace}(L) - 2}
\]

\[
GCV = \frac{n \hat{\sigma}^2}{(n \text{Trace}(L))^2}
\]

where \(n\) is the number of observations and

\[
\delta_1 \equiv \text{Trace}(I - L)^T(I - L)
\]

\[
\delta_2 \equiv \text{Trace}((I - L)^T(I - L))^2
\]

\[
\nu_1 \equiv \text{Equivalent Number of Parameters} \equiv \text{Trace}(L^T L)
\]

Note that the values of \(\delta_1, \delta_2,\) and the “Equivalent Number of Parameters” are reported in the “Fit Summary” table.

You invoke these methods for automatic smoothing parameter selection by specifying the SELECT=criterion option in the MODEL statement, where criterion is one of AICC1, AICC, or GCV. PROC LOESS evaluates the specified criterion for a sequence of smoothing parameter values and selects the value in this sequence that minimizes the specified criterion. If multiple values yield the optimum, then the largest of these values is selected.

A second class of methods seeks to set an approximate measure of model degrees of freedom to a specified target value. These methods are useful for making meaningful comparisons between loess fits and other nonparametric and parametric fits. The approximate model degrees of freedom in a nonparametric fit is a number that is analogous to the number of free parameters in a parametric model. There are three commonly used measures of model degrees of freedom in nonparametric models. These criteria are \(\text{Trace}(L), \text{Trace}(L^T L),\) and \(2\text{Trace}L - \text{Trace}(L^T L).\) A discussion of their properties can be found in Hastie and Tibshirani (1990). You invoke these
methods by specifying the SELECT=DFCriterion(target) option in the MODEL statement, where DFCriterion is one of DF1, DF2, or DF3. The criterion that is minimized is given in the following table:

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Minimization Criterion</th>
</tr>
</thead>
<tbody>
<tr>
<td>SELECT=DF1(target)</td>
<td>Trace(L − target)</td>
</tr>
<tr>
<td>SELECT=DF2(target)</td>
<td>Trace(L^T L − target)</td>
</tr>
<tr>
<td>SELECT=DF3(target)</td>
<td>2Trace(L) − Trace(L^T L) − target</td>
</tr>
</tbody>
</table>

The results are summarized in the “Smoothing Criterion” table. This table is displayed whenever automatic smoothing parameter selection is performed. You can obtain details of the sequence of models examined by specifying the DETAILS(MODELsummary) option in the model statement to display the “Model Summary” table.

There are several ways in which you can control the sequence of models examined by PROC LOESS. If you specify the SMOOTH=value-list option in the MODEL statement, then only the values in this list are examined in performing the selection. For example, the following statements select the model that minimizes the AICC1 criterion among the three models with smoothing parameter values 0.1, 0.3, and 0.4:

```plaintext
proc loess data=notReal;
   model y= x1/ smooth=0.1 0.3 0.4 select=AICC1;
run;
```

If you do not specify the SMOOTH= option in the model statement, then by default PROC LOESS uses a golden section search method to find a local minimum of the specified criterion in the range (0, 1]. You can use the RANGE(lower,upper) modifier in the SELECT= option to change the interval in which the golden section search is performed. For example, the following statements request a golden section search to find a local minimizer of the GCV criterion for smoothing parameter values in the interval [0.1,0.5]:

```plaintext
proc loess data=notReal;
   model y= x1/select=GCV( range(0.1,0.5) );
run;
```

If you want to be sure of obtaining a global minimum in the range of smoothing parameter values examined, you can specify the GLOBAL modifier in the SELECT= option. For example, the following statements request that a global minimizer of the AICC criterion be obtained for smoothing parameter values in the interval [0.2,0.8]:

```plaintext
proc loess data=notReal;
   model y= x1/select=AICC( global range(0.2,0.8) );
run;
```
Note that even though the smoothing parameter is a continuous variable, a given range of smoothing parameter values corresponds to a finite set of local models. For example, for a data set with 100 observations, the range \([0.2, 0.4]\) corresponds to models with 20, 21, 22, \ldots, 40 points in the local neighborhoods. If the GLOBAL modifier is specified, all possible models in the range are evaluated sequentially.

Note that by default PROC LOESS displays a “Fit Summary” and other optionally requested tables only for the selected model. You can request that these tables be displayed for all models in the selection process by adding the STEPS modifier in the SELECT= option. Also note that by default scoring requested with SCORE statements is done only for the selected model. However, if you specify the STEPS in both the MODEL and SCORE statements, then all models evaluated in the selection process are scored.

In terms of computation, $AIC_C$, $GCV$, and $DF1$ depend on the smoothing matrix $L$ only through its trace. In the direct method, this trace can be computed efficiently. In the interpolated method using kd trees, there is some additional computational cost but the overall work is not significant compared to the rest of the computation. In contrast, the quantities $\delta_1$, $\delta_2$, and $\nu_1$, which appear in the $AICC_1$ criterion, and the $DF2$ and $DF3$ criteria, depend on the entire $L$ matrix and for this reason, the time needed to compute these quantities dominates the time required for the model fitting. Hence $SELECT=AICC1$, $SELECT=DF2$, and $SELECT=DF3$ are much more computationally expensive than $SELECT=AICC$, $SELECT=GCV$, and $SELECT=DF1$, especially when combined with the GLOBAL modifier. Hurvich, Simonoff, and Tsai (1998) note that $AIC_C$ can be regarded as an approximation of $AICC_1$ and that “the $AICC$ selector generally performs well in all circumstances.”

For models with one dependent variable, PROC LOESS uses $SELECT=AICC$ as its default, if you specify neither the SMOOTH= nor SELECT= options in the MODEL statement. With two or more dependent variables, automatic smoothing parameter selection needs to be done separately for each dependent variable. For this reason automatic smoothing parameter selection is not available for models with multiple dependent variables. In such cases you should use a separate PROC LOESS step for each dependent variable, if you want to use automatic smoothing parameter selection.

**Sparse and Approximate Degrees of Freedom Computation**

As noted in the “Statistical Inference” section on page 2243, obtaining confidence limits in loess models requires the computation of the “lookup degrees of freedom.” This in turn requires the computation of

$$
\delta_2 \equiv \text{Trace}\left( (I - L)^T(I - L) \right)^2
$$

where $L$ is the LOESS smoothing matrix (see the “Automatic Smoothing Parameter Selection” section on page 2243).

The work in a direct implementation of this formula grows as $n^3$, where $n$ is the number of observations in analysis. For large $n$, this work dominates the time needed to fit the loess model itself. To alleviate this computational bottleneck, Cleveland
and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) developed approximate methods for estimating this quantity in terms of more readily computable statistics. A different approach to obtaining a computationally cheap estimate of $\delta_2$ has been implemented in PROC LOESS.

For large data sets with significant local structure, the LOESS model is often used with small values of the smoothing parameter. Recalling that the smoothing parameter defines the fraction of the data used in each local regression, this means that the loess fit at any point in regressor space depends on only a small fraction of the data. This is reflected in the smoothing matrix $L$ whose $(i,j)$th entry is nonzero only if the $i$th and $j$th observations lie in at least one common local neighborhood. Hence the smoothing matrix is a sparse matrix (has mostly zero entries) in such cases. By exploiting this sparsity PROC LOESS now computes $\delta_2$ orders of magnitude faster than in previous implementations.

When each local neighborhood contains a large subset of the data, i.e., when the smoothing parameter is large, then it is no longer true that the smoothing matrix is sparse. However, since a point in a local neighborhood is given a local weight that decreases with its distance from the center of the neighborhood, many of the coefficients in the smoothing matrix turn out to be nonzero but with orders of magnitude smaller than that of the larger coefficients in the matrix. The approximate method for computing $\delta_2$ that has been implemented in PROC LOESS exploits these disparities in magnitudes of the elements in the smoothing matrix by setting the small elements to zero. This creates a sparse approximation of the smoothing matrix to which the fast sparse methods can be applied.

In order to decide the threshold at which elements in the smoothing matrix are set to zero, PROC LOESS samples the elements in the smoothing matrix to obtain the value of the element in a specified lower quantile in this sample. The magnitude of the element at this quantile is used as a cutoff value, and all elements in the smoothing matrix whose magnitude is less than this cutoff are set to zero for the approximate computation. By default all elements in the lower $90^{th}$ percentile are set to zero. You can use the DFMETHOD=APPROX(QUANTILE= ) option in the MODEL statement to change this value. As you increase the value for the quantile to be zeroed, you speed up the degrees of freedom computation at the expense of increasing approximation errors. You can also use the DFMETHOD=APPROX(CUTOFF= ) option in the MODEL statement to specify the cutoff value directly.

For small data sets, the approximate computation is not needed and would be rougher than for larger data sets. Hence PROC LOESS performs the exact computation for analyses with less than 500 points, even if DFMETHOD=APPROX is specified in the model statement. Also, for small values of the smoothing parameter, elements in the lower specified quantile may already all be zero. In such cases the approximate method is the same as the exact method. PROC LOESS labels as approximate any statistics that depend on the approximate computation of $\delta_2$ only in the cases where the approximate computation was used and is different from the exact computation.
Scoring Data Sets

One or more SCORE statements can be used with PROC LOESS. A data set that includes all the variables specified in the MODEL and BY statements must be specified in each SCORE statement. Score results are placed in the ScoreResults table. This table is not displayed by default, but specifying the PRINT option in the SCORE statement produces this table. If you specify the CLM option in the SCORE statement, confidence intervals are included in the ScoreResults table.

Note that scoring is not supported when the DIRECT option is specified in the MODEL statement. Scoring at a point specified in a score data set is done by first finding the cell in the kd tree containing this point and then interpolating the scored value from the predicted values at the vertices of this cell. This methodology precludes scoring any points that are not contained in the box that surrounds the data used in fitting the loess model.

ODS Table Names

PROC LOESS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

ODS Graphics (Experimental)

This section describes the use of ODS for creating statistical graphs with the LOESS procedure. These graphics are experimental in this release, meaning that both the
graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

When the ODS GRAPHICS are in effect, the LOESS procedure produces a variety of plots. For models with multiple dependent variables, separate plots are produced for each dependent variable. For models where multiple smoothing parameters are requested with the SMOOTH= option in the MODEL statement and smoothing parameter value selection is not requested, then separate plots are produced for each smoothing parameter. If smoothing parameter value selection is requested with the SELECT=option in the MODEL statement, then the plots are produced for the selected model only. However, if the STEPS qualifier is included with the SELECT= option, then plots are produced for all smoothing parameters examined in the selection process.

The plots available are as follows:

- When smoothing parameter value selection is performed, the procedure displays a scatterplot of the value of SELECTION= criterion versus the smoothing parameter value for all smoothing parameter values examined in the selection process.
- With a single regressor, the procedure displays a scatterplot of the input data with the fitted LOESS curve overlayed. If the CLM option is specified in the model statement, then a confidence band at the significance level specified in the ALPHA= option is included in the plot. For each SCORE statement a scatterplot of the scored LOESS fit at the requested points is displayed.
- When you specify the RESIDUAL option in the MODEL statement, the procedure displays a panel containing plots of the residual versus each of the regressors in the model, and also a summary panel of fit diagnostics:
  - residuals versus the predicted values
  - histogram of the residuals
  - a normal quantile plot of the residuals
  - a “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals. This plot “shows how much variation in the data is explained by the fit and how much remains in the residuals” (Cleveland 1993).
  - dependent variable values versus the predicted values

Note that plots in the Fit Diagnostics panel can be requested individually by specifying the PLOTS(UNPACKPANELS) option in the PROC LOESS statement.
PLOTS (general-plot-options)
specifies characteristics of the graphics produced when you use the experimental
ODS GRAPHICS statement. You can specify the following general-plot-options in
parentheses after the PLOTS option:

UNPACK|UNPACKPANELS specifies that plots in the Fit Diagnostics Panel should
be displayed separately. Use this option if you want to access indi-
vidual diagnostic plots within the panel.

MAXPOINTS=number | NONE specifies that plots with elements that require pro-
cessing more than number points are suppressed. The default
is MAXPOINTS=5000. This cutoff is ignored if you specify
MAXPOINTS=NONE.

ODS Graph Names

PROC LOESS assigns a name to each graph it creates using ODS. You can use these
names to reference the graphs when using ODS. The names are listed in Table 41.5.

To request these graphs you must specify the ODS GRAPHICS statement. For more
information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics
Using ODS.”

Examples

Example 41.1. Engine Exhaust Emissions

Investigators studied the exhaust emissions of a one cylinder engine (Brinkman 1981). The SAS data set Gas contains the results data. The dependent variable, NOx, measures the concentration, in micrograms per joule, of nitric oxide and nitrogen dioxide normalized by the amount of work of the engine. The independent variable, E, is a measure of the richness of the air and fuel mixture.

The following PROC GPLOT statements produce the simple scatter plot of these data, displayed in Output 41.1.1.

symbol1 color=black value=dot ;
proc gplot data=Gas;
    plot NOx*E;
run;
The following statements fit two loess models for these data. Because this is a small data set, it is reasonable to do direct fitting at every data point. As there is substantial curvature in the data, quadratic local polynomials are used. An ODS OUTPUT statement creates two output data sets containing the “Output Statistics” and “Fit Summary” tables.

```plaintext
proc loess data=Gas;
  ods output OutputStatistics = GasFit
      FitSummary=Summary;
  model NOx = E / degree=2 direct smooth = 0.6 1.0
           alpha=.01 all details;
run;
```

The “Fit Summary” table for smoothing parameter value 0.6, shown in Output 41.1.2, records the fitting parameters specified and some overall fit statistics.
The matrix $L$ referenced in the “Fit Summary” table is the smoothing matrix. This matrix satisfies

$$\hat{y} = Ly$$

where $y$ is the vector of observed values and $\hat{y}$ is the corresponding vector of predicted values of the dependent variable. The quantities

$$\delta_1 \equiv \text{Trace}((I - L)^T(I - L))$$
$$\delta_2 \equiv \text{Trace}((I - L)^T(I - L))^2$$
$$\rho \equiv \text{Lookup Degrees of Freedom}$$

$$\equiv \frac{\delta_1^2}{\delta_2}$$

in the “Fit Summary” table are used in doing statistical inference.

The equivalent number of parameters and residual standard error in the “Fit Summary” table are defined by

$$\text{Equivalent Number of Parameters} \equiv \text{Trace}\, L^T L$$
$$\text{Residual Standard Error} \equiv \sqrt{\frac{\text{Residual SS}}{\delta_1}}$$

The “Output Statistics” table for smoothing parameter value 0.6 is shown in Output 41.1.3. Note that, as the ALL option in the MODEL statement is specified, this table includes all the relevant optional columns. Furthermore, because the ALPHA=0.01 option is specified in the MODEL statement, the confidence limits in this table are 99% limits.

Output 41.1.5. Scatter Plots of Loess Fit Residuals

The residual plots show that with smoothing parameter value 1, the loess model exhibits a lack of fit. Analysis of variance can be used to compare the model with smoothing parameter value 1, which serves as the null model, to the model with smoothing parameter value 0.6.

The statistic

\[ F = \frac{(\text{rss}(n) - \text{rss})/(\delta(n) - \delta_1)}{\text{rss}/\delta_1} \]
has a distribution that is well approximated by an $F$ distribution with

$$
\nu = \frac{(\delta_1^{(n)} - \delta_1)^2}{\delta_2^{(n)} - \delta_2}
$$

two numerator degrees of freedom and $\rho$ denominator degrees of freedom (Cleveland and Grosse 1991). Here quantities with superscript $n$ refer to the null model, $\text{rss}$ is the residual sum of squares, and $\delta_1$, $\delta_2$, and $\rho$ are as previously defined.

The “Fit Summary” tables contain the information needed to carry out such an analysis. These tables have been captured in the output data set named Summary using an ODS OUTPUT statement. The following statements extract the relevant information from this data set and carry out the analysis of variance:

```plaintext
data h0 h1;
  set Summary(keep=SmoothingParameter Label1 nValue1
    where=(Label1 in ('Residual Sum of Squares','Delta1',
    'Delta2','Lookup Degrees of Freedom')));
  if SmoothingParameter = 1 then output h0;
  else output h1;
run;

proc transpose data=h0(drop=SmoothingParameter Label1) out=h0;
  data h0(drop=_NAME_); set h0;
    rename Col1 = RSSNull
                  Col2 = delta1Null
                  Col3 = delta2Null;
  proc transpose data=h1(drop=SmoothingParameter Label1) out=h1;
    data h1(drop=_NAME_); set h1;
      rename Col1 = RSS
                      Col2 = delta1
                      Col3 = delta2
                      Col4 = rho;
    data ftest; merge h0 h1;
      nu = (delta1Null - delta1)**2 / (delta2Null - delta2);
      Numerator = (RSSNull - RSS)/(delta1Null - delta1);
      Denominator = RSS/delta1;
      FValue = Numerator / Denominator;
      PValue = 1 - ProbF(FValue, nu, rho);
      label nu = 'Num DF'
                     rho = 'Den DF'
                     FValue = 'F Value'
                     PValue = 'Pr > F';
    proc print data=ftest label;
      var nu rho Numerator Denominator FValue PValue;
      format nu rho FValue 7.2 PValue 6.4;
    run;
```

The results are shown in Output 41.1.6.
Output 41.6. Test ANOVA for LOESS MODELS of Gas Data

The highly significant $p$-value confirms that the loess model with smoothing parameter value 0.6 provides a better fit than the model with smoothing parameter value 1.

Example 41.2. Sulfate Deposits in the USA for 1990

The following data set contains measurements in grams per square meter of sulfate ($SO_4$) deposits during 1990 at 179 sites throughout the 48 states.

data SO4;
  input Latitude Longitude SO4 @@;
datalines;
32.45833 87.24222 1.403 34.28778 85.96889 2.103
33.07139 109.86472 0.299 36.07167 112.15500 0.304
31.95056 112.80000 0.263 33.60500 92.09722 1.950
42.92889 109.78667 0.182 43.22278 109.99111 0.161
43.87333 104.19222 0.306 44.91722 110.42028 0.210
45.07611 72.67556 2.646
;

The following statements produce the two scatter plots of the SO4 data shown in Output 41.2.1 and Output 41.2.2:

symbol1 color=black value=dot;
proc gplot data=SO4;
  plot Latitude*Longitude/hreverse;
run;

proc g3d data=SO4;
  format SO4 f4.1;
  scatter Longitude*Latitude=SO4 / shape='balloon'
    size=0.35
    rotate=80
    tilt=60;
run;
Output 41.2.1. Locations of Sulfate Measurements

Output 41.2.2. Scatter Plot of SO4 Data
From these scatter plots, it is clear that the largest concentrations are in the northeastern United States. These plots also indicate that a nonparametric surface, such as a loess fit, is appropriate for these data.

The sulfate measurements are irregularly spaced. The following statements create a SAS data set containing a regular grid of points that will be used in the SCORE statement:

```sas
data PredPoints;
   do Latitude = 26 to 46 by 1;
      do Longitude = 79 to 123 by 1;
         output;
      end;
   end;
end;
```

The following statements fit loess models for two values of the smoothing parameter and save the results in output data sets:

```sas
proc loess data=SO4;
   ods Output ScoreResults=ScoreOut
       OutputStatistics=StatOut;
   model SO4=Latitude Longitude/smooth=0.15 0.4 residual;
   score data=PredPoints;
run;
```

Notice that even though there are two predictors in the model, the SCALE= option is not appropriate because the predictors (Latitude and Longitude) are identically scaled.

Output 41.2.3 shows scatter plots of the fit residuals versus each of the predictors for the two smoothing parameter values specified. A loess fit of the residuals is also shown on these scatter plots and is obtained using PROC LOESS with the StatOut data set generated by the previous PROC LOESS step.

```sas
proc loess data=StatOut;
   by SmoothingParameter;
   ods output OutputStatistics=ResidLatOut;
   model residual=Latitude;
run;
proc loess data=StatOut;
   by SmoothingParameter;
   ods output OutputStatistics=ResidLongOut;
   model residual=Longitude;
run;
proc sort data=ResidLatOut;
   by SmoothingParameter Latitude;
run;
proc sort data=ResidLongOut;
   by SmoothingParameter Longitude;
run;
```
Example 41.2. Sulfate Deposits in the USA for 1990

```sas
goptions nodisplay;
symbol1 color=black value=dot;
symbol2 color=black interpol=join value=none;
%let opts = vaxis=axis1 overlay vref=0 lv=2;
axis1 label = (angle=90 rotate=0);
proc gplot data=ResidLatOut;
   by smoothingParameter;
   format DepVar 3.1;
   plot (DepVar Pred) * Latitude / &opts name='lat';
run;
proc gplot data=ResidLongOut;
   by smoothingParameter;
   format DepVar 3.1;
   plot (DepVar Pred) * Longitude / &opts name='long';
run;
goptions display;
proc greplay nofs tc=sashelp.templt template=l2r2;
   igout gseg;
   treplay 1:long 2:long1 3:lat 4:lat1;
run; quit;
```

Output 41.2.3. Scatter Plots of Loess Fit Residuals
The scatter plots in Output 41.2.3 reveal that, with smoothing parameter value 0.4, there is significant information in the data that is not being captured by the loess model. By contrast, the residuals for the more localized smoothing parameter value 0.15 show a better fit.

The ScoreOut data set contains the model predictions at the grid defined in the PredPoints data set. The following statements request a fitted surface and a contour plot of this surface with a smoothing parameter value 0.15:

```
proc g3d data=ScoreOut(where= (smoothingParameter=0.15));
    format Latitude f4.0;
    format Longitude f4.0;
    format p_SO4 f4.1;
    plot Longitude*Latitude=p_SO4/tilt=60 rotate=80;
run;

proc gcontour data=ScoreOut(where= (smoothingParameter=0.15));
    format latitude f4.0;
    format longitude f4.0;
    format p_SO4 f4.1;
    plot Latitude*Longitude = p_SO4/hreverse;
run;
```

**Output 41.2.4.** LOESS Fit of SO4 Data
Example 41.3. Catalyst Experiment

The following data set records the results of an experiment to determine how the yield of a chemical reaction varies with temperature and amount of a catalyst used.

data Experiment;
  input Temperature Catalyst Yield;
datalines;
  80  0.000  6.842
  80  0.002  7.944
  .
  .  more data lines
  .
  140  0.078  4.012
  140  0.080  5.212
;

Researchers know that about 10% of the yield measurements are corrupted due to an intermittent equipment problem. This can be seen in the surface plot of raw data shown in Output 41.3.1.

proc g3d data=Experiment;
  plot Temperature*Catalyst=Yield/zmin=0 zmax=25 zticknum=6;
run;
A robust fitting method is needed to estimate the underlying surface in the presence of data outliers. The following statements invoke PROC LOESS with iterative reweighting to fit a surface to these data:

```plaintext
proc loess data=Experiment;
  ods output OutputStatistics=Results;
  model Yield = Temperature Catalyst /
                  scale=sd(0.1)
                  iterations=3;
run;
```

The ITERATIONS=3 option in the MODEL statement requests two iteratively reweighted iterations. Note the use of the SCALE=SD(0.1) option in the MODEL statement. This specifies that the independent variables in the model are to be divided by their respective 10% trimmed standard deviations before the fitted model is computed. This is appropriate as the independent variables Temperature and Catalyst are not similarly scaled. The “Scale Details” table produced by PROC LOESS is shown in Output 41.3.2.
Output 41.3.2. Scale Details Table

   5.7  6.7  3.9  8.5  8.3 10.8 16.7 12.6
   12.5 12.5  9.8  7.2  4.1 10.6 10.1  1.1
   11.9 13.6 16.3 17.6 15.5 16.0 15.2 11.2
   14.3 14.5  8.5 12.0 12.7 11.3 14.5 15.1
   10.4 11.5 13.4  7.5  0.6  0.3  5.5  5.0
   4.6  8.2  9.9  9.2 12.5 10.9  9.9  8.9
   7.6  9.5  8.4 10.7 13.6 13.7 13.7 16.5
  16.8 17.1 15.4  9.5  6.1 10.1  9.3  5.3
  11.2 16.6 15.6 12.0 11.5  8.6 13.8  8.7
   8.6  8.6  8.7 12.8 13.2 14.0 13.4 14.8 
;
```

The following PROC GPLOT statements produce the simple scatter plot of these data, displayed in Output 41.4.1:

```
symbol1 color=black value=dot ;
proc gplot data=ENSO;
  plot Pressure*Month / hminor = 0
  vminor = 0
  vaxis = axis1
  frame;
  axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);
run;
```

You can compute a loess fit and plot the results for these data using the following statements:

```bash
ods output OutputStatistics=ENSOstats;
proc loess data=ENSO;
  model Pressure=Month ;
run;

symbol1 color=black value=dot h=2.5 pct;
symbol2 color=black interpol=join value=none width=2;
proc gplot data=ENSOstats;
  plot (depvar pred)*Month / overlay
    hminor = 0
    vminor = 0
    vaxis = axis1
    frame;
    axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);
run; quit;
```
The “Smoothing Criterion” and “Fit Summary” tables are shown in Output 41.4.2 and the fit is plotted in Output 41.4.3.

```

The smoothing parameter value used for the loess fit shown in Output 41.4.3 was chosen using the default method of PROC LOESS, namely a golden section minimization of the AICC criterion over the interval (0, 1]. The fit seems to be oversmoothed. What accounts for this poor fit?
One possibility is that the golden section search has found a local rather than a global minimum of the AICC criterion. You can test this by redoing the fit requesting a global minimum. It is also helpful to plot the AICC criterion as a function of the smoothing parameter value used. You do this with the following statements:

```plaintext
ods output ModelSummary=ENSOsummary;

proc loess data=ENSO;
  model Pressure=Month/select=AICC(global);
run;

proc sort data=ENSOsummary;
  by smooth;
run;

symbol1 color=black interpol=join value=none width=2;
proc gplot data=ENSOsummary;
  format AICC f4.1; format smooth f4.1;
  plot AICC*Smooth /
     hminor = 0 vminor = 0 vaxis = axis1 frame;
  axis1 label = ( r=0 a=90 );
run; quit;
```

The results are shown in Output 41.4.4.
The explanation for the oversmoothed fit in Output 41.4.3 is now apparent. The golden section search algorithm found the local minimum that occurs near the value 0.22 of the smoothing parameter rather than the global minimum that occurs near 0.06. Note that if you restrict the range of smoothing parameter values examined to lie below 0.2, then the golden section search finds the global minimum as the following statements demonstrate:

```plaintext
ods output OutputStatistics=ENSOstats;

proc loess data=ENSO;
  model Pressure=Month/select=AICC( range(0.03,0.2) );
run;

symbol1 color=black value=dot h=2.5 pct;
symbol2 color=black interpol=join value=none width=2;
proc gplot data=ENSOstats;
  plot (depvar pred)*Month / overlay
    hminor = 0
    vminor = 0
    vaxis = axis1
    frame;
    axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);
run; quit;
```

The fit obtained is shown in Output 41.4.5.
Output 41.4.5. Loess Fit for the ENSO Data

The loess fit shown in Output 41.4.5 clearly shows an annual cycle in the data. An interesting question is whether there is some phenomenon captured in the data that would explain the presence of the local minimum near 0.22 in the AICC curve. Note that there is some evidence of a cycle of about 42 months in the oversmoothed fit in Output 41.4.3. You can see this cycle because the strong annual cycle in Output 41.4.5 has been smoothed out. The physical phenomenon that accounts for the existence of this cycle has been identified as the periodic warming of the Pacific Ocean known as “El Niño.”

Example 41.5. ODS Graphics

This example highlights the use of ODS for creating statistical graphs with the LOESS procedure. The ENSO example is revisited to show how these graphics can be used to enrich the analysis and simplify the process for obtaining functionally equivalent plots to those previously presented with this example.

To request these plots you to need to specify the experimental ODS GRAPHICS statement. For general information about ODS graphics see Chapter 15, “Statistical Graphics Using ODS.” The following statements produce the default plots:
ods html;
ods graphics on;

proc loess data=ENSO;
    model Pressure=Month/select=AICC( range(0.03,0.4) global) clm
        alpha=0.01;
run;

ods graphics off;
ods html close;

Output 41.5.1. Smoothing Parameter Selection (Experimental)

Note that Output 41.5.1 has points corresponding to all models with smoothing parameters between 0.03 and 0.4, as these models were requested in the SELECT= option. By default, only the models evaluated in the golden section search for the optimal smoothing parameter appear on this plot.
Output 41.5.2.  LOESS Fit of ENSO Data (Experimental)

The fit plot shown in Output 41.5.2 is produced for models with a single regressor. Note that Output 41.5.2 includes the 99% confidence band that was requested in the MODEL statement using the CLM and ALPHA= options.

Diagnostic plots are produced when the RESIDUAL option is included in the model statement. The following statements produce these diagnostic plots:

```plaintext
ods html;
ods graphics on;

proc loess data=ENSO;
    model Pressure=Month/smooth = 0.0565 residual;
run;

ods graphics off;
ods html close;
```
The residuals in Output 41.5.3 do not exhibit any obvious patterns, suggesting that the signal in the data has been successfully modeled.

Additional information about the LOESS fit can be seen in the plots in the fit diagnostics panel that is also produced whenever the RESIDUAL option is specified in the MODEL statement. Output 41.5.4 shows this panel for the optimal smoothing parameter.
Output 41.5.4. Fit Diagnostics Panel (Experimental)

These diagnostic plots all suggest that the fit obtained is appropriate for these data:

- The plot of residuals versus predicted value shows no obvious pattern.
- The residual histogram with overlayed normal density supports the assumption of gaussian errors.
- The normal quantile plot is consistent with the assumption of gaussian errors.
- The “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals shows that the spread in the residuals is no greater than the spread in the centered fit. For inappropriate models, the spread of the residuals in such a plot is often greater than the spread of the centered fit.
- The plot of the dependent variable versus the predicted values is centered around a 45 degree line and shows no obvious outliers.

If you want to obtain the plots in the Diagnostics Panel as individual plots, you can do so by specifying the PLOTS(UNPACKPANELS) option in the PROC LOESS statement. The following statements provide an example:
Output 41.5.5. Residual Histogram (Experimental)

The residual histogram is shown in Output 41.5.5.

Chapter 42
The LOGISTIC Procedure
Overview

Binary responses (for example, success and failure), ordinal responses (for example, normal, mild, and severe), and nominal responses (for example, major TV networks viewed at a certain hour) arise in many fields of study. Logistic regression analysis is often used to investigate the relationship between these discrete responses and a set of explanatory variables. Several texts that discuss logistic regression are Collett (1991), Agresti (1990), Cox and Snell (1989), Hosmer and Lemeshow (2000), and Stokes, Davis, and Koch (2000).

For binary response models, the response, $Y$, of an individual or an experimental unit can take on one of two possible values, denoted for convenience by 1 and 2 (for example, $Y = 1$ if a disease is present, otherwise $Y = 2$). Suppose $x$ is a vector of explanatory variables and $\pi = \Pr(Y = 1 \mid x)$ is the response probability to be modeled. The linear logistic model has the form

$$\text{logit}(\pi) \equiv \log \left( \frac{\pi}{1 - \pi} \right) = \alpha + \beta' x$$

where $\alpha$ is the intercept parameter and $\beta$ is the vector of parameters. Notice that the LOGISTIC procedure, by default, models the probability of the lower response levels.

The logistic model shares a common feature with a more general class of linear models, that a function $g = g(\mu)$ of the mean of the response variable is assumed to be linearly related to the explanatory variables. Since the mean $\mu$ implicitly depends on the stochastic behavior of the response, and the explanatory variables are assumed to be fixed, the function $g$ provides the link between the random (stochastic) component and the systematic (deterministic) component of the response variable $Y$. For this reason, Nelder and Wedderburn (1972) refer to $g(\mu)$ as a link function. One advantage of the logit function over other link functions is that differences on the logistic scale are interpretable regardless of whether the data are sampled prospectively or retrospectively (McCullagh and Nelder 1989, Chapter 4). Other link functions that are widely used in practice are the probit function and the complementary log-log function. The LOGISTIC procedure enables you to choose one of these link functions, resulting in fitting a broader class of binary response models of the form

$$g(\pi) = \alpha + \beta' x$$

For ordinal response models, the response, $Y$, of an individual or an experimental unit may be restricted to one of a (usually small) number, $k + 1 (k \geq 1)$, of ordinal values, denoted for convenience by $1, \ldots, k, k + 1$. For example, the severity of
coronary disease can be classified into three response categories as 1=no disease, 2=angina pectoris, and 3=myocardial infarction. The LOGISTIC procedure fits a common slopes cumulative model, which is a parallel lines regression model based on the cumulative probabilities of the response categories rather than on their individual probabilities. The cumulative model has the form

\[ g(\Pr(Y \leq i \mid x)) = \alpha_i + \beta'x, \quad i = 1, \ldots, k \]

where \(\alpha_1, \ldots, \alpha_k\) are \(k\) intercept parameters, and \(\beta\) is the vector of parameters. This model has been considered by many researchers. Aitchison and Silvey (1957) and Ashford (1959) employ a probit scale and provide a maximum likelihood analysis; Walker and Duncan (1967) and Cox and Snell (1989) discuss the use of the log-odds scale. For the log-odds scale, the cumulative logit model is often referred to as the proportional odds model.

For nominal response logistic models, where the \(k+1\) possible responses have no natural ordering, the logit model can also be extended to a generalized logit model, which has the form

\[ \log \left( \frac{\Pr(Y = i \mid x)}{\Pr(Y = k + 1 \mid x)} \right) = \alpha_i + \beta_i'x, \quad i = 1, \ldots, k \]

where the \(\alpha_1, \ldots, \alpha_k\) are \(k\) intercept parameters, and the \(\beta_1, \ldots, \beta_k\) are \(k\) vectors of parameters. These models were introduced by McFadden (1974) as the discrete choice model, and they are also known as multinomial models.

The LOGISTIC procedure fits linear logistic regression models for discrete response data by the method of maximum likelihood. It can also perform conditional logistic regression for binary response data and exact conditional logistic regression for binary and nominal response data. The maximum likelihood estimation is carried out with either the Fisher-scoring algorithm or the Newton-Raphson algorithm. You can specify starting values for the parameter estimates. The logit link function in the logistic regression models can be replaced by the probit function, the complementary log-log function, or the generalized logit function.

The LOGISTIC procedure enables you to specify categorical variables (also known as CLASS variables) or continuous variables as explanatory variables. You can also specify more complex model terms such as interactions and nested terms in the same way as in the GLM procedure. Any term specified in the model is referred to as an effect, whether it is a continuous variable, a CLASS variable, an interaction, or a nested term.

The LOGISTIC procedure allows either a full-rank parameterization or a less-than-full-rank parameterization. The full-rank parameterization offers eight coding methods: effect, reference, ordinal, polynomial, and orthogonalizations of these. The effect coding is the same method that is used in the CATMOD procedure. The less-than-full-rank parameterization is the same coding as that used in the GLM procedure.

The LOGISTIC procedure provides four effect selection methods: forward selection, backward elimination, stepwise selection, and best subset selection. The best subset
selection is based on the likelihood score statistic. This method identifies a specified number of best models containing one, two, three effects, and so on, up to a single model containing effects for all the explanatory variables.

The LOGISTIC procedure has some additional options to control how to move effects in and out of a model with various model-building strategies such as forward selection, backward elimination, or stepwise selection. When there are no interaction terms, a main effect can enter or leave a model in a single step based on the $p$-value of the score or Wald statistic. When there are interaction terms, the selection process also depends on whether you want to preserve model hierarchy. These additional options enable you to specify whether model hierarchy is to be preserved, how model hierarchy is applied, and whether a single effect or multiple effects can be moved in a single step.

Odds ratio estimates are displayed along with parameter estimates. You can also specify the change in the explanatory variables for which odds ratio estimates are desired. Confidence intervals for the regression parameters and odds ratios can be computed based either on the profile likelihood function or on the asymptotic normality of the parameter estimators.

Various methods to correct for overdispersion are provided, including Williams’ method for grouped binary response data. The adequacy of the fitted model can be evaluated by various goodness-of-fit tests, including the Hosmer-Lemeshow test for binary response data.

Like many procedures in SAS/STAT software that enable the specification of CLASS variables, the LOGISTIC procedure provides a `CONTRAST` statement for specifying customized hypothesis tests concerning the model parameters. The `CONTRAST` statement also provides estimation of individual rows of contrasts, which is particularly useful for obtaining odds ratio estimates for various levels of the CLASS variables.

You can perform a conditional logistic regression on binary response data by specifying the `STRATA` statement. This enables you to perform matched-set and case-control analyses. The number of events and nonevents can vary across the strata. Many of the features available with the unconditional analysis are also available with a conditional analysis.

The LOGISTIC procedure enables you to perform exact conditional logistic regression using the method of Hirji, Mehta, and Patel (1987) and Mehta, Patel, and Senchaudhuri (1992) by specifying one or more `EXACT` statements. You can test individual parameters or conduct a joint test for several parameters. The procedure computes two exact tests: the exact conditional score test and the exact conditional probability test. You can request exact estimation of specific parameters and corresponding odds ratios where appropriate. Both point estimates and confidence intervals are provided.

Further features of the LOGISTIC procedure enable you to

- control the ordering of the response categories
- compute a generalized $R^2$ measure for the fitted model
reclassify binary response observations according to their predicted response probabilities

• test linear hypotheses about the regression parameters

• create a data set for producing a receiver operating characteristic curve for each fitted model

• create a data set containing the estimated response probabilities, residuals, and influence diagnostics

• score a data set using a previously fitted model

Experimental graphics are now available with the LOGISTIC procedure. For more information, see the “ODS Graphics” section on page 2388.

The remaining sections of this chapter describe how to use PROC LOGISTIC and discuss the underlying statistical methodology. The “Getting Started” section introduces PROC LOGISTIC with an example for binary response data. The “Syntax” section (page 2289) describes the syntax of the procedure. The “Details” section (page 2329) summarizes the statistical technique employed by PROC LOGISTIC. The “Examples” section (page 2391) illustrates the use of the LOGISTIC procedure with 10 applications.

Getting Started

The LOGISTIC procedure is similar in use to the other regression procedures in the SAS System. To demonstrate the similarity, suppose the response variable \( y \) is binary or ordinal, and \( x_1 \) and \( x_2 \) are two explanatory variables of interest. To fit a logistic regression model, you can use a MODEL statement similar to that used in the REG procedure:

```plaintext
proc logistic;
    model y=x1 x2;
run;
```

The response variable \( y \) can be either character or numeric. PROC LOGISTIC enumerates the total number of response categories and orders the response levels according to the response variable option ORDER= in the MODEL statement. The procedure also allows the input of binary response data that are grouped:

```plaintext
proc logistic;
    model r/n=x1 x2;
run;
```

Here, \( n \) represents the number of trials and \( r \) represents the number of events.
The following example illustrates the use of PROC LOGISTIC. The data, taken from Cox and Snell (1989, pp. 10–11), consist of the number, \( r \), of ingots not ready for rolling, out of \( n \) tested, for a number of combinations of heating time and soaking time. The following invocation of PROC LOGISTIC fits the binary logit model to the grouped data:

```
data ingots;
  input Heat Soak r n @@;
datalines;
  7 1.0  0  0 10 14 1.0  0  31 27 1.0  1  56 51 1.0  3  13
  7 1.7  0  1 17 14 1.7  0  43 27 1.7  4  44 51 1.7  0  1
  7 2.2  0  0  7 14 2.2  2  33 27 2.2  0  21 51 2.2  0  1
  7 2.8  0 12 14 2.8  0  31 27 2.8  1  22 51 4.0  0  1
  7 4.0  0  0  9 14 4.0  0  19 27 4.0  1  16
;

proc logistic data=ingots;
  model r/n=Heat Soak;
run;
```

The results of this analysis are shown in the following tables.

Figure 42.3. Fit Statistics and Hypothesis Tests

The “Model Fit Statistics” table (Figure 42.3) contains the Akaike Information Criterion (AIC), the Schwarz Criterion (SC), and the negative of twice the log likelihood (-2 Log L) for the intercept-only model and the fitted model. AIC and SC can be used to compare different models, and the ones with smaller values are preferred. Results of the likelihood ratio test and the efficient score test for testing the joint significance of the explanatory variables (Soak and Heat) are included in the “Testing Global Null Hypothesis: BETA=0” table (Figure 42.3).

**Figure 42.4.** Parameter Estimates and Odds Ratios

The “Analysis of Maximum Likelihood Estimates” table in Figure 42.4 lists the parameter estimates, their standard errors, and the results of the Wald test for individual parameters. The odds ratio for each effect parameter, estimated by exponentiating the corresponding parameter estimate, is shown in the “Odds Ratios Estimates” table (Figure 42.4), along with 95% Wald confidence intervals.

Using the parameter estimates, you can calculate the estimated logit of $\pi$ as

$$-5.5592 + 0.082 \times \text{Heat} + 0.0568 \times \text{Soak}$$

If Heat=7 and Soak=1, then logit($\hat{\pi}$) = -4.9284. Using this logit estimate, you can calculate $\hat{\pi}$ as follows:

$$\hat{\pi} = 1/(1 + e^{-4.9284}) = 0.0072$$

This gives the predicted probability of the event (ingot not ready for rolling) for Heat=7 and Soak=1. Note that PROC LOGISTIC can calculate these statistics for you; use the OUTPUT statement with the PREDICTED= option.

</tr>
</tbody>
</table>

**Figure 42.5.** Association Table

Finally, the “Association of Predicted Probabilities and Observed Responses” table (Figure 42.5) contains four measures of association for assessing the predictive abil-
ity of a model. They are based on the number of pairs of observations with different response values, the number of concordant pairs, and the number of discordant pairs, which are also displayed. Formulas for these statistics are given in the “Rank Correlation of Observed Responses and Predicted Probabilities” section on page 2350.

To illustrate the use of an alternative form of input data, the following program creates the INGOTS data set with new variables `NotReady` and `Freq` instead of `n` and `r`. The variable `NotReady` represents the response of individual units; it has a value of 1 for units not ready for rolling (event) and a value of 0 for units ready for rolling (nonevent). The variable `Freq` represents the frequency of occurrence of each combination of `Heat`, `Soak`, and `NotReady`. Note that, compared to the previous data set, `NotReady=1` implies `Freq=r`, and `NotReady=0` implies `Freq=n−r`.

```sas
data ingots;
  input Heat Soak NotReady Freq @@;
datalines;
7 1.0 0 10
7 1.7 0 17
7 2.2 0 7
7 2.8 0 12
7 4.0 0 9
14 1.0 0 31
14 1.7 0 43
14 2.2 1 2
14 2.8 0 31
14 4.0 0 31
27 1.0 0 19
27 1.0 1 1
27 1.0 0 55
27 1.7 1 2
27 1.7 0 55
27 1.7 1 4
27 1.7 0 21
27 1.7 1 2
27 4.0 0 15
51 1.0 1 3
51 1.0 0 10
51 1.7 0 1
51 1.7 0 1
51 4.0 0 1
;
```

The following SAS statements invoke PROC LOGISTIC to fit the same model using the alternative form of the input data set.

```sas
proc logistic data=ingots;
  model NotReady(event='1') = Soak Heat;
  freq Freq;
run;
```

Results of this analysis are the same as the previous one. The displayed output for the two runs are identical except for the background information of the model fit and the “Response Profile” table shown in Figure 42.6.

<table>
<thead>
<tr>
<th>Ordered Value</th>
<th>NotReady</th>
<th>Total Frequency</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0</td>
<td>375</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>12</td>
</tr>
</tbody>
</table>

*Probability modeled is NotReady=1.*

**Figure 42.6.** Response Profile with Single-Trial Syntax
By default, Ordered Values are assigned to the sorted response values in ascending order, and PROC LOGISTIC models the probability of the response level that corresponds to the Ordered Value 1. There are several methods to change these defaults; the preceding statements specify the response variable option EVENT= to model the probability of NotReady=1 as displayed in Figure 42.6. See the “Response Level Ordering” section on page 2329 for more details.

Syntax

The following statements are available in PROC LOGISTIC:

```
PROC LOGISTIC < options >;
   BY variables ;
   CLASS variable <(v-options)> <variable <(v-options)>... >
   < / v-options >;
   CONTRAST 'label' effect values <,... effect values > < / options >;
   EXACT < 'label' > < Intercept > < effects > < / options > ;
   FREQ variable ;
   MODEL events/trials = < effects > < / options > ;
   MODEL variable < (variable_options) > = < effects > < / options > ;
   OUTPUT < OUT=SAS-data-set >
   < keyword=name...keyword=name > < / option > ;
   SCORE < options > ;
   STRATA effects < / options > ;
   < label: > TEST equation1 < , ... , < equationk > < / option > ;
   UNITS independent1=list1 < ... independentk=listk > < / option > ;
   WEIGHT variable < / option > ;
```

The PROC LOGISTIC and MODEL statements are required; only one MODEL statement can be specified. The CLASS statement (if used) must precede the MODEL statement, and the CONTRAST, EXACT, and STRATA statements (if used) must follow the MODEL statement. The rest of this section provides detailed syntax information for each of the preceding statements, beginning with the PROC LOGISTIC statement. The remaining statements are covered in alphabetical order.
**PROC LOGISTIC Statement**

```latex
PROC LOGISTIC < options > ;
```

The PROC LOGISTIC statement starts the LOGISTIC procedure and optionally identifies input and output data sets and suppresses the display of results.

**ALPHA=$\alpha$**

specifies the level of significance $\alpha$ for $100(1 - \alpha)\%$ confidence intervals. The value $\alpha$ must be between 0 and 1; the default value is 0.05, which results in 95% intervals. This value is used as the default confidence level for limits computed by the following options.

<table>
<thead>
<tr>
<th>Statement</th>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td>CONTRAST</td>
<td>ESTIMATE=</td>
</tr>
<tr>
<td>EXACT</td>
<td>ESTIMATE=</td>
</tr>
<tr>
<td>MODEL</td>
<td>CLODDS= CLPARM=</td>
</tr>
<tr>
<td>OUTPUT</td>
<td>UCL= LCL=</td>
</tr>
<tr>
<td>SCORE</td>
<td>CLM</td>
</tr>
</tbody>
</table>

You can override the default in each of these cases by specifying the ALPHA= option for each statement individually.

**COVOUT**

adds the estimated covariance matrix to the OUTEST= data set. For the COVOUT option to have an effect, the OUTEST= option must be specified. See the section “OUTEST= Output Data Set” on page 2374 for more information.

**DATA=SAS-data-set**

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set. The INMODEL= option cannot be specified with this option.

**DESCENDING**

reverses the sorting order for the levels of the response variable. If both the DESCENDING and ORDER= options are specified, PROC LOGISTIC orders the levels according to the ORDER= option and then reverses that order. This option has the same effect as the response variable option DESCENDING in the MODEL statement. See the “Response Level Ordering” section on page 2329 for more detail.

**EXACTONLY**

requests only the exact analyses. The asymptotic analysis that PROC LOGISTIC usually performs is suppressed.
EXACTOPTIONS(options)
specifies options that apply to every EXACT statement in the program. The following options are available:

**ADDTOBS** adds the observed sufficient statistic to the sampled exact distribution if the statistic was not sampled. This option has no effect unless the METHOD=NETWORKMC option is specified and the ESTIMATE option is specified in the EXACT statement. If the observed statistic has not been sampled, then the parameter estimate does not exist; by specifying this option, you can produce (biased) estimates.

**MAXTIME=seconds** specifies the maximum clock time (in seconds) that PROC LOGISTIC can use to calculate the exact distributions. If the limit is exceeded, the procedure halts all computations and prints a note to the LOG. The default maximum clock time is seven days.

**METHOD=keyword** specifies which exact conditional algorithm to use for every EXACT statement specified. You can specify one of the following *keywords*:

- **DIRECT** invokes the multivariate shift algorithm of Hirji, Mehta, and Patel (1987). This method directly builds the exact distribution, but it may require an excessive amount of memory in its intermediate stages. METHOD=DIRECT is invoked by default when you are conditioning out at most the intercept, or when the LINK=GLOGIT option is specified in the MODEL statement.

- **NETWORK** invokes an algorithm similar to that described in Mehta, Patel, and Senchaudhuri (1992). This method builds a network for each parameter that you are conditioning out, combines the networks, then uses the multivariate shift algorithm to create the exact distribution. The NETWORK method can be faster and require less memory than the DIRECT method. The NETWORK method is invoked by default for most analyses.

- **NETWORKMC** invokes the hybrid network and Monte Carlo algorithm of Mehta, Patel, and Senchaudhuri (2000). This method creates a network then samples from that network; this method does not reject any of the samples at the cost of using a large amount of memory to create the network. METHOD=NETWORKMC is most useful for producing parameter estimates for problems that are too large for the DIRECT and NETWORK methods to handle and for which asymptotic methods are invalid; for example, for sparse data on a large grid.

**N=n** specifies the number of Monte Carlo samples to take when METHOD=NETWORKMC. By default n = 10,000. If the procedure cannot obtain n samples due to a lack of memory, then a note is printed in the LOG (the number of valid samples is also reported in the listing) and the analysis continues.

Note that the number of samples used to produce any particular statistic may be smaller than n. For example, let X1 and X2 be continuous variables, denote their joint distribution by f(X1, X2), and let f(X1|X2 = x2) denote the
marginal distribution of $X_1$ conditioned on the observed value of $X_2$. If you request the JOINT test of $X_1$ and $X_2$, then $n$ samples are used to generate the estimate $\hat{f}(X_1, X_2)$ of $f(X_1, X_2)$, from which the test is computed. However, the parameter estimate for $X_1$ is computed from the subset of $\hat{f}(X_1, X_2)$ having $X_2 = x_2$, and this subset need not contain $n$ samples. Similarly, the distribution for each level of a classification variable is created by extracting the appropriate subset from the joint distribution for the CLASS variable. The sample sizes used to compute the statistics are written to the ODS OUTPUT data set of the tables.

In some cases, the marginal sample size may be too small to admit accurate estimation of a particular statistic; a note is printed in the LOG when a marginal sample size is less than 100. Increasing $n$ will increase the number of samples used in a marginal distribution; however, if you want to control the sample size exactly, you can:

- Remove the JOINT option from the EXACT statement.
- Create dummy variables in a DATA step to represent the levels of a CLASS variable, and specify them as independent variables in the MODEL statement.

**ONDISK** uses disk-space instead of random access memory to build the exact conditional distribution. Use this option to handle larger problems at the cost of slower processing.

**SEED=n** specifies the initial seed for the random number generator used to take the Monte Carlo samples for METHOD=NETWORKMC. The value of the SEED= option must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC LOGISTIC uses the time of day from the computer’s clock to generate an initial seed. The seed is displayed in the “Model Information” table.

**STATUSN=n** prints a status line in the LOG after every $n$ Monte Carlo samples for METHOD=NETWORKMC. The number of samples taken and the current exact $p$-value for testing the significance of the model are displayed. You can use this status line to track the progress of the computation of the exact conditional distributions.

**STATUSTIME=seconds** specifies the time interval (in seconds) for printing a status line in the LOG. You can use this status line to track the progress of the computation of the exact conditional distributions. The time interval you specify is approximate; the actual time interval will vary. By default, no status reports are produced.

**INEST=SAS-data-set** names the SAS data set that contains initial estimates for all the parameters in the model. BY-group processing is allowed in setting up the INEST= data set. See the section “**INEST= Input Data Set**” on page 2376 for more information.
**PROC LOGISTIC Statement**

- **INMODEL=** *SAS-data-set*
  
  Specifies the name of the SAS data set that contains the model information needed for scoring new data. This INMODEL= data set is the OUTMODEL= data set saved in a previous PROC LOGISTIC call. The DATA= option cannot be specified with this option; instead, specify the data sets to be scored in the SCORE statements.

  When the INMODEL= data set is specified, FORMAT statements are not allowed; variables in the DATA= and PRIOR= data sets should be formatted within the data sets. If a SCORE statement is specified in the same run as fitting the model, FORMAT statements should be specified after the SCORE statement in order for the formats to apply to all the DATA= and PRIOR= data sets in the SCORE statement.

  You can specify the BY statement provided the INMODEL= data set is created under the same BY-group processing.

  The CLASS, EXACT, MODEL, OUTPUT, TEST, and UNIT statements are not available with the INMODEL= option.

- **NAMELEN=** *n*
  
  Specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

- **NOCOV**
  
  Specifies that the covariance matrix is not saved in the OUTMODEL= data set. The covariance matrix is needed for computing the confidence intervals for the posterior probabilities in the OUT= data set in the SCORE statement. Specifying this option will reduce the size of the OUTMODEL= data set.

- **NOPRINT**
  
  Suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

- **ORDER=** *DATA | FORMATTED | FREQ | INTERNAL*
  
  Specifies the sorting order for the levels of the response variable. See the response variable option ORDER= in the MODEL statement for more information.

- **OUTDESIGN=** *SAS-data-set*
  
  Specifies the name of the data set that contains design matrix for the model. The data set contains the same number of observations as the corresponding DATA= data set and includes the response variable (with the same format as in the input data), the FREQ variable, the WEIGHT variable, the OFFSET variable, and the design variables for the covariates, including the Intercept variable of constant value 1 unless the NOINT option in the MODEL statement is specified.

- **OUTDESIGNONLY**
  
  Suppresses the model fitting and only creates the OUTDESIGN= data set. This option is ignored if the OUTDESIGN= option is not specified.
OUTEST= SAS-data-set
creates an output SAS data set that contains the final parameter estimates and, optionally, their estimated covariances (see the preceding COVOUT option). The output data set also includes a variable named _LNLIKE_, which contains the log likelihood.

See the section “OUTEST= Output Data Set” on page 2374 for more information.

OUTMODEL=SAS-data-set
specifies the name of the SAS data set that contains the information about the fitted model. This data set contains sufficient information to score new data without having to refit the model. It is solely used as the input to the INMODEL= option in a subsequent PROC LOGISTIC call. Note: information is stored in this data set in a very compact form, hence you should not modify it manually.

SIMPLE

displays simple descriptive statistics (mean, standard deviation, minimum and maximum) for each continuous explanatory variable; and for each CLASS variable involved in the modeling, the frequency counts of the classification levels are displayed. The SIMPLE option generates a breakdown of the simple descriptive statistics or frequency counts for the entire data set and also for individual response categories.

TRUNCATE

specifies that class levels should be determined using no more than the first 16 characters of the formatted values of CLASS, response, and strata variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to Version 9. This option invokes the same option in the CLASS statement.

BY Statement

    BY variables ;

You can specify a BY statement with PROC LOGISTIC to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the LOGISTIC procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).
If a SCORE statement is specified, then define the primary data set to be the DATA= or the INMODEL=data set in the PROC LOGISTIC statement, and define the secondary data set to be the DATA= data set and PRIOR= data set in the SCORE statement. The primary data set contains all of the BY variables, and the secondary data set must contain either all of them or none of them. If the secondary data set contains all the BY-variables, matching is carried out between the primary and secondary data sets. If the secondary data set does not contain any of the BY-variables, the entire secondary data set is used for every BY-group in the primary data set and the BY-variables are added to the output data sets specified in the SCORE statement.

**Caution:** The order of your response and classification variables is determined by combining data across all BY groups; however, the observed levels may change between BY groups. This may affect the value of the reference level for these variables, and hence your interpretation of the model and the parameters.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

---

**CLASS Statement**

```plaintext
CLASS variable <(v-options)> <variable <(v-options)>> ... >
< / v-options > ;
```

The CLASS statement names the classification variables to be used in the analysis. The CLASS statement must precede the MODEL statement. You can specify various *v-options* for each variable by enclosing them in parentheses after the variable name. You can also specify global *v-options* for the CLASS statement by placing them after a slash (/). Global *v-options* are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the global *v-options* specified on any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *v-options* override the global *v-options*.

**CPREFIX= n**

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding design variables. The default is $32 - \min(32, \max(2, f))$, where *f* is the formatted length of the CLASS variable.

**DESCENDING**

**DESC**

reverses the sorting order of the classification variable. If both the DESCENDING and ORDER= options are specified, PROC LOGISTIC orders the categories according to the ORDER= option and then reverses that order.

**LPREFIX= n**

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding design variables. The default is $256 - \min(256, \max(2, f))$, where *f* is the formatted length of the CLASS variable.
MISSING
allows missing value (\' . \' for a numeric variable and blanks for a character variables) as a valid value for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the sorting order for the levels of classification variables. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use the CONTRAST statement.

The following table shows how PROC LOGISTIC interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

For more information on sorting order, see the chapter on the SORT procedure in the SAS Procedures Guide and the discussion of BY-group processing in SAS Language Reference: Concepts.

PARAM=keyword
specifies the parameterization method for the classification variable or variables. Design matrix columns are created from CLASS variables according to the following coding schemes. The default is PARAM=EFFECT. If PARAM=ORTHPOLY or PARAM=POLY, and the CLASS levels are numeric, then the ORDER= option in the CLASS statement is ignored, and the internal, unformatted values are used. See the “CLASS Variable Parameterization” section on page 2331 for further details.

EFFECT specifies effect coding
GLM specifies less-than-full-rank reference cell coding; this option can only be used as a global option
ORDINAL specifies the cumulative parameterization for an ordinal CLASS variable.
POLYNOMIAL POLY specifies polynomial coding
REFERENCE REF specifies reference cell coding
ORTHEFFECT orthogonalizes PARAM=EFFECT
ORTHORDINAL orthogonalizes PARAM=ORDINAL
ORTHPOLY orthogonalizes PARAM=POLYNOMIAL
ORTHREF orthogonalizes PARAM=REFERENCE

The EFFECT, POLYNOMIAL, REFERENCE, ORDINAL, and their orthogonal parameterizations are full rank. The REF= option in the CLASS statement determines the reference level for the EFFECT, REFERENCE, and their orthogonal parameterizations.

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization.

**REF= 'level' | keyword**

specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. For an individual (but not a global) variable REF= option, you can specify the level of the variable to use as the reference level. For a global or individual variable REF= option, you can use one of the following keywords. The default is REF=LAST.

- **FIRST** designates the first ordered level as reference
- **LAST** designates the last ordered level as reference

**TRUNCATE**
specifies that class levels should be determined using no more than the first 16 characters of the formatted values of CLASS, response, and strata variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to Version 9. The TRUNCATE option is only available as a global option. This option invokes the same option in the PROC LOGISTIC statement.

The CONTRAST statement provides a mechanism for obtaining customized hypothesis tests. It is similar to the CONTRAST and ESTIMATE statements in PROC GLM and PROC CATMOD, depending on the coding schemes used with any classification variables involved.

The CONTRAST statement enables you to specify a matrix, $L$, for testing the hypothesis $L \theta = 0$, where $\theta$ is the parameter vector. You must be familiar with the details of the model parameterization that PROC LOGISTIC uses (for more information, see the PARAM= option in the section “CLASS Statement” on page 2295).
Optionally, the CONTRAST statement enables you to estimate each row, \( l_i^\prime \theta \), of \( L\theta \) and test the hypothesis \( l_i^\prime \theta = 0 \). Computed statistics are based on the asymptotic chi-square distribution of the Wald statistic.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the MODEL statement.

The following parameters are specified in the CONTRAST statement:

- **label**: identifies the contrast on the output. A label is required for every contrast specified, and it must be enclosed in quotes.
- **effect**: identifies an effect that appears in the MODEL statement. The name INTERCEPT can be used as an effect when one or more intercepts are included in the model. You do not need to include all effects that are included in the MODEL statement.
- **values**: are constants that are elements of the \( L \) matrix associated with the effect. To correctly specify your contrast, it is crucial to know the ordering of parameters within each effect and the variable levels associated with any parameter. The “Class Level Information” table shows the ordering of levels within variables. The \( E \) option, described later in this section, enables you to verify the proper correspondence of values to parameters.

The rows of \( L \) are specified in order and are separated by commas. Multiple degree-of-freedom hypotheses can be tested by specifying multiple row-descriptions. For any of the full-rank parameterizations, if an effect is not specified in the CONTRAST statement, all of its coefficients in the \( L \) matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

When you use effect coding (by default or by specifying PARAM=EFFECT in the CLASS statement), all parameters are directly estimable (involve no other parameters). For example, suppose an effect coded CLASS variable \( A \) has four levels. Then there are three parameters \( (\alpha_1, \alpha_2, \alpha_3) \) representing the first three levels, and the fourth parameter is represented by

\[-\alpha_1 - \alpha_2 - \alpha_3\]

To test the first versus the fourth level of \( A \), you would test

\[\alpha_1 = -\alpha_1 - \alpha_2 - \alpha_3\]

or, equivalently,

\[2\alpha_1 + \alpha_2 + \alpha_3 = 0\]

which, in the form \( L\theta = 0 \), is

\[
\begin{bmatrix}
2 & 1 & 1
\end{bmatrix}
\begin{bmatrix}
\alpha_1 \\
\alpha_2 \\
\alpha_3
\end{bmatrix} = 0
\]
Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

\[
\frac{\alpha_1 + \alpha_2}{2} = \alpha_3
\]

or, equivalently,

\[
\alpha_1 + \alpha_2 - 2\alpha_3 = 0
\]

Therefore, you would use the following CONTRAST statement:

```
contrast '1\&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements are constructed similarly. For example,

```
contrast '1 vs. 2 ' A 1 -1 0;
contrast '1\&2 vs. 4 ' A 3 3 2;
contrast '1\&2 vs. 3\&4' A 2 2 0;
contrast 'Main Effect' A 1 0 0,
                    A 0 1 0,
                    A 0 0 1;
```

When you use the less-than-full-rank parameterization (by specifying PARAM=GLM in the CLASS statement), each row is checked for estimability. If PROC LOGISTIC finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. PROC LOGISTIC handles missing level combinations of classification variables in the same manner as PROC GLM. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the \(L\) matrix in your CONTRAST statement. If the elements of \(L\) are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you specify a CONTRAST statement involving A alone, the \(L\) matrix contains nonzero terms for both A and A*B, since A*B contains A.

The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement, that is, the rank of \(L\).

You can specify the following options after a slash (/).
ALPHA=\(\alpha\)

specifies the level of significance \(\alpha\) for the 100\((1 - \alpha)\)% confidence interval for each contrast when the ESTIMATE option is specified. The value \(\alpha\) must be between 0 and 1. By default, \(\alpha\) is equal to the value of the \texttt{ALPHA=} option in the \texttt{PROC LOGISTIC} statement, or 0.05 if that option is not specified.

\texttt{E}

displays the \(\mathbf{L}\) matrix.

\texttt{ESTIMATE=\textit{keyword}}

requests that each individual contrast (that is, each row, \(l'_i\theta\), of \(\mathbf{L}\theta\)) or exponentiated contrast (\(e^{l'_i\theta}\)) be estimated and tested. \texttt{PROC LOGISTIC} displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test for each contrast. The significance level of the confidence interval is controlled by the \texttt{ALPHA=} option. You can estimate the contrast or the exponentiated contrast (\(e^{l'_i\theta}\)), or both, by specifying one of the following \textit{keywords}:

- \texttt{PARM} specifies that the contrast itself be estimated
- \texttt{EXP} specifies that the exponentiated contrast be estimated
- \texttt{BOTH} specifies that both the contrast and the exponentiated contrast be estimated

\texttt{SINGULAR = \textit{number}}

tunes the estimability check. This option is ignored when the full-rank parameterization is used. If \(v\) is a vector, define \(\text{ABS}(v)\) to be the largest absolute value of the elements of \(v\). For a row vector \(l'\) of the contrast matrix \(\mathbf{L}\), define \(c\) to be equal to \(\text{ABS}(l)\) if \(\text{ABS}(l)\) is greater than 0; otherwise, \(c\) equals 1. If \(\text{ABS}(l' - l'T)\) is greater than \(c \times \text{number}\), then \(l\) is declared nonestimable. The \(T\) matrix is the Hermite form matrix \(\hat{I}_0^{-} I_0\), where \(\hat{I}_0^{-}\) represents a generalized inverse of the information matrix \(I_0\) of the null model. The value for \texttt{number} must be between 0 and 1; the default value is 1E−4.

**EXACT Statement**

\texttt{EXACT <\textit{label}> < Intercept > < effects > < / options > ;}

The \texttt{EXACT} statement performs exact tests of the parameters for the specified effects and optionally estimates the parameters and outputs the exact conditional distributions. You can specify the keyword \texttt{INTERCEPT} and any effects in the \texttt{MODEL} statement. Inference on the parameters of the specified effects is performed by conditioning on the sufficient statistics of all the other model parameters (possibly including the intercept).

You can specify several \texttt{EXACT} statements, but they must follow the \texttt{MODEL} statement. Each statement can optionally include an identifying label. If several \texttt{EXACT} statements are specified, any statement without a label will be assigned a label of the form “\texttt{Exactn}”, where “\texttt{n}” indicates the \texttt{n}th \texttt{EXACT} statement. The label is included in the headers of the displayed exact analysis tables.
If a STRATA statement is also specified, then a stratified exact conditional logistic regression is performed. The model contains a different intercept for each stratum, and these intercepts are conditioned out of the model along with any other nuisance parameters (essentially, any parameters specified in the MODEL statement which are not in the EXACT statement).

If the LINK=GLOGIT option is specified in the MODEL statement, then the EXACTOPTION option METHOD=DIRECT is invoked by default and a generalized logit model is fit. Since each effect specified in the MODEL statement adds \( k \) parameters to the model (where \( k + 1 \) is the number of response levels), exact analysis of the generalized logit model using this method is limited to rather small problems.

The CONTRAST, OUTPUT, SCORE, TEST, and UNITS statements are not available with an exact analysis. Exact analyses are not performed when you specify a WEIGHT statement, a link other than LINK=LOGIT or LINK=GLOGIT, an offset variable, the NOFIT option, or a model-selection method. Exact estimation is not available for ordinal response models.

The following options can be specified in each EXACT statement after a slash (/):

\textbf{ALPHA=\( \alpha \)}

specifies the level of significance \( \alpha \) for \( 100(1-\alpha)\% \) confidence limits for the parameters or odds ratios. The value \( \alpha \) must be between 0 and 1. By default, \( \alpha \) is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

\textbf{ESTIMATE < =\{keyword\}>}

estimates the individual parameters (conditional on all other parameters) for the effects specified in the EXACT statement. For each parameter, a point estimate, a confidence interval, and a \( p \)-value for a two-sided test that the parameter is zero are displayed. Note that the two-sided \( p \)-value is twice the one-sided \( p \)-value. You can optionally specify one of the following keywords:

- \textbf{PARM} specifies that the parameters be estimated. This is the default.
- \textbf{ODDS} specifies that the odds ratios be estimated. For classification variables, use of the reference parameterization is recommended.
- \textbf{BOTH} specifies that the parameters and odds ratios be estimated

\textbf{JOINT}

performs the joint test that all of the parameters are simultaneously equal to zero, individual hypothesis tests for the parameter of each continuous variable, and joint tests for the parameters of each classification variable. The joint test is indicated in the “Conditional Exact Tests” table by the label “Joint.”

\textbf{JOINTONLY}

performs only the joint test of the parameters. The test is indicated in the “Conditional Exact Tests” table by the label “Joint.” When this option is specified, individual tests for the parameters of each continuous variable and joint tests for the parameters of the classification variables are not performed.
CLTYPE=EXACT | MIDP
requests either the exact or mid-p confidence intervals for the parameter estimates. By default, the exact intervals are produced. The confidence coefficient can be specified with the ALPHA= option. The mid-p interval can be modified with the MIDPFACTOR= option. See the “Inference for a Single Parameter” section on page 2373 for details.

MIDPFACTOR=\(\delta_1\) | \(\delta_1, \delta_2\)
sets the tie factors used to produce the mid-p hypothesis statistics and the mid-p confidence intervals. \(\delta_1\) modifies both the hypothesis tests and confidence intervals, while \(\delta_2\) affects only the hypothesis tests. By default, \(\delta_1 = 0.5\) and \(\delta_2 = 1.0\). See the “Hypothesis Tests” section on page 2371 and the “Inference for a Single Parameter” section on page 2373 for details.

ONESIDED
requests one-sided confidence intervals and p-values for the individual parameter estimates and odds ratios. The one-sided p-value is the smaller of the left and right tail probabilities for the observed sufficient statistic of the parameter under the null hypothesis that the parameter is zero. The two-sided p-values (default) are twice the one-sided p-values. See the “Inference for a Single Parameter” section on page 2373 for more details.

OUTDIST=SAS-data-set
names the SAS data set containing the exact conditional distributions. This data set contains all of the exact conditional distributions required to process the corresponding EXACT statement. The data set contains the possible sufficient statistics for the parameters of the effects specified in the EXACT statement, the counts, and, when hypothesis tests are performed on the parameters, the probability of occurrence and the score value for each sufficient statistic. When you request an OUTDIST= data set, the observed sufficient statistics are displayed in the “Sufficient Statistics” table. See the “OUTDIST= Output Data Set” section on page 2377 for more information.

**EXACT Statement Examples**

- In the following example, two exact tests are computed: one for \(x_1\) and the other for \(x_2\). The test for \(x_1\) is based on the exact conditional distribution of the sufficient statistic for the \(x_1\) parameter given the observed values of the sufficient statistics for the intercept, \(x_2\), and \(x_3\) parameters; likewise, the test for \(x_2\) is conditional on the observed sufficient statistics for the intercept, \(x_1\), and \(x_3\):

  ```
  proc logistic;
  model y = x1 x2 x3;
  exact ’lab1’ x1 x2;
  run;
  ```

- You can specify multiple EXACT statements in the same PROC LOGISTIC invocation. PROC LOGISTIC determines, from all the EXACT statements, the distinct conditional distributions that need to be evaluated. For example, there is only one exact conditional distribution for the following two EXACT
statements, and it would be a waste of resources to compute the same exact conditional distribution twice:

```r
exact 'One' x1 / estimate=parm;
exact 'Two' x1 / estimate=parm onesided;
```

- For each EXACT statement, individual tests for the parameters of the specified effects are computed unless the JOINTONLY option is specified. Consider the following EXACT statements:

```r
exact 'E12' x1 x2 / estimate;
exact 'E1' x1 / estimate;
exact 'E2' x2 / estimate;
exact 'J12' x1 x2 / joint;
```

In the E12 statement, the parameters for x1 and x2 are estimated and tested separately. Specifying the E12 statement is equivalent to specifying both the E1 and E2 statements. In the J12 statement, the joint test for the parameters of x1 and x2 is computed as well as the individual tests for x1 and x2.

All exact conditional distributions for the tests and estimates computed in a single EXACT statement are output to the corresponding OUTDIST= data set. For example, consider the following EXACT statements:

```r
exact 'O1' x1 / outdist=o1;
exact 'OJ12' x1 x2 / jointonly outdist=oj12;
exact 'OA12' x1 x2 / joint outdist=oa12;
exact 'OE12' x1 x2 / estimate outdist=oe12;
```

The O1 statement outputs a single exact conditional distribution. The OJ12 statement outputs only the joint distribution for x1 and x2. The OA12 statement outputs three conditional distributions: one for x1, one for x2, and one jointly for x1 and x2. The OE12 statement outputs two conditional distributions: one for x1 and the other for x2. Data set oe12 contains both the x1 and x2 variables; the distribution for x1 has missing values in the x2 column while the distribution for x2 has missing values in the x1 column.

See the “OUTDIST= Output Data Set” section on page 2377 for more information.

### FREQ Statement

**FREQ** `variable`;

The `variable` in the FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC LOGISTIC treats each observation as if it appears `n` times, where `n` is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1.

If a SCORE statement is specified, then the FREQ variable is used for computing fit statistics and the ROC curve, but they are not required for scoring. If the DATA= data
set in the SCORE statement does not contain the FREQ variable, the frequency values are assumed to be 1 and a warning message is issued in the LOG. If you fit a model and perform the scoring in the same run, the same FREQ variable is used for fitting and scoring. If you fit a model in a previous run and input it with the INMODEL= option in the current run, then the FREQ variable can be different from the one used in the previous run; however, if a FREQ variable was not specified in the previous run you can still specify a FREQ variable in the current run.

### MODEL Statement

```
MODEL  events/trials= < effects >= / options > ;

MODEL  variable < (variable-options) >= < effects >= / options > ;
```

The MODEL statement names the response variable and the explanatory effects, including covariates, main effects, interactions, and nested effects; see the section “Specification of Effects” on page 1784 of Chapter 32, “The GLM Procedure,” for more information. If you omit the explanatory effects, the procedure fits an intercept-only model. Model options can be specified after a slash (/).

Two forms of the MODEL statement can be specified. The first form, referred to as single-trial syntax, is applicable to binary, ordinal, and nominal response data. The second form, referred to as events/trials syntax, is restricted to the case of binary response data. The single-trial syntax is used when each observation in the DATA= data set contains information on only a single trial, for instance, a single subject in an experiment. When each observation contains information on multiple binary-response trials, such as the counts of the number of subjects observed and the number responding, then events/trials syntax can be used.

In the events/trials syntax, you specify two variables that contain count data for a binomial experiment. These two variables are separated by a slash. The value of the first variable, events, is the number of positive responses (or events). The value of the second variable, trials, is the number of trials. The values of both events and (trials–events) must be nonnegative and the value of trials must be positive for the response to be valid.

In the single-trial syntax, you specify one variable (on the left side of the equal sign) as the response variable. This variable can be character or numeric. Options specific to the response variable can be specified immediately after the response variable with a pair of parentheses around them.

For both forms of the MODEL statement, explanatory effects follow the equal sign. Variables can be either continuous or classification variables. Classification variables can be character or numeric, and they must be declared in the CLASS statement. When an effect is a classification variable, the procedure enters a set of coded columns into the design matrix instead of directly entering a single column containing the values of the variable.
Response Variable Options

You can specify the following options by enclosing them in a pair of parentheses after the response variable.

DESCENDING | DESC

reverses the order of the response categories. If both the DESCENDING and ORDER= options are specified, PROC LOGISTIC orders the response categories according to the ORDER= option and then reverses that order. See the “Response Level Ordering” section on page 2329 for more detail.

EVENT=’category’ | keyword

specifies the event category for the binary response model. PROC LOGISTIC models the probability of the event category. The EVENT= option has no effect when there are more than two response categories. You can specify the value (formatted if a format is applied) of the event category in quotes or you can specify one of the following keywords. The default is EVENT=FIRST.

FIRST designates the first ordered category as the event
LAST designates the last ordered category as the event

One of the most common sets of response levels is {0,1}, with 1 representing the event for which the probability is to be modeled. Consider the example where Y takes the values 1 and 0 for event and nonevent, respectively, and Exposure is the explanatory variable. To specify the value 1 as the event category, use the MODEL statement

```plaintext
model Y(event='1') = Exposure;
```

ORDER= DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the response variable. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows the interpretation of the ORDER= values.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>
For more information on sorting order, see the chapter on the SORT procedure in the SAS Procedures Guide and the discussion of BY-group processing in SAS Language Reference: Concepts.

REFERENCE='category' | keyword

`REF='category' | keyword` specifies the reference category for the generalized logit model and the binary response model. For the generalized logit model, each nonreference category is contrasted with the reference category. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify the value (formatted if a format is applied) of the reference category in quotes or you can specify one of the following keywords. The default is `REF=LAST`.

FIRST designates the first ordered category as the reference
LAST designates the last ordered category as the reference

**Model Options**

Table 42.1 summarizes the options available in the MODEL statement, which can be specified after a slash (/).

**Table 42.1. Model Statement Options**

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>

</tr>
</thead>
<tbody>
<tr>
<td>NOLOGSCALE</td>
<td>performs calculations using normal scaling</td>
</tr>
</tbody>
</table>
**Chapter 42. The LOGISTIC Procedure**

**ABSFCONV=value**
specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations,

\[ |l_i - l_{i-1}| < value \]

where \( l_i \) is the value of the log-likelihood function at iteration \( i \). See the section “Convergence Criteria” on page 2338.

**AGGREGATE**

**AGGREGATE= (variable-list)**
specifies the subpopulations on which the Pearson chi-square test statistic and the likelihood ratio chi-square test statistic (deviance) are calculated. Observations with common values in the given list of variables are regarded as coming from the same subpopulation. Variables in the list can be any variables in the input data set. Specifying the AGGREGATE option is equivalent to specifying the AGGREGATE= option with a variable list that includes all explanatory variables in the MODEL statement. The deviance and Pearson goodness-of-fit statistics are calculated only when the SCALE= option is specified. Thus, the AGGREGATE (or AGGREGATE=) option has no effect if the SCALE= option is not specified. See the section “Rescaling the Covariance Matrix” on page 2354 for more detail.

**ALPHA=α**
sets the level of significance \( α \) for \( 100(1 - α) \)% confidence intervals for regression parameters or odds ratios. The value \( α \) must be between 0 and 1. By default, \( α \) is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if the option is not specified. This option has no effect unless confidence limits for the parameters or odds ratios are requested.

**BEST=n**
specifies that \( n \) models with the highest score chi-square statistics are to be displayed for each model size. It is used exclusively with the SCORE model selection method. If the BEST= option is omitted and there are no more than ten explanatory variables, then all possible models are listed for each model size. If the option is omitted and there are more than ten explanatory variables, then the number of models selected for each model size is, at most, equal to the number of explanatory variables listed in the MODEL statement.

**CLODDS=PL | WALD | BOTH**
requests confidence intervals for the odds ratios. Computation of these confidence intervals is based on the profile likelihood (CLODDS=PL) or based on individual Wald tests (CLODDS=WALD). By specifying CLODDS=BOTH, the procedure computes two sets of confidence intervals for the odds ratios, one based on the profile likelihood and the other based on the Wald tests. The confidence coefficient can be specified with the ALPHA= option.
requests confidence intervals for the parameters. Computation of these confidence intervals is based on the profile likelihood (CLP=PL) or individual Wald tests (CLP=WALD). By specifying CLP=BOTH, the procedure computes two sets of confidence intervals for the parameters, one based on the profile likelihood and the other based on individual Wald tests. The confidence coefficient can be specified with the ALPHA= option. See the “Confidence Intervals for Parameters” section on page 2345 for more information.

**CORRB**

displays the correlation matrix of the parameter estimates.

**COVB**

displays the covariance matrix of the parameter estimates.

**CTABLE**

classifies the input binary response observations according to whether the predicted event probabilities are above or below some cutpoint value \( z \) in the range \((0, 1)\). An observation is predicted as an event if the predicted event probability exceeds \( z \). You can supply a list of cutpoints other than the default list by using the PPROB= option (page 2315). The CTABLE option is ignored if the data have more than two response levels. Also, false positive and negative rates can be computed as posterior probabilities using Bayes’ theorem. You can use the PEVENT= option to specify prior probabilities for computing these rates. For more information, see the “Classification Table” section on page 2352.

**DETAILS**

produces a summary of computational details for each step of the effect selection process. It produces the “Analysis of Effects Not in the Model” table before displaying the effect selected for entry for FORWARD or STEPWISE selection. For each model fitted, it produces the “Type 3 Analysis of Effects” table if the fitted model involves CLASS variables, the “Analysis of Maximum Likelihood Estimates” table, and measures of association between predicted probabilities and observed responses. For the statistics included in these tables, see the “Displayed Output” section on page 2381. The DETAILS option has no effect when SELECTION=NONE.

**EXPB**

**EXPB**

**EXPEST**

displays the exponentiated values \( e^{\hat{\beta}_i} \) of the parameter estimates \( \hat{\beta}_i \) in the “Analysis of Maximum Likelihood Estimates” table for the logit model. These exponentiated values are the estimated odds ratios for the parameters corresponding to the continuous explanatory variables.

**FAST**

uses a computational algorithm of Lawless and Singhal (1978) to compute a first-order approximation to the remaining slope estimates for each subsequent elimination of a variable from the model. Variables are removed from the model based on these approximate estimates. The FAST option is extremely efficient because the model is not refitted for every variable removed. The FAST option is used when SELECTION=BACKWARD and in the backward elimina-
tion steps when SELECTION=STEPWISE. The FAST option is ignored when SELECTION=FORWARD or SELECTION=NONE.

**FCONV=value**

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations,

\[
\frac{|l_i - l_{i-1}|}{|l_{i-1}| + 1E^{-6}} < value
\]

where \( l_i \) is the value of the log likelihood at iteration \( i \). See the section “Convergence Criteria” on page 2338.

**GCONV=value**

specifies the relative gradient convergence criterion. Convergence requires that the normalized prediction function reduction is small,

\[
\frac{g_i' I_i g_i}{|l_i| + 1E^{-6}} < value
\]

where \( l_i \) is the value of the log-likelihood function, \( g_i \) is the gradient vector, and \( I_i \) is the (expected) information matrix, all at iteration \( i \). This is the default convergence criterion, and the default value is \( 1E^{-8} \). See the section “Convergence Criteria” on page 2338.

**HIERARCHY=keyword**

**HIER=keyword**

specifies whether and how the model hierarchy requirement is applied and whether a single effect or multiple effects are allowed to enter or leave the model in one step. You can specify that only CLASS effects, or both CLASS and interval effects, be subject to the hierarchy requirement. The HIERARCHY= option is ignored unless you also specify one of the following options: SELECTION=FORWARD, SELECTION=BACKWARD, or SELECTION=STEPWISE.

Model hierarchy refers to the requirement that, for any term to be in the model, all effects contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor B can leave the model while the interaction A*B is in the model.

The keywords you can specify in the HIERARCHY= option are as follows:

- **NONE**: Model hierarchy is not maintained. Any single effect can enter or leave the model at any given step of the selection process.
- **SINGLE**: Only one effect can enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that you specify the main effects A and B and the interaction A*B in the model. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter
the model. The interaction effect can enter the model only when both main effects have already been entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.

SINGLECLASS  This is the same as HIERARCHY=SINGLE except that only CLASS effects are subject to the hierarchy requirement.

MULTIPLE  More than one effect can enter or leave the model at one time, subject to the model hierarchy requirement. In a forward selection step, a single main effect can enter the model, or an interaction can enter the model together with all the effects that are contained in the interaction. In a backward elimination step, an interaction itself, or the interaction together with all the effects that the interaction contains, can be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.

MULTIPLECLASS  This is the same as HIERARCHY=MULTIPLE except that only CLASS effects are subject to the hierarchy requirement.

The default value is HIERARCHY=SINGLE, which means that model hierarchy is to be maintained for all effects (that is, both CLASS and interval effects) and that only a single effect can enter or leave the model at each step.

INCLUDE=n
includes the first $n$ effects in the MODEL statement in every model. By default, INCLUDE=0. The INCLUDE= option has no effect when SELECTION=NONE.

Note that the INCLUDE= and START= options perform different tasks: the INCLUDE= option includes the first $n$ effects variables in every model, whereas the START= option only requires that the first $n$ effects appear in the first model.

INFLUENCE
displays diagnostic measures for identifying influential observations in the case of a binary response model. It has no effect otherwise. For each observation, the INFLUENCE option displays the case number (which is the sequence number of the observation), the values of the explanatory variables included in the final model, and the regression diagnostic measures developed by Pregibon (1981). For a discussion of these diagnostic measures, see the “Regression Diagnostics” section on page 2359. When a STRATA statement is specified, the diagnostics are computed following Storer and Crowley (1985); see the “Regression Diagnostic Details” section on page 2367 for details.

IPLOTS
produces an index plot for each regression diagnostic statistic. An index plot is a scatterplot with the regression diagnostic statistic represented on the y-axis and the case number on the x-axis. See Example 42.6 on page 2422 for an illustration.
ITPRINT displays the iteration history of the maximum-likelihood model fitting. The ITPRINT option also displays the last evaluation of the gradient vector and the final change in the $-2 \text{Log Likelihood}$.

LACKFIT performs the Hosmer and Lemeshow goodness-of-fit test (Hosmer and Lemeshow 2000) for the case of a binary response model. The subjects are divided into approximately ten groups of roughly the same size based on the percentiles of the estimated probabilities. The discrepancies between the observed and expected number of observations in these groups are summarized by the Pearson chi-square statistic, which is then compared to a chi-square distribution with $t$ degrees of freedom, where $t$ is the number of groups minus $n$. By default, $n=2$. A small $p$-value suggests that the fitted model is not an adequate model. See the “The Hosmer-Lemeshow Goodness-of-Fit Test” section on page 2356 for more information.

LINK=keyword specifies the link function linking the response probabilities to the linear predictors. You can specify one of the following keywords. The default is LINK=LOGIT.

CLOGLOG the complementary log-log function. PROC LOGISTIC fits the binary complementary log-log model when there are two response categories and fits the cumulative complementary log-log model when there are more than two response categories. Aliases: CCLOGLOG, CCLL, CUMCLOGLOG.

GLOGIT the generalized logit function. PROC LOGISTIC fits the generalized logit model where each nonreference category is contrasted with the reference category. You can use the response variable option REF= to specify the reference category.

LOGIT the log odds function. PROC LOGISTIC fits the binary logit model when there are two response categories and fits the cumulative logit model when there are more than two response categories. Aliases: CLOGIT, CUMLOGIT.

PROBIT the inverse standard normal distribution function. PROC LOGISTIC fits the binary probit model when there are two response categories and fits the cumulative probit model when there are more than two response categories. Aliases: NORMIT, CPROBIT, CUMPROBIT.

See the section “Link Functions and the Corresponding Distributions” on page 2334 for details.
MAXFUNCTION=n
specifies the maximum number of function calls to perform when maximizing the conditional likelihood. This option is only valid when a STRATA statement is specified. The default values are

- 125 when the number of parameters p < 40
- 500 when 40 ≤ p < 400
- 1000 when p ≥ 400

Since the optimization is terminated only after completing a full iteration, the number of function calls that are actually performed can exceed n. If convergence is not attained, the displayed output and all output data sets created by the procedure contain results based on the last maximum likelihood iteration.

MAXITER=n
specifies the maximum number of iterations to perform. By default, MAXITER=25. If convergence is not attained in n iterations, the displayed output and all output data sets created by the procedure contain results that are based on the last maximum likelihood iteration.

MAXSTEP=n
specifies the maximum number of times any explanatory variable is added to or removed from the model when SELECTION=STEPWISE. The default number is twice the number of explanatory variables in the MODEL statement. When the MAXSTEP= limit is reached, the stepwise selection process is terminated. All statistics displayed by the procedure (and included in output data sets) are based on the last model fitted. The MAXSTEP= option has no effect when SELECTION=NONE, FORWARD, or BACKWARD.

NOCHECK
disables the checking process to determine whether maximum likelihood estimates of the regression parameters exist. If you are sure that the estimates are finite, this option can reduce the execution time if the estimation takes more than eight iterations. For more information, see the “Existence of Maximum Likelihood Estimates” section on page 2338.

NODUMMYPRINT
NODESIGNPRINT
NODP
suppresses the “Class Level Information” table, which shows how the design matrix columns for the CLASS variables are coded.

NOINT
suppresses the intercept for the binary response model, the first intercept for the ordinal response model (which forces all intercepts to be nonnegative), or all intercepts for the generalized logit model. This can be particularly useful in conditional logistic analysis; see Example 42.10 on page 2443.
NOFIT
performs the global score test without fitting the model. The global score test evaluates the joint significance of the effects in the MODEL statement. No further analyses are performed. If the NOFIT option is specified along with other MODEL statement options, NOFIT takes effect and all other options except LINK=, TECHNIQUE=, and OFFSET= are ignored.

NOLOGSCALE
specifies that computations for the conditional and exact conditional logistic model should be computed using normal scaling. Log-scaling can handle numerically larger problems than normal scaling; however, computations in the log-scale are slower than computations in normal-scale.

OFFSET= name
names the offset variable. The regression coefficient for this variable will be fixed at 1.

OUTROC=SAS-data-set
OUTR=SAS-data-set
creates, for binary response models, an output SAS data set that contains the data necessary to produce the receiver operating characteristic (ROC) curve. See the section “OUTROC= Output Data Set” on page 2378 for the list of variables in this data set.

PARMLABEL
displays the labels of the parameters in the “Analysis of Maximum Likelihood Estimates” table.

PEVENT= value
PEVENT= (list)
specifies one prior probability or a list of prior probabilities for the event of interest. The false positive and false negative rates are then computed as posterior probabilities by Bayes’ theorem. The prior probability is also used in computing the rate of correct prediction. For each prior probability in the given list, a classification table of all observations is computed. By default, the prior probability is the total sample proportion of events. The PEVENT= option is useful for stratified samples. It has no effect if the CTABLE option is not specified. For more information, see the section “False Positive and Negative Rates Using Bayes’ Theorem” on page 2353. Also see the PPROB= option for information on how the list is specified.

PLCL
is the same as specifying CLPARM=PL.

PLCONV= value
controls the convergence criterion for confidence intervals based on the profile likelihood function. The quantity value must be a positive number, with a default value of 1E−4. The PLCONV= option has no effect if profile likelihood confidence intervals (CLPARM=PL) are not requested.
PLRL

is the same as specifying CLODDS=PL.

PPROB=value
PPROB= (list)
specifies one critical probability value (or cutpoint) or a list of critical probability values for classifying observations with the CTABLE option. Each value must be between 0 and 1. A response that has a cross validated predicted probability greater than or equal to the current PPROB= value is classified as an event response. The PPROB= option is ignored if the CTABLE option is not specified.

A classification table for each of several cutpoints can be requested by specifying a list. For example,

\texttt{pprob= (0.3, 0.5 to 0.8 by 0.1)}

requests a classification of the observations for each of the cutpoints 0.3, 0.5, 0.6, 0.7, and 0.8. If the PPROB= option is not specified, the default is to display the classification for a range of probabilities from the smallest estimated probability (rounded down to the nearest 0.02) to the highest estimated probability (rounded up to the nearest 0.02) with 0.02 increments.

RIDGING=ABSOLUTE | RELATIVE | NONE
specifies the technique used to improve the log-likelihood function when its value in the current iteration is less than that in the previous iteration. If you specify the RIDGING=ABSOLUTE option, the diagonal elements of the negative (expected) Hessian are inflated by adding the ridge value. If you specify the RIDGING=RELATIVE option, the diagonal elements are inflated by a factor of 1 plus the ridge value. If you specify the RIDGING=NONE option, the crude line search method of taking half a step is used instead of ridging. By default, RIDGING=RELATIVE.

RISKLIMITS
RL
WALDRL

is the same as specifying CLODDS=WALD.

ROCEPS= number

specifies the criterion for grouping estimated event probabilities that are close to each other for the ROC curve. In each group, the difference between the largest and the smallest estimated event probabilities does not exceed the given value. The value for number must be between 0 and 1; the default value is 1E−4. The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The ROCEPS= option has no effect if the OUTROC= option is not specified.

RSQUARE
RSQ

requests a generalized $R^2$ measure for the fitted model. For more information, see the “Generalized Coefficient of Determination” section on page 2342.
SCALE= scale

enables you to supply the value of the dispersion parameter or to specify the method for estimating the dispersion parameter. It also enables you to display the “Deviance and Pearson Goodness-of-Fit Statistics” table. To correct for overdispersion or underdispersion, the covariance matrix is multiplied by the estimate of the dispersion parameter. Valid values for `scale` are as follows:

- **D | DEVIANCE** specifies that the dispersion parameter be estimated by the deviance divided by its degrees of freedom.
- **P | PEARSON** specifies that the dispersion parameter be estimated by the Pearson chi-square statistic divided by its degrees of freedom.
- **WILLIAMS <(constant)>** specifies that Williams’ method be used to model overdispersion. This option can be used only with the `events/trials` syntax. An optional `constant` can be specified as the scale parameter; otherwise, a scale parameter is estimated under the full model. A set of weights is created based on this scale parameter estimate. These weights can then be used in fitting subsequent models of fewer terms than the full model. When fitting these submodels, specify the computed scale parameter as `constant`. See Example 42.9 on page 2438 for an illustration.
- **N | NONE** specifies that no correction is needed for the dispersion parameter; that is, the dispersion parameter remains as 1. This specification is used for requesting the deviance and the Pearson chi-square statistic without adjusting for overdispersion.

`constant` sets the estimate of the dispersion parameter to be the square of the given `constant`. For example, SCALE=2 sets the dispersion parameter to 4. The value `constant` must be a positive number.

You can use the AGGREGATE (or AGGREGATE=) option to define the subpopulations for calculating the Pearson chi-square statistic and the deviance. In the absence of the AGGREGATE (or AGGREGATE=) option, each observation is regarded as coming from a different subpopulation. For the `events/trials` syntax, each observation consists of `n` Bernoulli trials, where `n` is the value of the `trials` variable. For single-trial syntax, each observation consists of a single response, and for this setting it is not appropriate to carry out the Pearson or deviance goodness-of-fit analysis. Thus, PROC LOGISTIC ignores specifications SCALE=P, SCALE=D, and SCALE=N when single-trial syntax is specified without the AGGREGATE (or AGGREGATE=) option.

The “Deviance and Pearson Goodness-of-Fit Statistics” table includes the Pearson chi-square statistic, the deviance, their degrees of freedom, the ratio of each statistic
divided by its degrees of freedom, and the corresponding $p$-value. For more information, see the “Overdispersion” section on page 2354.

**SELECTION=**BACKWARD | B 
| FORWARD | F 
| NONE | N 
| STEPWISE | S 
| SCORE

specifies the method used to select the variables in the model. BACKWARD requests backward elimination, FORWARD requests forward selection, NONE fits the complete model specified in the MODEL statement, and STEPWISE requests stepwise selection. SCORE requests best subset selection. By default, SELECTION=NONE. For more information, see the “Effect Selection Methods” section on page 2340.

**SEQUENTIAL**

SEQ

forces effects to be added to the model in the order specified in the MODEL statement or eliminated from the model in the reverse order specified in the MODEL statement. The model-building process continues until the next effect to be added has an insignificant adjusted chi-square statistic or until the next effect to be deleted has a significant Wald chi-square statistic. The SEQUENTIAL option has no effect when SELECTION=NONE.

**SINGULAR=**value

specifies the tolerance for testing the singularity of the Hessian matrix (Newton-Raphson algorithm) or the expected value of the Hessian matrix (Fisher-scoring algorithm). The Hessian matrix is the matrix of second partial derivatives of the log-likelihood function. The test requires that a pivot for sweeping this matrix be at least this number times a norm of the matrix. Values of the SINGULAR= option must be numeric. By default, value is the machine epsilon times $10^{-7}$, which is approximately $10^{-9}$ on most machines.

**SLENTRY=**value 
**SLE=**value

specifies the significance level of the score chi-square for entering an effect into the model in the FORWARD or STEPWISE method. Values of the SLENTRY= option should be between 0 and 1, inclusive. By default, SLENTRY=0.05. The SLENTRY= option has no effect when SELECTION=NONE, SELECTION=BACKWARD, or SELECTION=SCORE.

**SLSTAY=**value 
**SLS=**value

specifies the significance level of the Wald chi-square for an effect to stay in the model in a backward elimination step. Values of the SLSTAY= option should be between 0 and 1, inclusive. By default, SLSTAY=0.05. The SLSTAY= option has no effect when SELECTION=NONE, SELECTION=FORWARD, or SELECTION=SCORE.
START=\(n\) begins the FORWARD, BACKWARD, or STEPWISE effect selection process with the first \(n\) effects listed in the MODEL statement. The value of \(n\) ranges from 0 to \(s\), where \(s\) is the total number of effects in the MODEL statement. The default value of \(n\) is \(s\) for the BACKWARD method and 0 for the FORWARD and STEPWISE methods. Note that \(START=\(n\)\) specifies only that the first \(n\) effects appear in the first model, while \(INCLUDE=\(n\)\) requires that the first \(n\) effects be included in every model. For the SCORE method, \(START=\(n\)\) specifies that the smallest models contain \(n\) effects, where \(n\) ranges from 1 to \(s\); the default value is 1. The \(START=\) option has no effect when \(SELECTION=\text{NONE}\).

STB displays the standardized estimates for the parameters for the continuous explanatory variables in the “Analysis of Maximum Likelihood Estimates” table. The standardized estimate of \(\beta_i\) is given by \(\hat{\beta}_i/(s/s_i)\), where \(s_i\) is the total sample standard deviation for the \(i\)th explanatory variable and

\[
s = \begin{cases} 
\pi/\sqrt{3} & \text{Logistic} \\
1 & \text{Normal} \\
\pi/\sqrt{6} & \text{Extreme-value}
\end{cases}
\]

For the intercept parameters and parameters associated with a CLASS variable, the standardized estimates are set to missing.

STOP=\(n\) specifies the maximum (FORWARD method) or minimum (BACKWARD method) number of effects to be included in the final model. The effect selection process is stopped when \(n\) effects are found. The value of \(n\) ranges from 0 to \(s\), where \(s\) is the total number of effects in the MODEL statement. The default value of \(n\) is \(s\) for the FORWARD method and 0 for the BACKWARD method. For the SCORE method, \(STOP=\(n\)\) specifies that the largest models contain \(n\) effects, where \(n\) ranges from 1 to \(s\); the default value of \(n\) is \(s\). The \(STOP=\) option has no effect when \(SELECTION=\text{NONE}\) or \(STEPWISE\).

STOPRES \(SR\) specifies that the removal or entry of effects be based on the value of the residual chi-square. If \(SELECTION=\text{FORWARD}\), then the STOPRES option adds the effects into the model one at a time until the residual chi-square becomes insignificant (until the \(p\)-value of the residual chi-square exceeds the \(SLENSTRY=\text{value}\)). If \(SELECTION=\text{BACKWARD}\), then the STOPRES option removes effects from the model one at a time until the residual chi-square becomes significant (until the \(p\)-value of the residual chi-square becomes less than the \(SLSTA=\text{value}\)). The STOPRES option has no effect when \(SELECTION=\text{NONE}\) or \(SELECTION=\text{STEPWISE}\).

TECHNIQUE=FISHER | NEWTON  
TECH=FISHER | NEWTON specifies the optimization technique for estimating the regression parameters. NEWTON (or NR) is the Newton-Raphson algorithm and FISHER (or FS) is the
Fisher-scoring algorithm. Both techniques yield the same estimates, but the estimated covariance matrices are slightly different except for the case when the LOGIT link is specified for binary response data. The default is TECHNIQUE=FISHER. See the section “Iterative Algorithms for Model-Fitting” on page 2336 for details.

**WALDCL**

**CL**

is the same as specifying CLPARM=WALD.

**XCONV=value**

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

\[
\max_j |\delta_j^{(i)}| < value
\]

where

\[
\delta_j^{(i)} = \begin{cases} 
\theta_j^{(i)} - \theta_j^{(i-1)} & |\theta_j^{(i-1)}| < 0.01 \\
\frac{\theta_j^{(i)} - \theta_j^{(i-1)}}{\theta_j^{(i-1)}} & \text{otherwise}
\end{cases}
\]

and \(\theta_j^{(i)}\) is the estimate of the \(j\)th parameter at iteration \(i\). See the section “Convergence Criteria” on page 2338.

**OUTPUT Statement**

**OUTPUT < OUT=SAS-data-set >< options > ;**

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors and their standard error estimates, the estimates of the cumulative or individual response probabilities, and the confidence limits for the cumulative probabilities. Regression diagnostic statistics and estimates of cross validated response probabilities are also available for binary response models. Formulas for the statistics are given in the “Linear Predictor, Predicted Probability, and Confidence Limits” section on page 2350, the “Regression Diagnostics” section on page 2359, and, for conditional logistic regression, in the “Conditional Logistic Regression” section on page 2365.

If you use the single-trial syntax, the data set also contains a variable named _LEVEL_, which indicates the level of the response that the given row of output is referring to. For instance, the value of the cumulative probability variable is the probability that the response variable is as large as the corresponding value of _LEVEL_. For details, see the section “OUT= Output Data Set in the OUTPUT Statement” on page 2376.

The estimated linear predictor, its standard error estimate, all predicted probabilities, and the confidence limits for the cumulative probabilities are computed for all observations in which the explanatory variables have no missing values, even if the
response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the explanatory variables not present in the data without affecting the model fit.

**OUT= SAS-data-set**

names the output data set. If you omit the OUT= option, the output data set is created and given a default name using the DATA$n convention.

The following sections explain options in the OUTPUT statement, divided into statistic options for any type of categorical responses, statistic options only for binary response, and other options. The statistic options specify the statistics to be included in the output data set and name the new variables that contain the statistics. If a STRATA statement is specified, only the PREDICTED=, DFBETAS=, and H= options are available; see the “Regression Diagnostic Details” section on page 2367 for details.

**Statistic Options for Any Type of Categorical Response**

- **LOWER=name**
- **L=name**

names the variable containing the lower confidence limits for $\pi$, where $\pi$ is the probability of the event response if events/trials syntax or single-trial syntax with binary response is specified; for a cumulative model, $\pi$ is cumulative probability (that is, the probability that the response is less than or equal to the value of _LEVEL_;); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of _LEVEL_;). See the ALPHA= option to set the confidence level.

- **PREDICTED=name**
- **PRED=name**
- **PROB=name**
- **P=name**

names the variable containing the predicted probabilities. For the events/trials syntax or single-trial syntax with binary response, it is the predicted event probability. For a cumulative model, it is the predicted cumulative probability (that is, the probability that the response variable is less than or equal to the value of _LEVEL_;); and for the generalized logit model, it is the predicted individual probability (that is, the probability of the response category represented by the value of _LEVEL_;).

- **PREDPROBS=(keywords)**

requests individual, cumulative, or cross validated predicted probabilities. Descriptions of the _keywords_ are as follows.

- **INDIVIDUAL | I** requests the predicted probability of each response level. For a response variable $Y$ with three levels, 1, 2, and 3, the individual probabilities are $Pr(Y=1)$, $Pr(Y=2)$, and $Pr(Y=3)$.

- **CUMULATIVE | C** requests the cumulative predicted probability of each response level. For a response variable $Y$ with three levels, 1, 2, and 3, the cumulative probabilities are $Pr(Y \leq 1)$, $Pr(Y \leq 2)$, and $Pr(Y \leq 3)$. The cumulative probability for the last response level always has the
constant value of 1. For generalized logit models, the cumulative predicted probabilities are not computed and are set to missing.

CROSSVALIDATE | XVALIDATE | X requests the cross validated individual predicted probability of each response level. These probabilities are derived from the leave-one-out principle; that is, dropping the data of one subject and reestimating the parameter estimates. PROC LOGISTIC uses a less expensive one-step approximation to compute the parameter estimates. This option is only valid for binary response models; for nominal and ordinal models, the cross validated probabilities are not computed and are set to missing.

See the “Details of the PREDPROBS= Option” section on page 2322 at the end of this section for further details.

STDXBETA=name
names the variable containing the standard error estimates of XBETA (the definition of which follows).

UPPER=name
U=name
names the variable containing the upper confidence limits for \( \pi \), where \( \pi \) is the probability of the event response if events/trials syntax or single-trial syntax with binary response is specified; for a cumulative model, \( \pi \) is cumulative probability (that is, the probability that the response is less than or equal to the value of \_LEVEL\_); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of \_LEVEL\_). See the ALPHA= option to set the confidence level.

XBETA=name
names the variable containing the estimates of the linear predictor \( \alpha_i + \beta'x \), where \( i \) is the corresponding ordered value of \_LEVEL\_.

**Statistic Options Only for Binary Response**

C=name
specifies the confidence interval displacement diagnostic that measures the influence of individual observations on the regression estimates.

CBAR=name
specifies the another confidence interval displacement diagnostic, which measures the overall change in the global regression estimates due to deleting an individual observation.

DFBETAS= _ALL_
DFBETAS=var-list
specifies the standardized differences in the regression estimates for assessing the effects of individual observations on the estimated regression parameters in the fitted model. You can specify a list of up to \( s + 1 \) variable names, where \( s \) is the number of explanatory variables in the MODEL statement, or you can specify just the
keyword _ALL_. In the former specification, the first variable contains the standardized differences in the intercept estimate, the second variable contains the standardized differences in the parameter estimate for the first explanatory variable in the MODEL statement, and so on. In the latter specification, the DFBETAS statistics are named DFBETA––xxx, where xxx is the name of the regression parameter. For example, if the model contains two variables X1 and X2, the specification DFBETAS=ALL produces three DFBETAS statistics: DFBETA–Intercept, DFBETA–X1, and DFBETA–X2. If an explanatory variable is not included in the final model, the corresponding output variable named in DFBETAS=var-list contains missing values.

DIFCHISQ=name
specifies the change in the chi-square goodness-of-fit statistic attributable to deleting the individual observation.

DIFDEV=name
specifies the change in the deviance attributable to deleting the individual observation.

H=name
specifies the diagonal element of the hat matrix for detecting extreme points in the design space.

RESCHI=name
specifies the Pearson (Chi) residual for identifying observations that are poorly accounted for by the model.

RESDEV=name
specifies the deviance residual for identifying poorly fitted observations.

Other Options
You can specify the following option after a slash.

ALPHA=\( \alpha \)
sets the level of significance \( \alpha \) for 100\( (1 - \alpha) \)% confidence limits for the appropriate response probabilities. The value \( \alpha \) must be between 0 and 1. By default, \( \alpha \) is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

Details of the PREDPROBS= Option
You can request any of the three given types of predicted probabilities. For example, you can request both the individual predicted probabilities and the cross validated probabilities by specifying PREDPROBS=(I X).

When you specify the PREDPROBS= option, two automatic variables _FROM_ and _INTO_ are included for the single-trial syntax and only one variable, _INTO_, is included for the events/trials syntax. The _FROM_ variable contains the formatted value of the observed response. The variable _INTO_ contains the formatted value of the response level with the largest individual predicted probability.

If you specify PREDPROBS=INDIVIDUAL, the OUTPUT data set contains \( k \) additional variables representing the individual probabilities, one for each response level,
where \( k \) is the maximum number of response levels across all BY-groups. The names of these variables have the form \( \text{IP}_-xxx \), where \( xxx \) represents the particular level. The representation depends on the following situations.

- If you specify events/trials syntax, \( xxx \) is either ‘Event’ or ‘Nonevent’. Thus, the variable containing the event probabilities is named \( \text{IP}_-\text{Event} \) and the variable containing the nonevent probabilities is named \( \text{IP}_-\text{Nonevent} \).

- If you specify the single-trial syntax with more than one BY group, \( xxx \) is 1 for the first ordered level of the response, 2 for the second ordered level of the response, ..., and so forth, as given in the “Response Profile” table. The variable containing the predicted probabilities \( \Pr(Y=1) \) is named \( \text{IP}_-1 \), where \( Y \) is the response variable. Similarly, \( \text{IP}_-2 \) is the name of the variable containing the predicted probabilities \( \Pr(Y=2) \), and so on.

- If you specify the single-trial syntax with no BY-group processing, \( xxx \) is the left-justified formatted value of the response level (the value may be truncated so that \( \text{IP}_-xxx \) does not exceed 32 characters.) For example, if \( Y \) is the response variable with response levels ‘None’, ‘Mild’, and ‘Severe’, the variables representing individual probabilities \( \Pr(Y=\text{None}), \Pr(Y=\text{Mild}), \) and \( \Pr(Y=\text{Severe}) \) are named \( \text{IP}_-\text{None}, \text{IP}_-\text{Mild}, \) and \( \text{IP}_-\text{Severe} \), respectively.

If you specify PREDPROBS=CUMULATIVE, the OUTPUT data set contains \( k \) additional variables representing the cumulative probabilities, one for each response level, where \( k \) is the maximum number of response levels across all BY-groups. The names of these variables have the form \( \text{CP}_-xxx \), where \( xxx \) represents the particular response level. The naming convention is similar to that given by PREDPROBS=INDIVIDUAL. The PREDPROBS=CUMULATIVE values are the same as those output by the PREDICT=keyword, but are arranged in variables on each output observation rather than in multiple output observations.

If you specify PREDPROBS=CROSSVALIDATE, the OUTPUT data set contains \( k \) additional variables representing the cross validated predicted probabilities of the \( k \) response levels, where \( k \) is the maximum number of response levels across all BY-groups. The names of these variables have the form \( \text{XP}_-xxx \), where \( xxx \) represents the particular level. The representation is the same as that given by PREDPROBS=INDIVIDUAL except that for the events/trials syntax there are four variables for the cross validated predicted probabilities instead of two:

\[
\begin{align*}
\text{XP\_EVENT\_R1E} & \quad \text{is the cross validated predicted probability of an event when a current event trial is removed.} \\
\text{XP\_NONEVENT\_R1E} & \quad \text{is the cross validated predicted probability of a nonevent when a current event trial is removed.} \\
\text{XP\_EVENT\_R1N} & \quad \text{is the cross validated predicted probability of an event when a current nonevent trial is removed.} \\
\text{XP\_NONEVENT\_R1N} & \quad \text{is the cross validated predicted probability of a nonevent when a current nonevent trial is removed.}
\end{align*}
\]
The cross validated predicted probabilities are precisely those used in the CTABLE option. See the “Predicted Probability of an Event for Classification” section on page 2352 for details of the computation.

**SCORE Statement**

```plaintext
SCORE < options >;
```

The SCORE statement creates a data set that contains all the data in the DATA= data set together with posterior probabilities and, optionally, prediction confidence intervals. Fit statistics are displayed on request. If you have binary response data, the SCORE statement can be used to create the OUTROC= data set containing data for the ROC curve. You can specify several SCORE statements. FREQ, WEIGHT, and BY statements can be used with the SCORE statements.

See the “Scoring Data Sets” section on page 2362 for more information, and see Example 42.13 on page 2462 for an illustration of how to use this statement.

You can specify the following options:

- **ALPHA=** \( \alpha \)
  specifies the significance level \( \alpha \) for \( 100(1 - \alpha)\% \) confidence intervals. By default, \( \alpha \) is equal to the value of the ALPH A= option in the PROC LOGISTIC statement, or 0.05 if that option is not specified. This option has no effect unless the CLM option in the SCORE statement is requested.

- **CLM**
  outputs the Wald-test-based confidence limits for the predicted probabilities. This option is not available when the INMODEL= data set is created with the NOCOV option.

- **DATA=** SAS-data-set
  names the SAS data set that you want to score. If you omit the DATA= option in the SCORE statement, then scoring is performed on the DATA= input data set in the PROC LOGISTIC statement, if specified; otherwise, the DATA=LAST data set is used.

  It is not necessary for the DATA= data set in the SCORE statement to contain the response variable unless you are specifying the FITSTAT or OUTROC= option.

  Only those variables involved in the fitted model effects are required in the DATA= data set in the SCORE statement. For example, the following code uses forward selection to select effects.

```plaintext
proc logistic data=Neuralgia outmodel=sasuser.Model;
  class Treatment Sex;
  model Pain(event=’Yes’) = Treatment|Sex Age
    / selection=forward sle=.01;
run;
```
Suppose Treatment and Age are the effects selected for the final model. You can score a data set which does not contain the variable Sex since the effect Sex is not in the model that the scoring is based on.

```
proc logistic inmodel=sasuser.Model;
   score data=Neuralgia(drop=Sex);
run;
```

FITSTAT displays a table of fit statistics. Four statistics are computed: total frequency, total weight, log likelihood, and misclassification rate.

OUT=SAS-data-set names the SAS data set that contains the predicted information. If you omit the OUT= option, the output data set is created and given a default name using the DATAn convention.

OUTROC=SAS-data-set names the SAS data set that contains the ROC curve for the DATA= data set. The ROC curve is computed only for binary response data. See the section “OUTROC= Output Data Set” on page 2378 for the list of variables in this data set.

PRIOR=SAS-data-set names the SAS data set that contains the priors of the response categories. The priors may be values proportional to the prior probabilities; thus, they do not necessarily sum to one. This data set should include a variable named _PRIOR_ that contains the prior probabilities. For events/trials MODEL syntax, this data set should also include an _OUTCOME_ variable that contains the values EVENT and NONEVENT; for single-trial MODEL syntax, this data set should include the response variable that contains the unformatted response categories. See Example 42.13 on page 2462 for an example.

PRIOREVENT=value specifies the prior event probability for a binary response model. If both PRIOR= and PRIOREVENT= options are specified, the PRIOR= option takes precedence.

ROCEPS=value specifies the criterion for grouping estimated event probabilities that are close to each other for the ROC curve. In each group, the difference between the largest and the smallest estimated event probability does not exceed the given value. The value must be between 0 and 1; the default value is 1E-4. The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The ROCEPS= option has no effect if the OUTROC= option is not specified.
The STRATA statement names the variables that define strata or matched sets to use in a stratified conditional logistic regression of binary response data. Observations having the same variable levels are in the same matched set. At least one variable must be specified to invoke the stratified analysis, and the usual unconditional asymptotic analysis is not performed. The stratified logistic model has the form

$$\text{logit} (\pi_{hi}) = \alpha_h + x_{hi}' \beta$$

where $\pi_{hi}$ is the event probability for the $i$th observation in stratum $h$ having covariates $x_{hi}$, and where the stratum-specific intercepts $\alpha_h$ are the nuisance parameters which are to be conditioned out.

STRATA variables can also be specified in the MODEL statement as classification or continuous covariates; however, the effects are nondegenerate only when crossed with a non-stratification variable. Specifying several STRATA statements is the same as specifying one STRATA statement containing all the strata variables. The STRATA variables can be either character or numeric, and the formatted values of the STRATA variables determine the levels. Thus, you can use also use formats to group values into levels. See the discussion of the FORMAT procedure in the SAS Procedures Guide.

If an EXACT statement is also specified, then a stratified exact conditional logistic regression is performed.

The SCORE and WEIGHT statements are not available with a STRATA statement. The following MODEL options are also not supported with a STRATA statement: CLPARM=PL, CLODDS=PL, CTABLE, LACKFIT, LINK=, NOFIT, OUTMODEL=, OUTROC=, and SCALE=.

The “Strata Summary” table is displayed by default; it displays the number of strata which have a specific number of events and nonevents. For example, if you are analyzing a 1:5 matched study, this table enables you to verify that every stratum in the analysis has exactly one event and five non-events. Strata containing only events or only non-events are reported in this table, but such strata are uninformative and are not used in the analysis. (Note that you can use the response variable option EVENT= to identify the events; otherwise, the first ordered response category is the event.)

The following option can be specified for a stratification variable by enclosing the option in parentheses after the variable name, or it can be specified globally for all STRATA variables after a slash (/).

MISSING

treats missing values (‘.’, ‘A’,...,‘Z’ for numeric variables and blanks for character variables) as valid STRATA variable values.

The following strata options are also available after the slash.
NOSUMMARY
suppresses the display of the “Strata Summary” table.

INFO
displays the “Strata Information” table, which includes the stratum number, levels of
the STRATA variables that define the stratum, the number of events, the number of
nonevents, and the total frequency for each stratum. Since the number of strata can
be very large, this table is only displayed on request.

TEST Statement

< label: > TEST equation1 < , . . . , < equationk >> < / option > ;

The TEST statement tests linear hypotheses about the regression coefficients. The
Wald test is used to test jointly the null hypotheses \( H_0: L \theta = c \) specified in a single
TEST statement. When \( c = 0 \) you should specify a CONTRAST statement instead.

Each equation specifies a linear hypothesis (a row of the \( L \) matrix and the corre-
sponding element of the \( c \) vector); multiple equations are separated by commas. The
label, which must be a valid SAS name, is used to identify the resulting output and
should always be included. You can submit multiple TEST statements.

The form of an equation is as follows:

\[
\text{term} < \pm \text{term} \ldots > < = \pm \text{term} < \pm \text{term} \ldots >>
\]

where term is a parameter of the model, or a constant, or a constant times a param-
eter. For a binary response model, the intercept parameter is named INTERCEPT;
for an ordinal response model, the intercept parameters are named INTERCEPT,
INTERCEPT2, INTERCEPT3, and so on. See the “Parameter Names in the
OUTEST= Data Set” section on page 2375 for details on parameter naming con-
ventions. When no equal sign appears, the expression is set to 0. The following code
illustrates possible uses of the TEST statement:

```sas
proc logistic;
  model y= a1 a2 a3 a4;
  test1: test intercept + .5 * a2 = 0;
  test2: test intercept + .5 * a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and
fourth TEST statements.

You can specify the following option in the TEST statement after a slash(/).

PRINT
displays intermediate calculations in the testing of the null hypothesis \( H_0: L \theta = c \). This includes
\( \tilde{L} \hat{V}(\hat{\theta}) L' \) bordered by \( (L\hat{\theta} - c) \) and \( [L \hat{V}(\hat{\theta}) L']^{-1} \) bordered by
\( [L \tilde{V}(\hat{\theta}) L']^{-1} (L\hat{\theta} - c) \), where \( \hat{\theta} \) is the maximum likelihood estimator of \( \theta \) and \( \tilde{V}(\hat{\theta}) \)
is the estimated covariance matrix of \( \hat{\theta} \).
UNITS Statement

UNITS independent1 = list1 < ... independentk = listk >> / option >;

The UNITS statement enables you to specify units of change for the continuous explanatory variables so that customized odds ratios can be estimated. An estimate of the corresponding odds ratio is produced for each unit of change specified for an explanatory variable. The UNITS statement is ignored for CLASS variables. If the CLODDS= option is specified in the MODEL statement, the corresponding confidence limits for the odds ratios are also displayed.

The term independent is the name of an explanatory variable and list represents a list of units of change, separated by spaces, that are of interest for that variable. Each unit of change in a list has one of the following forms:

- number
- SD or -SD
- number * SD

where number is any nonzero number, and SD is the sample standard deviation of the corresponding independent variable. For example, \( X = -2 \) requests an odds ratio that represents the change in the odds when the variable \( X \) is decreased by two units. \( X = 2 \times SD \) requests an estimate of the change in the odds when \( X \) is increased by two sample standard deviations.

You can specify the following option in the UNITS statement after a slash(/).

DEFAULT= list
gives a list of units of change for all explanatory variables that are not specified in the UNITS statement. Each unit of change can be in any of the forms described previously. If the DEFAULT= option is not specified, PROC LOGISTIC does not produce customized odds ratio estimates for any explanatory variable that is not listed in the UNITS statement.

For more information, see the “Odds Ratio Estimation” section on page 2347.

WEIGHT Statement

WEIGHT variable < / option >;

When a WEIGHT statement appears, each observation in the input data set is weighted by the value of the WEIGHT variable. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with negative, zero, or missing values for the WEIGHT variable are not used in the model fitting. When the WEIGHT statement is not specified, each observation is assigned a weight of 1.

If a SCORE statement is specified, then the WEIGHT variable is used for computing fit statistics and the ROC curve, but it is not required for scoring. If the DATA= data
set in the SCORE statement does not contain the WEIGHT variable, the weights are assumed to be 1 and a warning message is issued in the LOG. If you fit a model and perform the scoring in the same run, the same WEIGHT variable is used for fitting and scoring. If you fit a model in a previous run and input it with the INMODEL= option in the current run, then the WEIGHT variable can be different from the one used in the previous run; however, if a WEIGHT variable was not specified in the previous run you can still specify a WEIGHT variable in the current run.

The following option can be added to the WEIGHT statement after a slash (/).

NORMALIZE
NORM
causes the weights specified by the WEIGHT variable to be normalized so that they add up to the actual sample size. With this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT variable.

Details

Missing Values

Any observation with missing values for the response, offset, strata, or explanatory variables is excluded from the analysis; however, missing values are valid for variables specified with the MISSING option in the CLASS or STRATA statements. The estimated linear predictor and its standard error estimate, the fitted probabilities and confidence limits, and the regression diagnostic statistics are not computed for any observation with missing offset or explanatory variable values. However, if only the response value is missing, the linear predictor, its standard error, the fitted individual and cumulative probabilities, and confidence limits for the cumulative probabilities can be computed and output to a data set using the OUTPUT statement.

Response Level Ordering

Response level ordering is important because, by default, PROC LOGISTIC models the probability of response levels with lower Ordered Value. Ordered Values are assigned to response levels in ascending sorted order (that is, the lowest response level is assigned Ordered Value 1, the next lowest is assigned Ordered Value 2, and so on) and are displayed in the “Response Profiles” table. If your response variable \( Y \) takes values in \( \{1, \ldots, k+1\} \), then, by default, the functions modeled with the cumulative model are

\[
\logit(\Pr(Y \leq i|\mathbf{x})), \quad i = 1, \ldots, k
\]

and for the generalized logit model the functions modeled are

\[
\log\left( \frac{\Pr(Y = i|\mathbf{x})}{\Pr(Y = k+1|\mathbf{x})} \right), \quad i = 1, \ldots, k
\]

where the highest Ordered Value \( Y = k + 1 \) is the reference level. You can change which probabilities are modeled by specifying the EVENT=, REF=, DESCENDING, or ORDER= response variable options in the MODEL statement.
For binary response data with event and nonevent categories, if your event category has a higher Ordered Value, then the nonevent is modeled and, since the default response function modeled is

\[
\text{logit}(\pi) = \log \left( \frac{\pi}{1 - \pi} \right)
\]

where \(\pi\) is the probability of the response level assigned Ordered Value 1, and since

\[
\text{logit}(\pi) = -\text{logit}(1 - \pi)
\]

the effect of reversing the order of the two response values is to change the signs of \(\alpha\) and \(\beta\) in the model \(\text{logit}(\pi) = \alpha + \beta' x\).

For example, suppose the binary response variable \(Y\) takes the values 1 and 0 for event and nonevent, respectively, and \texttt{Exposure} is the explanatory variable. By default, PROC LOGISTIC assigns Ordered Value 1 to response level \(Y=0\), and Ordered Value 2 to response level \(Y=1\). As a result, PROC LOGISTIC models the probability of the nonevent (Ordered Value=1) category. To model the event without changing the values of the variable \(Y\), you can do the following:

- Explicitly state which response level is to be modeled using the response variable option \texttt{EVENT=} in the MODEL statement,

  \[
  \text{model } Y(\text{event}='1') = \text{Exposure};
  \]

- Specify the response variable option \texttt{REF=} in the MODEL statement as the nonevent category for the response variable. This option is most useful for generalized logit models.

  \[
  \text{model } Y(\text{ref}='0') = \text{Exposure};
  \]

- Specify the response variable option \texttt{DESCENDING} in the MODEL statement,

  \[
  \text{model } Y(\text{descending})=\text{Exposure};
  \]

- Assign a format to \(Y\) such that the first formatted value (when the formatted values are put in sorted order) corresponds to the event. For this example, \(Y=1\) is assigned formatted value ‘event’ and \(Y=0\) is assigned formatted value ‘nonevent’. Since \texttt{ORDER=FORMATTED} by default, Ordered Value 1 is assigned to response level \(Y=1\) so the procedure models the event.

  \[
  \text{proc format;}
  \text{value Disease 1='event' 0='nonevent';}
  \text{run;}
  \text{proc logistic;}
  \text{format Y Disease.;;}
  \text{model Y=Exposure;}
  \text{run;}
  \]
Consider a model with one CLASS variable \( A \) with four levels, 1, 2, 5, and 7. Details of the possible choices for the PARAM= option follow.

**EFFECT**  Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three design variables have a value of −1. For instance, if the reference level is 7 (REF='7'), the design matrix columns for \( A \) are as follows.

<table>
<thead>
<tr>
<th>Effect Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>A1 A2 A5</td>
</tr>
<tr>
<td>1</td>
<td>1 0 0</td>
</tr>
<tr>
<td>2</td>
<td>0 1 0</td>
</tr>
<tr>
<td>5</td>
<td>0 0 1</td>
</tr>
<tr>
<td>7</td>
<td>−1 −1 −1</td>
</tr>
</tbody>
</table>

Parameter estimates of CLASS main effects using the effect coding scheme estimate the difference in the effect of each nonreference level compared to the average effect over all 4 levels.

**Caution:** PROC LOGISTIC initially parameterizes the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables, then the design matrix and the parameter interpretation may be different from what you expect. For instance, suppose that in addition to the four-level variable \( A \) discussed above, you have another variable \( B \) with two levels, where the fourth level of \( A \) only occurs with the first level of \( B \). If your model contains the effect \( A(B) \), then the design for \( A \) within the second level of \( B \) will not be a differential effect. In particular, the design will look like the following.

<table>
<thead>
<tr>
<th>Effect Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>B  A</td>
<td>A(B=1) A(B=2)</td>
</tr>
<tr>
<td></td>
<td>A1 A2 A5  A1 A2 A5</td>
</tr>
<tr>
<td>1 1</td>
<td>1 0 0 0 0 0 0</td>
</tr>
<tr>
<td>1 2</td>
<td>0 1 0 0 0 0 0</td>
</tr>
<tr>
<td>1 5</td>
<td>0 0 1 0 0 0 0</td>
</tr>
<tr>
<td>1 7</td>
<td>−1 −1 −1 0 0 0 0</td>
</tr>
<tr>
<td>2 1</td>
<td>0 0 0 1 0 0 0</td>
</tr>
<tr>
<td>2 2</td>
<td>0 0 0 0 1 0 0</td>
</tr>
<tr>
<td>2 5</td>
<td>0 0 0 0 0 0 1</td>
</tr>
</tbody>
</table>
PROC LOGISTIC will then detect linear dependency among the last three design variables and set the parameter for A5(B=2) to zero, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The GLM or REFERENCE parameterization may be more appropriate for such problems.

**GLM**

As in PROC GLM, four columns are created to indicate group membership. The design matrix columns for A are as follows.

<table>
<thead>
<tr>
<th>GLM Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>A1</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
</tr>
<tr>
<td>5</td>
<td>0</td>
</tr>
<tr>
<td>7</td>
<td>0</td>
</tr>
</tbody>
</table>

Parameter estimates of CLASS main effects using the GLM coding scheme estimate the difference in the effects of each level compared to the last level.

**ORDINAL**

Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for A is 1), all three design variables have a value of 0. The design matrix columns for A are as follows.

<table>
<thead>
<tr>
<th>Ordinal Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>A2</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>1</td>
</tr>
<tr>
<td>7</td>
<td>1</td>
</tr>
</tbody>
</table>

The first level of the effect is a control or baseline level. Parameter estimates of CLASS main effects using the ORDINAL coding scheme estimate the effect on the response as the ordinal factor is set to each succeeding level. When the parameters for an ordinal main effect have the same sign, the response effect is monotonic across the levels.
POLYNOMIAL

POLY

Three columns are created. The first represents the linear term \(x\), the second represents the quadratic term \(x^2\), and the third represents the cubic term \(x^3\), where \(x\) is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, \ldots according to their sorting order. The design matrix columns for \(A\) are as follows.

<table>
<thead>
<tr>
<th>Polynomial Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>(A)</td>
<td>APOLY1     APOLY2 APOLY3</td>
</tr>
<tr>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>5</td>
<td>5</td>
</tr>
<tr>
<td>7</td>
<td>7</td>
</tr>
</tbody>
</table>

REFERENCE

REF

Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three design variables have a value of 0. For instance, if the reference level is 7 (REF='7'), the design matrix columns for \(A\) are as follows.

<table>
<thead>
<tr>
<th>Reference Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>(A)</td>
<td>A1 A2 A5</td>
</tr>
<tr>
<td>1</td>
<td>1 0 0</td>
</tr>
<tr>
<td>2</td>
<td>0 1 0</td>
</tr>
<tr>
<td>5</td>
<td>0 0 1</td>
</tr>
<tr>
<td>7</td>
<td>0 0 0</td>
</tr>
</tbody>
</table>

Parameter estimates of CLASS main effects using the reference coding scheme estimate the difference in the effect of each nonreference level compared to the effect of the reference level.

ORTHEFFECT

The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for \(A\) are as follows.

<table>
<thead>
<tr>
<th>Orthogonal Effect Coding</th>
<th>Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>(A)</td>
<td>AOEFF1 AOEFF2 AOEFF3</td>
</tr>
<tr>
<td>1</td>
<td>1.41421 -0.81650 -0.57735</td>
</tr>
<tr>
<td>2</td>
<td>0.00000 1.63299 -0.57735</td>
</tr>
<tr>
<td>5</td>
<td>0.00000 0.00000 1.73205</td>
</tr>
<tr>
<td>7</td>
<td>-1.41421 -0.81649 -0.57735</td>
</tr>
</tbody>
</table>
ORTHORDINAL The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=ORDINAL. The design matrix columns for A are as follows.

<table>
<thead>
<tr>
<th>Orthogonal Ordinal Coding Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
</tr>
<tr>
<td>---</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>5</td>
</tr>
<tr>
<td>7</td>
</tr>
</tbody>
</table>

ORTHPOLY The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=POLY. The design matrix columns for A are as follows.

<table>
<thead>
<tr>
<th>Orthogonal Polynomial Coding Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
</tr>
<tr>
<td>---</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>5</td>
</tr>
<tr>
<td>7</td>
</tr>
</tbody>
</table>

ORTHREF The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=REFERENCE. The design matrix columns for A are as follows.

<table>
<thead>
<tr>
<th>Orthogonal Reference Coding Design Matrix</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
</tr>
<tr>
<td>---</td>
</tr>
<tr>
<td>1</td>

</tr>
</tbody>
</table>

**Link Functions and the Corresponding Distributions**

Four link functions are available in the LOGISTIC procedure. The logit function is the default. To specify a different link function, use the LINK= option in the MODEL statement. The link functions and the corresponding distributions are as follows:
Link Functions and the Corresponding Distributions

- The logit function
  \[ g(p) = \log(p/(1 - p)) \]
  is the inverse of the cumulative logistic distribution function, which is
  \[ F(x) = 1/(1 + \exp(-x)) = \exp(x)/(1 + \exp(x)) \]

- The probit (or normit) function
  \[ g(p) = \Phi^{-1}(p) \]
  is the inverse of the cumulative standard normal distribution function, which is
  \[ F(x) = \Phi(x) = (2\pi)^{-1/2} \int_{-\infty}^{x} \exp(-z^2/2)dz \]
  Traditionally, the probit function contains the additive constant 5, but throughout PROC LOGISTIC, the terms probit and normit are used interchangeably.

- The complementary log-log function
  \[ g(p) = \log(-\log(1 - p)) \]
  is the inverse of the cumulative extreme-value function (also called the Gompertz distribution), which is
  \[ F(x) = 1 - \exp(-\exp(x)) \]

- The generalized logit function extends the binary logit link to a vector of levels \( p_1, \ldots, p_{k+1} \) by contrasting each level with a fixed level
  \[ g(p_i) = \log(p_i/p_{k+1}) \quad i = 1, \ldots, k \]

The variances of the normal, logistic, and extreme-value distributions are not the same. Their respective means and variances are

<table>
<thead>
<tr>
<th>Distribution</th>
<th>Mean</th>
<th>Variance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Logistic</td>
<td>0</td>
<td>( \pi^2/3 )</td>
</tr>
<tr>
<td>Extreme-value</td>
<td>( -\gamma )</td>
<td>( \pi^2/6 )</td>
</tr>
</tbody>
</table>

where \( \gamma \) is the Euler constant. In comparing parameter estimates using different link functions, you need to take into account the different scalings of the corresponding distributions and, for the complementary log-log function, a possible shift in location. For example, if the fitted probabilities are in the neighborhood of 0.1 to 0.9, then the parameter estimates using the logit link function should be about \( \pi/\sqrt{3} \) larger than the estimates from the probit link function.
Determining Observations for Likelihood Contributions

If you use events/trials MODEL syntax, each observation is split into two observations. One has response value 1 with a frequency equal to the frequency of the original observation (which is 1 if the FREQ statement is not used) times the value of the events variable. The other observation has response value 2 and a frequency equal to the frequency of the original observation times the value of (trials – events). These two observations will have the same explanatory variable values and the same FREQ and WEIGHT values as the original observation.

For either single-trial or events/trials syntax, let \( j \) index all observations. In other words, for single-trial syntax, \( j \) indexes the actual observations. And, for events/trials syntax, \( j \) indexes the observations after splitting (as described previously). If your data set has 30 observations and you use single-trial syntax, \( j \) has values from 1 to 30; if you use events/trials syntax, \( j \) has values from 1 to 60.

Suppose the response variable in a cumulative response model can take on the ordered values \( 1, \ldots, k, k+1 \) where \( k \) is an integer \( \geq 1 \). The likelihood for the \( j \)th observation with ordered response value \( y_j \) and explanatory variables vector \( x_j \) is given by

\[
L_j = \begin{cases} 
F(\alpha_1 + \beta' x_j) & y_j = 1 \\
F(\alpha_i + \beta' x_j) - F(\alpha_{i-1} + \beta' x_j) & 1 < y_j = i \leq k \\
1 - F(\alpha_k + \beta' x_j) & y_j = k+1 
\end{cases}
\]

where \( F(\cdot) \) is the logistic, normal, or extreme-value distribution function, \( \alpha_1, \ldots, \alpha_k \) are ordered intercept parameters, and \( \beta \) is the slope parameter vector.

For the generalized logit model, letting the \( k+1 \)st level be the reference level, the intercepts \( \alpha_1, \ldots, \alpha_k \) are unordered and the slope vector \( \beta_i \) varies with each logit. The likelihood for the \( j \)th observation with ordered response value \( y_j \) and explanatory variables vector \( x_j \) is given by

\[
L_j = \Pr(Y = y_j | x_j) = \begin{cases} 
e^{-\alpha_i + x_j' \beta_i} & 1 \leq y_j = i \leq k \\
\frac{1 + \sum_{m=1}^{k} e^{\alpha_m + x_j' \beta_m}}{1 + \sum_{m=1}^{k} e^{\alpha_m + x_j' \beta_m}} & y_j = k+1 
\end{cases}
\]

Iterative Algorithms for Model-Fitting

Two iterative maximum likelihood algorithms are available in PROC LOGISTIC. The default is the Fisher-scoring method, which is equivalent to fitting by iteratively reweighted least squares. The alternative algorithm is the Newton-Raphson method. Both algorithms give the same parameter estimates; however, the estimated covariance matrix of the parameter estimators may differ slightly. This is due to the fact that the Fisher-scoring method is based on the expected information matrix while the Newton-Raphson method is based on the observed information matrix. In the case of a binary logit model, the observed and expected information matrices are identical, resulting in identical estimated covariance matrices for both algorithms. For a generalized logit model, only the Newton-Raphson technique is available. You can use the TECHNIQUE= option to select a fitting algorithm.
Iteratively Reweighted Least-Squares Algorithm (Fisher Scoring)

Consider the multinomial variable $Z_j = (Z_{1j}, \ldots, Z_{kj})'$ such that

$$Z_{ij} = \begin{cases} 
1 & \text{if } Y_j = i \\
0 & \text{otherwise}
\end{cases}$$

With $\pi_{ij}$ denoting the probability that the $j$th observation has response value $i$, the expected value of $Z_j$ is $\pi_j = (\pi_{1j}, \ldots, \pi_{kj})'$, and $\pi_{(k+1)j} = 1 - \sum_{i=1}^{k} \pi_{ij}$. The covariance matrix of $Z_j$ is $V_j$, which is the covariance matrix of a multinomial random variable for one trial with parameter vector $\pi_j$. Let $\theta$ be the vector of regression parameters; in other words, $\theta = (\alpha_1, \ldots, \alpha_k, \beta')'$. Let $D_j$ be the matrix of partial derivatives of $\pi_j$ with respect to $\theta$. The estimating equation for the regression parameters is

$$\sum_j D_j' W_j (Z_j - \pi_j) = 0$$

where $W_j = w_j f_j V_j^{-1}$, $w_j$ and $f_j$ are the WEIGHT and FREQ values of the $j$th observation, and $V_j^{-1}$ is a generalized inverse of $V_j$. PROC LOGISTIC chooses $V_j^{-1}$ as the inverse of the diagonal matrix with $\pi_j$ as the diagonal.

With a starting value of $\theta_0$, the maximum likelihood estimate of $\theta$ is obtained iteratively as

$$\theta_{m+1} = \theta_m + \left(\sum_j D_j' W_j D_j\right)^{-1} \sum_j D_j' W_j (Z_j - \pi_j)$$

where $D_j$, $W_j$, and $\pi_j$ are evaluated at $\theta_m$. The expression after the plus sign is the step size. If the likelihood evaluated at $\theta_{m+1}$ is less than that evaluated at $\theta_m$, then $\theta_{m+1}$ is recomputed by step-halving or ridging. The iterative scheme continues until convergence is obtained, that is, until $\theta_{m+1}$ is sufficiently close to $\theta_m$. Then the maximum likelihood estimate of $\theta$ is $\hat{\theta} = \theta_m$.

The covariance matrix of $\hat{\theta}$ is estimated by

$$\hat{\text{cov}}(\hat{\theta}) = \left(\sum_j \hat{D}_j' \hat{W}_j \hat{D}_j\right)^{-1}$$

where $\hat{D}_j$ and $\hat{W}_j$ are, respectively, $D_j$ and $W_j$ evaluated at $\hat{\theta}$.

By default, starting values are zero for the slope parameters, and for the intercept parameters, starting values are the observed cumulative logits (that is, logits of the observed cumulative proportions of response). Alternatively, the starting values may be specified with the INEST= option.
Newton-Raphson Algorithm

For cumulative models, let the parameter vector be \( \mathbf{\theta} = (\alpha_1, \ldots, \alpha_k, \beta')' \), and for the generalized logit model denote \( \mathbf{\theta} = (\alpha_1, \ldots, \alpha_k, \beta'_1, \ldots, \beta'_k)' \). The gradient vector and the Hessian matrix are given, respectively, by

\[
\mathbf{g} = \sum_j w_j f_j \frac{\partial l_j}{\partial \mathbf{\theta}}
\]

\[
\mathbf{H} = \sum_j -w_j f_j \frac{\partial^2 l_j}{\partial \mathbf{\theta}^2}
\]

where \( l_j = \log L_j \) is the log likelihood for the \( j \)th observation. With a starting value of \( \mathbf{\theta}_0 \), the maximum likelihood estimate \( \hat{\mathbf{\theta}} \) of \( \mathbf{\theta} \) is obtained iteratively until convergence is obtained:

\[
\mathbf{\theta}_{m+1} = \mathbf{\theta}_m + \mathbf{H}^{-1} \mathbf{g}
\]

where \( \mathbf{H} \) and \( \mathbf{g} \) are evaluated at \( \mathbf{\theta}_m \). If the likelihood evaluated at \( \mathbf{\theta}_{m+1} \) is less than that evaluated at \( \mathbf{\theta}_m \), then \( \mathbf{\theta}_{m+1} \) is recomputed by step-halving or ridging.

The covariance matrix of \( \hat{\mathbf{\theta}} \) is estimated by

\[
\hat{\text{cov}}(\hat{\mathbf{\theta}}) = \hat{\mathbf{H}}^{-1}
\]

where \( \hat{\mathbf{H}} \) is \( \mathbf{H} \) evaluated at \( \hat{\mathbf{\theta}} \).

Convergence Criteria

Four convergence criteria are allowed, namely, \text{ABSFCONV}=, \text{FCONV}=, \text{GCONV}=, and \text{XCONV}=. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is \text{GCONV}=1E−8.

If you specify a \text{STRATA} statement, then all unspecified (or non-default) criteria are also compared to zero. For example, only specifying the criterion \text{XCONV}=1e−8 but attaining \text{FCONV}=0 terminates the optimization even if the \text{XCONV}= criterion is not satisfied, because the log likelihood has reached its maximum.

Existence of Maximum Likelihood Estimates

The likelihood equation for a logistic regression model does not always have a finite solution. Sometimes there is a nonunique maximum on the boundary of the parameter space, at infinity. The existence, finiteness, and uniqueness of maximum likelihood estimates for the logistic regression model depend on the patterns of data points in the observation space (Albert and Anderson 1984; Santner and Duffy 1986). The existence checks are not performed for conditional logistic regression.
Consider a binary response model. Let $Y_j$ be the response of the $i$th subject and let $x_j$ be the vector of explanatory variables (including the constant 1 associated with the intercept). There are three mutually exclusive and exhaustive types of data configurations: complete separation, quasi-complete separation, and overlap.

**Complete Separation**
There is a complete separation of data points if there exists a vector $b$ that correctly allocates all observations to their response groups; that is,

\[
\begin{align*}
    b'x_j > 0 & \quad Y_j = 1 \\
    b'x_j < 0 & \quad Y_j = 2
\end{align*}
\]

This configuration gives nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the log likelihood diminishes to zero, and the dispersion matrix becomes unbounded.

**Quasi-Complete Separation**
The data are not completely separable but there is a vector $b$ such that

\[
\begin{align*}
    b'x_j \geq 0 & \quad Y_j = 1 \\
    b'x_j \leq 0 & \quad Y_j = 2
\end{align*}
\]

and equality holds for at least one subject in each response group. This configuration also yields nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the dispersion matrix becomes unbounded and the log likelihood diminishes to a nonzero constant.

**Overlap**
If neither complete nor quasi-complete separation exists in the sample points, there is an overlap of sample points. In this configuration, the maximum likelihood estimates exist and are unique.

Complete separation and quasi-complete separation are problems typically encountered with small data sets. Although complete separation can occur with any type of data, quasi-complete separation is not likely with truly continuous explanatory variables.

The LOGISTIC procedure uses a simple empirical approach to recognize the data configurations that lead to infinite parameter estimates. The basis of this approach is that any convergence method of maximizing the log likelihood must yield a solution giving complete separation, if such a solution exists. In maximizing the log likelihood, there is no checking for complete or quasi-complete separation if convergence is attained in eight or fewer iterations. Subsequent to the eighth iteration, the probability of the observed response is computed for each observation. If the probability of the observed response is one for all observations, there is a complete separation
of data points and the iteration process is stopped. If the complete separation of data has not been determined and an observation is identified to have an extremely large probability (≥0.95) of the observed response, there are two possible situations. First, there is overlap in the data set, and the observation is an atypical observation of its own group. The iterative process, if allowed to continue, will stop when a maximum is reached. Second, there is quasi-complete separation in the data set, and the asymptotic dispersion matrix is unbounded. If any of the diagonal elements of the dispersion matrix for the standardized observations vectors (all explanatory variables standardized to zero mean and unit variance) exceeds 5000, quasi-complete separation is declared and the iterative process is stopped. If either complete separation or quasi-complete separation is detected, a warning message is displayed in the procedure output.

Checking for quasi-complete separation is less foolproof than checking for complete separation. The NOCHECK option in the MODEL statement turns off the process of checking for infinite parameter estimates. In cases of complete or quasi-complete separation, turning off the checking process typically results in the procedure failing to converge. The presence of a WEIGHT statement also turns off the checking process.

**Effect Selection Methods**

Five effect-selection methods are available. The simplest method (and the default) is SELECTION=NONE, for which PROC LOGISTIC fits the complete model as specified in the MODEL statement. The other four methods are FORWARD for forward selection, BACKWARD for backward elimination, STEPWISE for stepwise selection, and SCORE for best subsets selection. These methods are specified with the SELECTION= option in the MODEL statement. Intercept parameters are forced to stay in the model unless the NOINT option is specified.

When SELECTION=FORWARD, PROC LOGISTIC first estimates parameters for effects forced into the model. These effects are the intercepts and the first \( n \) explanatory effects in the MODEL statement, where \( n \) is the number specified by the START= or INCLUDE= option in the MODEL statement (\( n \) is zero by default). Next, the procedure computes the score chi-square statistic for each effect not in the model and examines the largest of these statistics. If it is significant at the SLENTRY= level, the corresponding effect is added to the model. Once an effect is entered in the model, it is never removed from the model. The process is repeated until none of the remaining effects meet the specified level for entry or until the STOP= value is reached.

When SELECTION=BACKWARD, parameters for the complete model as specified in the MODEL statement are estimated unless the START= option is specified. In that case, only the parameters for the intercepts and the first \( n \) explanatory effects in the MODEL statement are estimated, where \( n \) is the number specified by the START= option. Results of the Wald test for individual parameters are examined. The least significant effect that does not meet the SLSTAY= level for staying in the model is removed. Once an effect is removed from the model, it remains excluded. The process is repeated until no other effect in the model meets the specified level for removal or removal.
until the STOP= value is reached. Backward selection is often less successful than forward or stepwise selection because the full model fit in the first step is the model most likely to result in a complete or quasi-complete separation of response values as described in the previous section.

The SELECTION=STEPWISE option is similar to the SELECTION=FORWARD option except that effects already in the model do not necessarily remain. Effects are entered into and removed from the model in such a way that each forward selection step may be followed by one or more backward elimination steps. The stepwise selection process terminates if no further effect can be added to the model or if the effect just entered into the model is the only effect removed in the subsequent backward elimination.

For SELECTION=SCORE, PROC LOGISTIC uses the branch and bound algorithm of Furnival and Wilson (1974) to find a specified number of models with the highest likelihood score (chi-square) statistic for all possible model sizes, from 1, 2, 3 effect models, and so on, up to the single model containing all of the explanatory effects. The number of models displayed for each model size is controlled by the BEST= option. You can use the START= option to impose a minimum model size, and you can use the STOP= option to impose a maximum model size. For instance, with BEST=3, START=2, and STOP=5, the SCORE selection method displays the best three models (that is, the three models with the highest score chi-squares) containing 2, 3, 4, and 5 effects. The SELECTION=SCORE option is not available for models with CLASS variables.

The options FAST, SEQUENTIAL, and STOPRES can alter the default criteria for entering or removing effects from the model when they are used with the FORWARD, BACKWARD, or STEPWISE selection methods.

Model Fitting Information

Suppose the model contains s explanatory effects. For the jth observation, let \( \hat{\pi}_j \) be the estimated probability of the observed response. The three criteria displayed by the LOGISTIC procedure are calculated as follows:

- **−2 Log Likelihood:**

  \[
  -2 \log L = -2 \sum_j w_j f_j \log(\hat{\pi}_j)
  \]

  where \( w_j \) and \( f_j \) are the weight and frequency values of the jth observation. For binary response models using events/trials MODEL syntax, this is equivalent to

  \[
  -2 \log L = -2 \sum_j w_j f_j \{ r_j \log(\hat{\pi}_j) + (n_j - r_j) \log(1 - \hat{\pi}_j) \}
  \]

  where \( r_j \) is the number of events, \( n_j \) is the number of trials, and \( \hat{\pi}_j \) is the estimated event probability.
• Akaike Information Criterion:

\[ AIC = -2 \log L + 2p \]

where \( p \) is the number of parameters in the model. For cumulative response models, \( p = k + s \) where \( k \) is the total number of response levels minus one, and \( s \) is the number of explanatory effects. For the generalized logit model, \( p = k(s + 1) \).

• Schwarz Criterion:

\[ SC = -2 \log L + p \log(\sum_j f_j) \]

where \( p \) is as defined previously.

The \(-2 \log \) Likelihood statistic has a chi-square distribution under the null hypothesis (that all the explanatory effects in the model are zero) and the procedure produces a \( p \)-value for this statistic. The AIC and SC statistics give two different ways of adjusting the \(-2 \log \) Likelihood statistic for the number of terms in the model and the number of observations used. These statistics should be used when comparing different models for the same data (for example, when you use the METHOD=STEPWISE option in the MODEL statement); lower values of the statistic indicate a more desirable model.

**Generalized Coefficient of Determination**

Cox and Snell (1989, pp. 208–209) propose the following generalization of the coefficient of determination to a more general linear model:

\[ R^2 = 1 - \left\{ \frac{L(0)}{L(\hat{\theta})} \right\}^{\frac{1}{n}} \]

where \( L(0) \) is the likelihood of the intercept-only model, \( L(\hat{\theta}) \) is the likelihood of the specified model, and \( n \) is the sample size. The quantity \( R^2 \) achieves a maximum of less than one for discrete models, where the maximum is given by

\[ R^2_{\text{max}} = 1 - \left\{ L(0) \right\}^{\frac{1}{n}} \]

Nagelkerke (1991) proposes the following adjusted coefficient, which can achieve a maximum value of one:

\[ \tilde{R}^2 = \frac{R^2}{R^2_{\text{max}}} \]

Properties and interpretation of \( R^2 \) and \( \tilde{R}^2 \) are provided in Nagelkerke (1991). In the “Testing Global Null Hypothesis: BETA=0” table, \( R^2 \) is labeled as “RSquare” and \( \tilde{R}^2 \) is labeled as “Max-rescaled RSquare.” Use the RSQUARE option to request \( R^2 \) and \( \tilde{R}^2 \).
Score Statistics and Tests

To understand the general form of the score statistics, let \( U(\theta) \) be the vector of first partial derivatives of the log likelihood with respect to the parameter vector \( \theta \), and let \( H(\theta) \) be the matrix of second partial derivatives of the log likelihood with respect to \( \theta \). That is, \( U(\theta) \) is the gradient vector, and \( H(\theta) \) is the Hessian matrix. Let \( I(\theta) \) be either \(-H(\theta)\) or the expected value of \(-H(\theta)\). Consider a null hypothesis \( H_0 \). Let \( \hat{\theta}_0 \) be the MLE of \( \theta \) under \( H_0 \). The chi-square score statistic for testing \( H_0 \) is defined by

\[
U'(\hat{\theta}_0)I^{-1}(\hat{\theta}_0)U(\hat{\theta}_0)
\]

and it has an asymptotic \( \chi^2 \) distribution with \( r \) degrees of freedom under \( H_0 \), where \( r \) is the number of restrictions imposed on \( \theta \) by \( H_0 \).

Residual Chi-Square

When you use SELECTION=FORWARD, BACKWARD, or STEPWISE, the procedure calculates a residual score chi-square score statistic and reports the statistic, its degrees of freedom, and the \( p \)-value. This section describes how the statistic is calculated.

Suppose there are \( s \) explanatory effects of interest. The full cumulative response model has a parameter vector

\[
\theta = (\alpha_1, \ldots, \alpha_k, \beta_1, \ldots, \beta_s)'
\]

where \( \alpha_1, \ldots, \alpha_k \) are intercept parameters, and \( \beta_1, \ldots, \beta_s \) are the common slope parameters for the explanatory effects, and the full generalized logit model has a parameter vector

\[
\theta = (\alpha_1, \ldots, \alpha_k, \beta'_1, \ldots, \beta'_k)'
\]

with

\[
\beta'_i = (\beta_{i1}, \ldots, \beta_{is}), \quad i = 1, \ldots, k
\]

where \( \beta_{ij} \) is the slope parameter for the \( j \)th effect in the \( i \)th logit.

Consider the null hypothesis \( H_0: \beta_{t+1} = \ldots = \beta_s = 0 \) where \( t < s \) for the cumulative response model, and \( H_0: \beta_{t+1} = \ldots = \beta_{is} = 0, t < s, i = 1, \ldots, k \) for the generalized logit model. For the reduced model with \( t \) explanatory effects, let \( \hat{\alpha}_1, \ldots, \hat{\alpha}_k \) be the MLEs of the unknown intercept parameters, let \( \hat{\beta}_1, \ldots, \hat{\beta}_i \) be the MLEs of the unknown slope parameters, and let \( \hat{\beta}'_{i(t)} = (\hat{\beta}_{i1}, \ldots, \hat{\beta}_{it}), i = 1, \ldots, k \) be those for the generalized logit model. The residual chi-square is the chi-square score statistic testing the null hypothesis \( H_0 \); that is, the residual chi-square is

\[
U'(\hat{\theta}_0)I^{-1}(\hat{\theta}_0)U(\hat{\theta}_0)
\]
where for the cumulative response model \( \hat{\theta}_0 = (\hat{\alpha}_1, \ldots, \hat{\alpha}_k, \hat{\beta}_t, 0, \ldots, 0)' \), and for the generalized logit model \( \hat{\theta}_0 = (\hat{\alpha}_1, \ldots, \hat{\alpha}_k, \hat{\beta}_1'(t), 0'_{(s-t)}, \ldots, \hat{\beta}_t'(t), 0'_{(s-t)})' \), where \( 0'_{(s-t)} \) denote a vector of \( s-t \) zeros.

The residual chi-square has an asymptotic chi-square distribution with \( s-t \) degrees of freedom \( (k(s-t) \) for the generalized logit model). A special case is the global score chi-square, where the reduced model consists of the \( k \) intercepts and no explanatory effects. The global score statistic is displayed in the “Testing Global Null Hypothesis: BETA=0” table. The table is not produced when the NOFIT option is used, but the global score statistic is displayed.

**Testing Individual Effects Not in the Model**

These tests are performed in the FORWARD or STEPWISE method, and are displayed when the DETAILS option is specified. In the displayed output, the tests are labeled “Score Chi-Square” in the “Analysis of Effects Not in the Model” table and in the “Summary of Stepwise (Forward) Selection” table. This section describes how the tests are calculated.

Suppose that \( k \) intercepts and \( t \) explanatory variables (say \( v_1, \ldots, v_t \)) have been fitted to a model and that \( v_{t+1} \) is another explanatory variable of interest. Consider a full model with the \( k \) intercepts and \( t+1 \) explanatory variables \( (v_1, \ldots, v_t, v_{t+1}) \) and a reduced model with \( v_{t+1} \) excluded. The significance of \( v_{t+1} \) adjusted for \( v_1, \ldots, v_t \) can be determined by comparing the corresponding residual chi-square with a chi-square distribution with one degree of freedom \( (k \) degrees of freedom for the generalized logit model).

**Testing the Parallel Lines Assumption**

For an ordinal response, PROC LOGISTIC performs a test of the parallel lines assumption. In the displayed output, this test is labeled “Score Test for the Equal Slopes Assumption” when the LINK= option is NORMIT or CLOGLOG. When LINK=LOGIT, the test is labeled as “Score Test for the Proportional Odds Assumption” in the output. For small sample sizes, this test may be too liberal (Stokes, Davis, and Koch 2000). This section describes the methods used to calculate the test.

For this test the number of response levels, \( k+1 \), is assumed to be strictly greater than 2. Let \( Y \) be the response variable taking values \( 1, \ldots, k, k+1 \). Suppose there are \( s \) explanatory variables. Consider the general cumulative model without making the parallel lines assumption

\[
g(\Pr(Y \leq i \mid \mathbf{x})) = (1, \mathbf{x}') \theta_i, \quad 1 \leq i \leq k
\]

where \( g(\cdot) \) is the link function, and \( \theta_i = (\alpha_i, \beta_{i1}, \ldots, \beta_{is})' \) is a vector of unknown parameters consisting of an intercept \( \alpha_i \) and \( s \) slope parameters \( \beta_{i1}, \ldots, \beta_{is} \). The parameter vector for this general cumulative model is

\[
\theta = (\theta_1', \ldots, \theta_k')'
\]
Under the null hypothesis of parallelism \( H_0: \beta_{1m} = \beta_{2m} = \ldots = \beta_{km}, 1 \leq m \leq s \), there is a single common slope parameter for each of the \( s \) explanatory variables. Let \( \beta_1, \ldots, \beta_s \) be the common slope parameters. Let \( \hat{\alpha}_1, \ldots, \hat{\alpha}_k \) and \( \hat{\beta}_1, \ldots, \hat{\beta}_s \) be the MLEs of the intercept parameters and the common slope parameters. Then, under \( H_0 \), the MLE of \( \theta \) is

\[
\hat{\theta}_0 = (\hat{\theta}_1', \ldots, \hat{\theta}_k')' \quad \text{with} \quad \hat{\theta}_i = (\hat{\alpha}_i, \hat{\beta}_1, \ldots, \hat{\beta}_s)'
\]

and the chi-squared score statistic \( U'(\hat{\theta}_0)I^{-1}(\hat{\theta}_0)U(\hat{\theta}_0) \) has an asymptotic chi-square distribution with \( s(k - 1) \) degrees of freedom. This tests the parallel lines assumption by testing the equality of separate slope parameters simultaneously for all explanatory variables.

**Confidence Intervals for Parameters**

There are two methods of computing confidence intervals for the regression parameters. One is based on the profile likelihood function, and the other is based on the asymptotic normality of the parameter estimators. The latter is not as time-consuming as the former, since it does not involve an iterative scheme; however, it is not thought to be as accurate as the former, especially with small sample size. You use the CLPARM= option to request confidence intervals for the parameters.

**Likelihood Ratio-Based Confidence Intervals**

The likelihood ratio-based confidence interval is also known as the profile likelihood confidence interval. The construction of this interval is derived from the asymptotic \( \chi^2 \) distribution of the generalized likelihood ratio test (Venzo and Moolgavkar 1988). Suppose that the parameter vector is \( \beta = (\beta_0, \beta_1, \ldots, \beta_s)' \) and you want to compute a confidence interval for \( \beta_j \). The profile likelihood function for \( \beta_j = \gamma \) is defined as

\[
l_j^*(\gamma) = \max_{\beta \in B_j(\gamma)} l(\beta)
\]

where \( B_j(\gamma) \) is the set of all \( \beta \) with the \( j \)th element fixed at \( \gamma \), and \( l(\beta) \) is the log-likelihood function for \( \beta \). If \( l_{\max} = l(\hat{\beta}) \) is the log likelihood evaluated at the maximum likelihood estimate \( \hat{\beta} \), then \( 2(l_{\max} - l_j^*(\beta_j)) \) has a limiting chi-square distribution with one degree of freedom if \( \beta_j \) is the true parameter value. Let \( l_0 = l_{\max} - .5\chi_1^2(1 - \alpha) \), where \( \chi_1^2(1 - \alpha) \) is the 100\( (1 - \alpha) \% \) percentile of the chi-square distribution with one degree of freedom. A 100\( (1 - \alpha) \% \) confidence interval for \( \beta_j \) is

\[
\{ \gamma : l_j^*(\gamma) \geq l_0 \}
\]

The endpoints of the confidence interval are found by solving numerically for values of \( \beta_j \) that satisfy equality in the preceding relation. To obtain an iterative algorithm...
for computing the confidence limits, the log-likelihood function in a neighborhood of 
\( \beta \) is approximated by the quadratic function

\[
\tilde{l}(\beta + \delta) = l(\beta) + \delta^t g + \frac{1}{2} \delta^t V \delta
\]

where \( g = g(\beta) \) is the gradient vector and \( V = V(\beta) \) is the Hessian matrix. The
increment \( \delta \) for the next iteration is obtained by solving the likelihood equations

\[
\frac{d}{d\delta} \{ \tilde{l}(\beta + \delta) + \lambda(e_j^t \delta - \gamma) \} = 0
\]

where \( \lambda \) is the Lagrange multiplier, \( e_j \) is the \( j \)th unit vector, and \( \gamma \) is an unknown
constant. The solution is

\[
\delta = -V^{-1}(g + \lambda e_j)
\]

By substituting this \( \delta \) into the equation \( \tilde{l}(\beta + \delta) = l_0 \), you can estimate \( \lambda \) as

\[
\lambda = \pm \left( 2(l_0 - l(\beta)) + \frac{1}{2} g^t V^{-1} g \right)^{1/2}
\]

The upper confidence limit for \( \beta_j \) is computed by starting at the maximum likelihood
estimate of \( \beta \) and iterating with positive values of \( \lambda \) until convergence is attained.
The process is repeated for the lower confidence limit using negative values of \( \lambda \).

Convergence is controlled by value \( \epsilon \) specified with the PLCONV= option in the
MODEL statement (the default value of \( \epsilon \) is 1E−4). Convergence is declared on the
current iteration if the following two conditions are satisfied:

\[
|l(\beta) - l_0| \leq \epsilon
\]

and

\[
(g + \lambda e_j)^t V^{-1} (g + \lambda e_j) \leq \epsilon
\]

**Wald Confidence Intervals**

Wald confidence intervals are sometimes called the normal confidence intervals. They
are based on the asymptotic normality of the parameter estimators. The \( 100(1 - \alpha) \)%
Wald confidence interval for \( \beta_j \) is given by

\[
\hat{\beta}_j \pm z_{1-\alpha/2} \hat{\sigma}_j
\]

where \( z_p \) is the \( 100p \)th percentile of the standard normal distribution, \( \hat{\beta}_j \) is the maxi-
mum likelihood estimate of \( \beta_j \), and \( \hat{\sigma}_j \) is the standard error estimate of \( \hat{\beta}_j \).
Odds Ratio Estimation

Consider a dichotomous response variable with outcomes event and nonevent. Consider a dichotomous risk factor variable X that takes the value 1 if the risk factor is present and 0 if the risk factor is absent. According to the logistic model, the log odds function, \( g(X) \), is given by

\[
g(X) \equiv \log \left( \frac{\Pr(\text{event} \mid X)}{\Pr(\text{nonevent} \mid X)} \right) = \beta_0 + \beta_1 X
\]

The odds ratio \( \psi \) is defined as the ratio of the odds for those with the risk factor \( (X = 1) \) to the odds for those without the risk factor \( (X = 0) \). The log of the odds ratio is given by

\[
\log(\psi) \equiv \log(\psi(X = 1, X = 0)) = g(X = 1) - g(X = 0) = \beta_1
\]

The parameter, \( \beta_1 \), associated with \( X \) represents the change in the log odds from \( X = 0 \) to \( X = 1 \). So, the odds ratio is obtained by simply exponentiating the value of the parameter associated with the risk factor. The odds ratio indicates how the odds of event change as you change \( X \) from 0 to 1. For instance, \( \psi = 2 \) means that the odds of an event when \( X = 1 \) are twice the odds of an event when \( X = 0 \).

Suppose the values of the dichotomous risk factor are coded as constants \( a \) and \( b \) instead of 0 and 1. The odds when \( X = a \) become \( \exp(\beta_0 + a\beta_1) \), and the odds when \( X = b \) become \( \exp(\beta_0 + b\beta_1) \). The odds ratio corresponding to an increase in \( X \) from \( a \) to \( b \) is

\[
\psi = \exp[(b - a)\beta_1] = [\exp(\beta_1)]^{b-a} \equiv [\exp(\beta_1)]^c
\]

Note that for any \( a \) and \( b \) such that \( c = b - a = 1, \psi = \exp(\beta_1) \). So the odds ratio can be interpreted as the change in the odds for any increase of one unit in the corresponding risk factor. However, the change in odds for some amount other than one unit is often of greater interest. For example, a change of one pound in body weight may be too small to be considered important, while a change of 10 pounds may be more meaningful. The odds ratio for a change in \( X \) from \( a \) to \( b \) is estimated by raising the odds ratio estimate for a unit change in \( X \) to the power of \( c = b - a \) as shown previously.

For a polytomous risk factor, the computation of odds ratios depends on how the risk factor is parameterized. For illustration, suppose that Race is a risk factor with four categories: White, Black, Hispanic, and Other.

For the effect parameterization scheme (PARAM=EFFECT) with White as the reference group, the design variables for Race are as follows.

<table>
<thead>
<tr>
<th>Race</th>
<th>Design Variables</th>
</tr>
</thead>
<tbody>
<tr>
<td>White</td>
<td>□1 □1 □1</td>
</tr>
<tr>
<td>Other</td>
<td>0 0 1</td>
</tr>
<tr>
<td>Hispanic</td>
<td>0 1 0</td>
</tr>
<tr>
<td>Black</td>
<td>1 0 0</td>
</tr>
</tbody>
</table>
The log odds for Black is
\[ g(\text{Black}) = \beta_0 + \beta_1 (X_1 = 1) + \beta_2 (X_2 = 0) + \beta_3 (X_3 = 0) \]
\[ = \beta_0 + \beta_1 \]

The log odds for White is
\[ g(\text{White}) = \beta_0 + \beta_1 (X_1 = -1) + \beta_2 (X_2 = -1) + \beta_3 (X_3 = -1) \]
\[ = \beta_0 - \beta_1 - \beta_2 - \beta_3 \]

Therefore, the log odds ratio of Black versus White becomes
\[ \log(\psi(\text{Black, White})) = g(\text{Black}) - g(\text{White}) \]
\[ = 2\beta_1 + \beta_2 + \beta_3 \]

For the reference cell parameterization scheme (PARAM=REF) with White as the reference cell, the design variables for race are as follows.

<table>
<thead>
<tr>
<th>Race</th>
<th>Design Variables</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>(X_1)</td>
</tr>
<tr>
<td>Black</td>
<td>1</td>
</tr>
<tr>
<td>Hispanic</td>
<td>0</td>
</tr>
<tr>
<td>Other</td>
<td>0</td>
</tr>
<tr>
<td>White</td>
<td>0</td>
</tr>
</tbody>
</table>

The log odds ratio of Black versus White is given by
\[ \log(\psi(\text{Black, White})) \]
\[ = g(\text{Black}) - g(\text{White}) \]
\[ = (\beta_0 + \beta_1 (X_1 = 1) + \beta_2 (X_2 = 0)) - \beta_3 (X_3 = 0) \]
\[ = \beta_1 \]

For the GLM parameterization scheme (PARAM=GLM), the design variables are as follows.

<table>
<thead>
<tr>
<th>Race</th>
<th>Design Variables</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>(X_1)</td>
</tr>
<tr>
<td>Black</td>
<td>1</td>
</tr>
<tr>
<td>Hispanic</td>
<td>0</td>
</tr>
<tr>
<td>Other</td>
<td>0</td>
</tr>
<tr>
<td>White</td>
<td>0</td>
</tr>
</tbody>
</table>
The log odds ratio of Black versus White is

\[
\log(\psi(\text{Black, White})) = g(\text{Black}) - g(\text{White}) = (\beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 0)) - (\beta_0 + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 1)) = \beta_1 - \beta_4
\]

Consider the hypothetical example of heart disease among race in Hosmer and Lemeshow (2000, p 56). The entries in the following contingency table represent counts.

<table>
<thead>
<tr>
<th>Disease Status</th>
<th>White</th>
<th>Black</th>
<th>Hispanic</th>
<th>Other</th>
</tr>
</thead>
<tbody>
<tr>
<td>Present</td>
<td>5</td>
<td>20</td>
<td>15</td>
<td>10</td>
</tr>
<tr>
<td>Absent</td>
<td>20</td>
<td>10</td>
<td>10</td>
<td>10</td>
</tr>
</tbody>
</table>

The computation of odds ratio of Black versus White for various parameterization schemes is tabulated in the following table.

<table>
<thead>
<tr>
<th>Odds Ratio of Heart Disease Comparing Black to White</th>
</tr>
</thead>
<tbody>
<tr>
<td>PARAM</td>
</tr>
<tr>
<td>EFFECT</td>
</tr>
<tr>
<td>REF</td>
</tr>
<tr>
<td>GLM</td>
</tr>
<tr>
<td></td>
</tr>
</tbody>
</table>

Since the log odds ratio \(\log(\psi)\) is a linear function of the parameters, the Wald confidence interval for \(\log(\psi)\) can be derived from the parameter estimates and the estimated covariance matrix. Confidence intervals for the odds ratios are obtained by exponentiating the corresponding confidence intervals for the log odd ratios. In the displayed output of PROC LOGISTIC, the “Odds Ratio Estimates” table contains the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

To customize odds ratios for specific units of change for a continuous risk factor, you can use the UNITS statement to specify a list of relevant units for each explanatory variable in the model. Estimates of these customized odds ratios are given in a separate table. Let \((L_j, U_j)\) be a confidence interval for \(\log(\psi)\). The corresponding lower and upper confidence limits for the customized odds ratio \(\exp(c\beta_j)\) are \(\exp(cL_j)\) and \(\exp(cU_j)\), respectively (for \(c > 0\)), or \(\exp(cU_j)\) and \(\exp(cL_j)\), respectively (for
Chapter 42. The LOGISTIC Procedure

c < 0). You use the CLODDS= option to request the confidence intervals for the odds ratios.

For a generalized logit model, odds ratios are computed similarly, except \( k \) odds ratios are computed for each effect, corresponding to the \( k \) logits in the model.

**Rank Correlation of Observed Responses and Predicted Probabilities**

The predicted mean score of an observation is the sum of the Ordered Values (shown in the Response Profile table) minus one, weighted by the corresponding predicted probabilities for that observation; that is, the predicted mean score = \( \sum_{i=1}^{k+1} (i - 1) \hat{\pi}_i \), where \( k + 1 \) is the number of response levels and \( \hat{\pi}_i \) is the predicted probability of the \( i \)th (ordered) response.

A pair of observations with different observed responses is said to be *concordant* if the observation with the lower ordered response value has a lower predicted mean score than the observation with the higher ordered response value. If the observation with the lower ordered response value has a higher predicted mean score than the observation with the higher ordered response value, then the pair is *discordant*. If the pair is neither concordant nor discordant, it is a *tie*. Enumeration of the total numbers of concordant and discordant pairs is carried out by categorizing the predicted mean score into intervals of length \( k/500 \) and accumulating the corresponding frequencies of observations.

Let \( N \) be the sum of observation frequencies in the data. Suppose there is a total of \( t \) pairs with different responses, \( n_c \) of them are concordant, \( n_d \) of them are discordant, and \( t - n_c - n_d \) of them are tied. PROC LOGISTIC computes the following four indices of rank correlation for assessing the predictive ability of a model:

\[
\begin{align*}
c & = (n_c + 0.5(t - n_c - n_d))/t \\
\text{Somers’} \ D & = (n_c - n_d)/t \\
\text{Goodman-Kruskal Gamma} & = (n_c - n_d)/(n_c + n_d) \\
\text{Kendall’s} \ Tau-a & = (n_c - n_d)/(0.5N(N - 1))
\end{align*}
\]

Note that \( c \) also gives an estimate of the area under the receiver operating characteristic (ROC) curve when the response is binary (Hanley and McNeil 1982).

For binary responses, the predicted mean score is equal to the predicted probability for Ordered Value 2. As such, the preceding definition of concordance is consistent with the definition used in previous releases for the binary response model.

**Linear Predictor, Predicted Probability, and Confidence Limits**

This section describes how predicted probabilities and confidence limits are calculated using the maximum likelihood estimates (MLEs) obtained from PROC LOGISTIC. For a specific example, see the “Getting Started” section on page 2284. Predicted probabilities and confidence limits can be output to a data set with the OUTPUT statement.
Cumulative Response Models

For a vector of explanatory variables $x$, the linear predictor

$$\eta_i = g(\Pr(Y \leq i \mid x)) = \alpha_i + \beta'x \quad 1 \leq i \leq k$$

is estimated by

$$\hat{\eta}_i = \hat{\alpha}_i + \hat{\beta}'x$$

where $\hat{\alpha}_i$ and $\hat{\beta}$ are the MLEs of $\alpha_i$ and $\beta$. The estimated standard error of $\eta_i$ is $\hat{\sigma} (\hat{\eta}_i)$, which can be computed as the square root of the quadratic form $(1, x') \hat{V}_b (1, x')'$ where $\hat{V}_b$ is the estimated covariance matrix of the parameter estimates. The asymptotic $100(1 - \alpha)%$ confidence interval for $\eta_i$ is given by

$$\hat{\eta}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\eta}_i)$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of a standard normal distribution.

The predicted value and the $100(1 - \alpha)%$ confidence limits for $\Pr(Y \leq i \mid x)$ are obtained by back-transforming the corresponding measures for the linear predictor.

<table>
<thead>
<tr>
<th>Link</th>
<th>Predicted Probability</th>
<th>$100(1-\alpha)$ Confidence Limits</th>
</tr>
</thead>
<tbody>
<tr>
<td>LOGIT</td>
<td>$1/(1 + e^{-\hat{\eta}_i})$</td>
<td>$1/(1 + e^{-\hat{\eta}<em>i} \pm z</em>{\alpha/2} \hat{\sigma}(\hat{\eta}_i))$</td>
</tr>
<tr>
<td>PROBIT</td>
<td>$\Phi(\hat{\eta}_i)$</td>
<td>$\Phi(\hat{\eta}<em>i) \pm z</em>{\alpha/2} \hat{\sigma}(\hat{\eta}_i))$</td>
</tr>
<tr>
<td>CLOGLOG</td>
<td>$1 - e^{-e^{\hat{\eta}_i}}$</td>
<td>$1 - e^{-e^{\hat{\eta}<em>i} \pm z</em>{\alpha/2} \hat{\sigma}(\hat{\eta}_i)}$</td>
</tr>
</tbody>
</table>

Generalized Logit Model

For a vector of explanatory variables $x$, let $\pi_i$ denote the probability of obtaining the response value $i$:

$$\pi_i = \begin{cases} \pi_{k+1} e^{\alpha_i + x'\beta_i} & 1 \leq i \leq k \\ \frac{1}{1 + \sum_{i=1}^{k} e^{\alpha_i + x'\beta_i}} & i = k + 1 \end{cases}$$

By the delta method,

$$\sigma^2(\pi_i) = \left( \frac{\partial \pi_i}{\partial \theta} \right)' V(\theta) \frac{\partial \pi_i}{\partial \theta}$$

A $100(1 - \alpha)%$ confidence level for $\pi_i$ is given by

$$\hat{\pi}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\pi}_i)$$

where $\hat{\pi}_i$ is the estimated expected probability of response $i$, and $\hat{\sigma}(\hat{\pi}_i)$ is obtained by evaluating $\sigma(\pi_i)$ at $\theta = \hat{\theta}$. 

Classification Table

For binary response data, the response is either an event or a nonevent. In PROC LOGISTIC, the response with Ordered Value 1 is regarded as the event, and the response with Ordered Value 2 is the nonevent. PROC LOGISTIC models the probability of the event. From the fitted model, a predicted event probability can be computed for each observation. The method to compute a reduced-bias estimate of the predicted probability is given in the “Predicted Probability of an Event for Classification” section on page 2352, which follows. If the predicted event probability exceeds some cutpoint value \( z \in [0, 1] \), the observation is predicted to be an event observation; otherwise, it is predicted as a nonevent. A 2 \( \times \) 2 frequency table can be obtained by cross-classifying the observed and predicted responses. The CTABLE option produces this table, and the PPROB= option selects one or more cutpoints. Each cutpoint generates a classification table. If the PEVENT= option is also specified, a classification table is produced for each combination of PEVENT= and PPROB= values.

The accuracy of the classification is measured by its sensitivity (the ability to predict an event correctly) and specificity (the ability to predict a nonevent correctly). Sensitivity is the proportion of event responses that were predicted to be events. Specificity is the proportion of nonevent responses that were predicted to be non-events. PROC LOGISTIC also computes three other conditional probabilities: false positive rate, false negative rate, and rate of correct classification. The false positive rate is the proportion of predicted event responses that were observed as non-events. The false negative rate is the proportion of predicted nonevent responses that were observed as events. Given prior probabilities specified with the PEVENT= option, these conditional probabilities can be computed as posterior probabilities using Bayes’ theorem.

Predicted Probability of an Event for Classification

When you classify a set of binary data, if the same observations used to fit the model are also used to estimate the classification error, the resulting error-count estimate is biased. One way of reducing the bias is to remove the binary observation to be classified from the data, reestimate the parameters of the model, and then classify the observation based on the new parameter estimates. However, it would be costly to fit the model leaving out each observation one at a time. The LOGISTIC procedure provides a less expensive one-step approximation to the preceding parameter estimates. Let \( \mathbf{b} \) be the MLE of the parameter vector \((\alpha, \beta')'\) based on all observations. Let \( \mathbf{b}_j \) denote the MLE computed without the \( j \)th observation. The one-step estimate of \( \mathbf{b}_j \) is given by

\[
\mathbf{b}_j^1 = \mathbf{b} - \frac{w_j (y_j - \hat{\pi}_j)}{1 - h_{jj}} \hat{V}_\mathbf{b} \left( \frac{1}{\mathbf{x}_j} \right)
\]

where

\(y_j\) is 1 for an event response and 0 otherwise
\(w_j\) is the WEIGHT value

\(\hat{\pi}_j\) is the predicted event probability based on \(b\)

\(h_{jj}\) is the hat diagonal element (defined on page 2359) with \(n_j = 1\) and \(r_j = y_j\)

\(\hat{V}_b\) is the estimated covariance matrix of \(b\)

\textbf{False Positive and Negative Rates Using Bayes’ Theorem}

Suppose \(n_1\) of \(n\) individuals experience an event, for example, a disease. Let this group be denoted by \(C_1\), and let the group of the remaining \(n_2 = n - n_1\) individuals who do not have the disease be denoted by \(C_2\). The \(j\)th individual is classified as giving a positive response if the predicted probability of disease (\(\hat{\pi}_j^*\)) is large. The probability \(\hat{\pi}_j^*\) is the reduced-bias estimate based on a one-step approximation given in the preceding section. For a given cutpoint \(z\), the \(j\)th individual is predicted to give a positive response if \(\hat{\pi}_j^* \geq z\).

Let \(B\) denote the event that a subject has the disease and \(\bar{B}\) denote the event of not having the disease. Let \(A\) denote the event that the subject responds positively, and let \(\bar{A}\) denote the event of responding negatively. Results of the classification are represented by two conditional probabilities, \(\Pr(A|B)\) and \(\Pr(A|\bar{B})\), where \(\Pr(A|B)\) is the sensitivity, and \(\Pr(A|\bar{B})\) is one minus the specificity.

These probabilities are given by

\[
\Pr(A|B) = \frac{\sum_{j \in C_1} I(\hat{\pi}_j^* \geq z)}{n_1}
\]

\[
\Pr(A|\bar{B}) = \frac{\sum_{j \in C_2} I(\hat{\pi}_j^* \geq z)}{n_2}
\]

where \(I(\cdot)\) is the indicator function.

Bayes’ theorem is used to compute the error rates of the classification. For a given prior probability \(\Pr(B)\) of the disease, the false positive rate \(P_{F+}\) and the false negative rate \(P_{F-}\) are given by Fleiss (1981, pp. 4–5) as follows:

\[
P_{F+} = \Pr(\bar{B}|A) = \frac{\Pr(A|\bar{B})[1 - \Pr(B)]}{\Pr(A|\bar{B}) + \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}
\]

\[
P_{F-} = \Pr(B|\bar{A}) = \frac{[1 - \Pr(A|B)]\Pr(B)}{1 - \Pr(A|B) - \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}
\]

The prior probability \(\Pr(B)\) can be specified by the \texttt{PEVENT=} option. If the \texttt{PEVENT=} option is not specified, the sample proportion of diseased individuals is used; that is, \(\Pr(B) = n_1/n\). In such a case, the false positive rate and the false negative rate reduce to

\[
P_{F+} = \frac{\sum_{j \in C_2} I(\hat{\pi}_j^* \geq z)}{\sum_{j \in C_1} I(\hat{\pi}_j^* \geq z) + \sum_{j \in C_2} I(\hat{\pi}_j^* \geq z)}
\]

\[
P_{F-} = \frac{\sum_{j \in C_1} I(\hat{\pi}_j^* < z)}{\sum_{j \in C_1} I(\hat{\pi}_j^* < z) + \sum_{j \in C_2} I(\hat{\pi}_j^* < z)}
\]
Note that for a stratified sampling situation in which \( n_1 \) and \( n_2 \) are chosen a priori, \( n_1/n \) is not a desirable estimate of \( \Pr(B) \). For such situations, the \texttt{PEVENT=} option should be specified.

### Overdispersion

For a correctly specified model, the Pearson chi-square statistic and the deviance, divided by their degrees of freedom, should be approximately equal to one. When their values are much larger than one, the assumption of binomial variability may not be valid and the data are said to exhibit overdispersion. Underdispersion, which results in the ratios being less than one, occurs less often in practice.

When fitting a model, there are several problems that can cause the goodness-of-fit statistics to exceed their degrees of freedom. Among these are such problems as outliers in the data, using the wrong link function, omitting important terms from the model, and needing to transform some predictors. These problems should be eliminated before proceeding to use the following methods to correct for overdispersion.

### Rescaling the Covariance Matrix

One way of correcting overdispersion is to multiply the covariance matrix by a dispersion parameter. This method assumes that the sample sizes in each subpopulation are approximately equal. You can supply the value of the dispersion parameter directly, or you can estimate the dispersion parameter based on either the Pearson chi-square statistic or the deviance for the fitted model.

The Pearson chi-square statistic \( \chi^2_P \) and the deviance \( \chi^2_D \) are given by

\[
\chi^2_P = \sum_{i=1}^{m} \sum_{j=1}^{k+1} \frac{(r_{ij} - n_i \hat{\pi}_{ij})^2}{n_i \hat{\pi}_{ij}}
\]

\[
\chi^2_D = 2 \sum_{i=1}^{m} \sum_{j=1}^{k+1} r_{ij} \log \left( \frac{r_{ij}}{n_i \hat{\pi}_{ij}} \right)
\]

where \( m \) is the number of subpopulation profiles, \( k + 1 \) is the number of response levels, \( r_{ij} \) is the total weight (sum of the product of the frequencies and the weights) associated with \( j \)th level responses in the \( i \)th profile, \( n_i = \sum_{j=1}^{k+1} r_{ij} \), and \( \hat{\pi}_{ij} \) is the fitted probability for the \( j \)th level at the \( i \)th profile. Each of these chi-square statistics has \( mk - p \) degrees of freedom, where \( p \) is the number of parameters estimated. The dispersion parameter is estimated by

\[
\hat{\sigma}^2 = \begin{cases} 
\frac{\chi^2_P}{mk - p} & \text{SCALE=PEARSON} \\
\frac{\chi^2_D}{mk - p} & \text{SCALE=DEVIANCE} \\
(constant)^2 & \text{SCALE=constant}
\end{cases}
\]

In order for the Pearson statistic and the deviance to be distributed as chi-square, there must be sufficient replication within the subpopulations. When this is not true, the data are sparse, and the \( p \)-values for these statistics are not valid and should be
ignored. Similarly, these statistics, divided by their degrees of freedom, cannot serve as indicators of overdispersion. A large difference between the Pearson statistic and the deviance provides some evidence that the data are too sparse to use either statistic.

You can use the AGGREGATE (or AGGREGATE=) option to define the subpopulation profiles. If you do not specify this option, each observation is regarded as coming from a separate subpopulation. For events/trials syntax, each observation represents \( n \) Bernoulli trials, where \( n \) is the value of the trials variable; for single-trial syntax, each observation represents a single trial. Without the AGGREGATE (or AGGREGATE=) option, the Pearson chi-square statistic and the deviance are calculated only for events/trials syntax.

Note that the parameter estimates are not changed by this method. However, their standard errors are adjusted for overdispersion, affecting their significance tests.

**Williams’ Method**

Suppose that the data consist of \( n \) binomial observations. For the \( i \)th observation, let \( r_i/n_i \) be the observed proportion and let \( x_i \) be the associated vector of explanatory variables. Suppose that the response probability for the \( i \)th observation is a random variable \( P_i \) with mean and variance

\[
E(P_i) = \pi_i \quad \text{and} \quad V(P_i) = \phi \pi_i (1 - \pi_i)
\]

where \( \pi_i \) is the probability of the event, and \( \phi \) is a nonnegative but otherwise unknown scale parameter. Then the mean and variance of \( r_i \) are

\[
E(r_i) = n_i \pi_i \quad \text{and} \quad V(r_i) = n_i \pi_i (1 - \pi_i) [1 + (n_i - 1) \phi]
\]

Williams (1982) estimates the unknown parameter \( \phi \) by equating the value of Pearson’s chi-square statistic for the full model to its approximate expected value. Suppose \( w_i^* \) is the weight associated with the \( i \)th observation. The Pearson chi-square statistic is given by

\[
\chi^2 = \sum_{i=1}^{n} \frac{w_i^* (r_i - n_i \pi_i)^2}{n_i \pi_i (1 - \pi_i)}
\]

Let \( g'(\cdot) \) be the first derivative of the link function \( g(\cdot) \). The approximate expected value of \( \chi^2 \) is

\[
E_{\chi^2} = \sum_{i=1}^{n} w_i^* (1 - w_i^* v_i d_i) [1 + \phi (n_i - 1)]
\]

where \( v_i = n_i/\pi_i (1 - \pi_i) [g'(\pi_i)^2] \) and \( d_i \) is the variance of the linear predictor \( \hat{\alpha}_i + x'_i \hat{\beta} \). The scale parameter \( \phi \) is estimated by the following iterative procedure.
At the start, let \( w^*_i = 1 \) and let \( \pi_i \) be approximated by \( r_i / n_i, \) \( i = 1, 2, \ldots, n. \) If you apply these weights and approximated probabilities to \( \chi^2 \) and \( E \chi^2 \) and then equate them, an initial estimate of \( \phi \) is therefore

\[
\hat{\phi}_0 = \frac{\chi^2 - (n - p)}{\sum_i (n_i - 1)(1 - v_id)}
\]

where \( p \) is the total number of parameters. The initial estimates of the weights become \( \hat{w}_i^* = [1 + (n_i - 1)\hat{\phi}_0]^{-1} \). After a weighted fit of the model, \( \hat{\beta} \) is recalculated, and so is \( \chi^2 \). Then a revised estimate of \( \phi \) is given by

\[
\hat{\phi}_1 = \frac{\chi^2 - \sum_i w_i^*(1 - w_i^*v_id_i)}{w_i^*(n_i - 1)(1 - w_i^*v_id_i)}
\]

The iterative procedure is repeated until \( \chi^2 \) is very close to its degrees of freedom.

Once \( \phi \) has been estimated by \( \hat{\phi} \) under the full model, weights of \( (1 + (n_i - 1)\hat{\phi})^{-1} \) can be used in fitting models that have fewer terms than the full model. See Example 42.9 on page 2438 for an illustration.

### The Hosmer-Lemeshow Goodness-of-Fit Test

Sufficient replication within subpopulations is required to make the Pearson and deviance goodness-of-fit tests valid. When there are one or more continuous predictors in the model, the data are often too sparse to use these statistics. Hosmer and Lemeshow (2000) proposed a statistic that they show, through simulation, is distributed as chi-square when there is no replication in any of the subpopulations. This test is only available for binary response models.

First, the observations are sorted in increasing order of their estimated event probability. The event is the response level specified in the response variable option EVENT=, or the response level which is not specified in the REF= option, or, if neither of these options were specified, then the event is the response level identified in the “Response Profiles” table as “Ordered Value 1”. The observations are then divided into approximately ten groups according to the following scheme. Let \( N \) be the total number of subjects. Let \( M \) be the target number of subjects for each group given by

\[
M = [0.1 \times N + 0.5]
\]

where \( [x] \) represents the integral value of \( x \). If the single-trial syntax is used, blocks of subjects are formed of observations with identical values of the explanatory variables. Blocks of subjects are not divided when being placed into groups.

Suppose there are \( n_1 \) subjects in the first block and \( n_2 \) subjects in the second block. The first block of subjects is placed in the first group. Subjects in the second block are added to the first group if

\[
n_1 < M \quad \text{and} \quad n_1 + [0.5 \times n_2] \leq M
\]
Otherwise, they are placed in the second group. In general, suppose subjects of the 
\((j-1)\)th block have been placed in the \(k\)th group. Let \(c\) be the total number of subjects 
currently in the \(k\)th group. Subjects for the \(j\)th block (containing \(n_j\) subjects) are also 
placed in the \(k\)th group if

\[ c < M \quad \text{and} \quad c + \lfloor 0.5 \times n_j \rfloor \leq M \]

Otherwise, the \(n_j\) subjects are put into the next group. In addition, if the number of 
subjects in the last group does not exceed \([0.05 \times N]\) (half the target group size), the 
last two groups are collapsed to form only one group.

Note that the number of groups, \(g\), may be smaller than 10 if there are fewer than 10 
patterns of explanatory variables. There must be at least three groups in order for the 
Hosmer-Lemeshow statistic to be computed.

The Hosmer-Lemeshow goodness-of-fit statistic is obtained by calculating the 
Pearson chi-square statistic from the \(2 \times g\) table of observed and expected frequencies, 
where \(g\) is the number of groups. The statistic is written

\[
\chi^2_{HL} = \sum_{i=1}^{g} \frac{(O_i - N_i \bar{\pi}_i)^2}{N_i \bar{\pi}_i (1 - \bar{\pi}_i)}
\]

where \(N_i\) is the total frequency of subjects in the \(i\)th group, \(O_i\) is the total frequency 
of event outcomes in the \(i\)th group, and \(\bar{\pi}_i\) is the average estimated predicted proba-
bility of an event outcome for the \(i\)th group. The Hosmer-Lemeshow statistic is then 
compared to a chi-square distribution with \((g - n)\) degrees of freedom, where the 
value of \(n\) can be specified in the LACKFIT option in the MODEL statement. The 
default is \(n = 2\). Large values of \(\chi^2_{HL}\) (and small \(p\)-values) indicate a lack of fit of 
the model.

**Receiver Operating Characteristic Curves**

In a sample of \(n\) individuals, suppose \(n_1\) individuals are observed to have a certain 
condition or event. Let this group be denoted by \(C_1\), and let the group of the remaining 
\(n_2 = n - n_1\) individuals who do not have the condition be denoted by \(C_2\). Risk 
factors are identified for the sample, and a logistic regression model is fitted to the 
data. For the \(j\)th individual, an estimated probability \(\hat{\pi}_j\) of the event of interest is cal-
culated. Note that the \(\hat{\pi}_j\) are computed as shown in the “Linear Predictor, Predicted 
Probability, and Confidence Limits” section on page 2350 and are not the cross vali-
dated estimates discussed in the “Classification Table” section on page 2352.

Suppose the \(n\) individuals undergo a test for predicting the event and the test is based 
on the estimated probability of the event. Higher values of this estimated probability 
are assumed to be associated with the event. A receiver operating characteristic 
(ROC) curve can be constructed by varying the cutpoint that determines which es-
timated event probabilities are considered to predict the event. For each cutpoint \(z\), 
the following measures can be output to a data set using the OUTROC= option in the
MODEL statement or the `OUTROC=` option in the `SCORE` statement:

\[ \_\text{POS}_{\_}(z) = \sum_{i \in C_1} I(\hat{\pi}_i \geq z) \]
\[ \_\text{NEG}_{\_}(z) = \sum_{i \in C_2} I(\hat{\pi}_i < z) \]
\[ \_\text{FALPOS}_{\_}(z) = \sum_{i \in C_2} I(\hat{\pi}_i \geq z) \]
\[ \_\text{FALNEG}_{\_}(z) = \sum_{i \in C_1} I(\hat{\pi}_i < z) \]
\[ \_\text{SENSIT}_{\_}(z) = \frac{\_\text{POS}_{\_}(z)}{n_1} \]
\[ \_1\text{MSPEC}_{\_}(z) = \frac{\_\text{FALPOS}_{\_}(z)}{n_2} \]

where \( I(\cdot) \) is the indicator function.

Note that \( \_\text{POS}_{\_}(z) \) is the number of correctly predicted event responses, \( \_\text{NEG}_{\_}(z) \) is the number of correctly predicted nonevent responses, \( \_\text{FALPOS}_{\_}(z) \) is the number of falsely predicted event responses, \( \_\text{FALNEG}_{\_}(z) \) is the number of falsely predicted nonevent responses, \( \_\text{SENSIT}_{\_}(z) \) is the sensitivity of the test, and \( \_1\text{MSPEC}_{\_}(z) \) is one minus the specificity of the test.

A plot of the ROC curve can be constructed by using the `PLOT` or `GPLOT` procedure with the `OUTROC=` data set and plotting sensitivity \( \_\text{SENSIT}_{\_}(z) \) against 1-specificity \( \_1\text{MSPEC}_{\_}(z) \); see Example 42.7 on page 2429 for an illustration. The area under the ROC curve, as determined by the trapezoidal rule, is estimated by the statistic \( c \) in the “Association of Predicted Probabilities and Observed Responses” table.

### Testing Linear Hypotheses about the Regression Coefficients

Linear hypotheses for \( \theta \) are expressed in matrix form as

\[
H_0: \mathbf{L}\theta = \mathbf{c}
\]

where \( \mathbf{L} \) is a matrix of coefficients for the linear hypotheses, and \( \mathbf{c} \) is a vector of constants. The vector of regression coefficients \( \theta \) includes slope parameters as well as intercept parameters. The Wald chi-square statistic for testing \( H_0 \) is computed as

\[
\chi^2_W = (\mathbf{L}\hat{\theta} - \mathbf{c})'(\mathbf{L}\hat{\Sigma}(\hat{\theta})\mathbf{L})^{-1}(\mathbf{L}\hat{\theta} - \mathbf{c})
\]

where \( \hat{\Sigma}(\hat{\theta}) \) is the estimated covariance matrix. Under \( H_0 \), \( \chi^2_W \) has an asymptotic chi-square distribution with \( r \) degrees of freedom, where \( r \) is the rank of \( \mathbf{L} \).
Regression Diagnostics

For binary response data, regression diagnostics developed by Pregibon (1981) can be requested by specifying the INFLUENCE option. For diagnostics available with conditional logistic regression, see the “Regression Diagnostic Details” section on page 2367.

This section uses the following notation:

\( r_j, n_j \)

- \( r_j \) is the number of event responses out of \( n_j \) trials for the \( j \)th observation. If events/trials syntax is used, \( r_j \) is the value of events and \( n_j \) is the value of trials. For single-trial syntax, \( n_j = 1 \), and \( r_j = 1 \) if the ordered response is 1, and \( r_j = 0 \) if the ordered response is 2.

\( w_j \)

- is the weight of the \( j \)th observation.

\( \pi_j \)

- is the probability of an event response for the \( j \)th observation given by \( \pi_j = F(\alpha + \beta' x_j) \), where \( F(\cdot) \) is the inverse link function defined on page 2335.

\( b \)

- is the maximum likelihood estimate (MLE) of \((\alpha, \beta')\).

\( \hat{V}_b \)

- is the estimated covariance matrix of \( b \).

\( \hat{p}_j, \hat{q}_j \)

- \( \hat{p}_j \) is the estimate of \( \pi_j \) evaluated at \( b \), and \( \hat{q}_j = 1 - \hat{p}_j \).

Pregibon suggests using the index plots of several diagnostic statistics to identify influential observations and to quantify the effects on various aspects of the maximum likelihood fit. In an index plot, the diagnostic statistic is plotted against the observation number. In general, the distributions of these diagnostic statistics are not known, so cutoff values cannot be given for determining when the values are large. However, the IPLOTS and INFLUENCE options provide displays of the diagnostic values allowing visual inspection and comparison of the values across observations. In these plots, if the model is correctly specified and fits all observations well, then no extreme points should appear.

The next five sections give formulas for these diagnostic statistics.

Hat Matrix Diagonal

The diagonal elements of the hat matrix are useful in detecting extreme points in the design space where they tend to have larger values. The \( j \)th diagonal element is

\[
 h_{jj} = \begin{cases} 
 \tilde{w}_j(1,x'_j)\hat{V}_b(1,x'_j)' & \text{Fisher-Scoring} \\
 w_j(1,x'_j)\hat{V}_b(1,x'_j)' & \text{Newton-Raphson} 
 \end{cases}
\]

where

\[
 \tilde{w}_j = \frac{w_j n_j}{\hat{p}_j \hat{q}_j [g'(\hat{p}_j)]^2} \\
 \hat{w}_j = \frac{w_j (r_j - n_j \hat{p}_j) [\hat{p}_j \hat{q}_j g''(\hat{p}_j) + (\hat{q}_j - \hat{p}_j) g'(\hat{p}_j)]}{(\hat{p}_j \hat{q}_j)^2 [g'(\hat{p}_j)]^3}
\]
and \(g'(\cdot)\) and \(g''(\cdot)\) are the first and second derivatives of the link function \(g(\cdot)\), respectively.

For a binary response logit model, the hat matrix diagonal elements are

\[
h_{jj} = w_j n_j \hat{p}_j \hat{q}_j (1, \mathbf{x}_j' \hat{\mathbf{V}}_b \hat{x}_j)
\]

If the estimated probability is extreme (less than 0.1 and greater than 0.9, approximately), then the hat diagonal may be greatly reduced in value. Consequently, when an observation has a very large or very small estimated probability, its hat diagonal value is not a good indicator of the observation’s distance from the design space (Hosmer and Lemeshow 2000, p 171).

**Pearson Residuals and Deviance Residuals**

Pearson and Deviance residuals are useful in identifying observations that are not explained well by the model. Pearson residuals are components of the Pearson chi-square statistic and deviance residuals are components of the deviance. The Pearson residual for the \(j\)th observation is

\[
\chi_j = \frac{\sqrt{w_j (r_j - n_j \hat{p}_j)}}{\sqrt{n_j \hat{p}_j \hat{q}_j}}
\]

The Pearson chi-square statistic is the sum of squares of the Pearson residuals. The deviance residual for the \(j\)th observation is

\[
d_j = \begin{cases} 
-\sqrt{-2 w_j n_j \log(\hat{q}_j)} & \text{if } r_j = 0 \\
\pm \sqrt{-2 w_j [r_j \log \left( \frac{r_j}{n_j \hat{p}_j} \right) + (n_j - r_j) \log \left( \frac{n_j - r_j}{n_j \hat{d}_j} \right)]} & \text{if } 0 < r_j < n_j \\
\sqrt{-2 w_j n_j \log(\hat{p}_j)} & \text{if } r_j = n_j
\end{cases}
\]

where the plus (minus) in \(\pm\) is used if \(r_j/n_j\) is greater (less) than \(\hat{p}_j\). The deviance is the sum of squares of the deviance residuals.

**DFBETAS**

For each parameter estimate, the procedure calculates a DFBETAS diagnostic for each observation. The DFBETAS diagnostic for an observation is the standardized difference in the parameter estimate due to deleting the observation, and it can be used to assess the effect of an individual observation on each estimated parameter of the fitted model. Instead of re-estimating the parameter every time an observation is deleted, PROC LOGISTIC uses the one-step estimate. See the section “Predicted Probability of an Event for Classification” on page 2352. For the \(j\)th observation, the DFBETAS are given by

\[
\text{DFBETAS}_{ij} = \frac{\Delta_i b^1_j / \hat{\sigma}(b_i)}
\]
where \( i = 0, 1, \ldots, s \), \( \hat{\sigma}(b_i) \) is the standard error of the \( i \)th component of \( b \), and \( \Delta b^1_j \) is the \( i \)th component of the one-step difference

\[
\Delta b^1_j = \frac{w_j(r_j - n_j\hat{p}_j)}{1 - h_{jj}} \hat{V}_b \begin{pmatrix} 1 \\ x_j \end{pmatrix}
\]

\( \Delta b^1_j \) is the approximate change \((b - b^1_j)\) in the vector of parameter estimates due to the omission of the \( j \)th observation. The DFBETAS are useful in detecting observations that are causing instability in the selected coefficients.

**C and CBAR**

C and CBAR are confidence interval displacement diagnostics that provide scalar measures of the influence of individual observations on \( b \). These diagnostics are based on the same idea as the Cook distance in linear regression theory, and by using the one-step estimate, C and CBAR for the \( j \)th observation are computed as

\[
C_j = \chi^2_j h_{jj}/(1 - h_{jj})^2
\]

and

\[
\overline{C}_j = \chi^2_j h_{jj}/(1 - h_{jj})
\]

respectively.

Typically, to use these statistics, you plot them against an index (as the IPLOT option does) and look for outliers.

**DIFDEV and DIFCHISQ**

DIFDEV and DIFCHISQ are diagnostics for detecting ill-fitted observations; in other words, observations that contribute heavily to the disagreement between the data and the predicted values of the fitted model. DIFDEV is the change in the deviance due to deleting an individual observation while DIFCHISQ is the change in the Pearson chi-square statistic for the same deletion. By using the one-step estimate, DIFDEV and DIFCHISQ for the \( j \)th observation are computed as

\[
\text{DIFDEV} = d^2_j + \overline{C}_j
\]

and

\[
\text{DIFCHISQ} = \overline{C}_j/h_{jj}
\]
Scoring Data Sets

Scoring a data set, which is especially important for predictive modeling, means applying a previously fitted model to a new data set in order to compute the conditional, or posterior, probabilities of each response category given the values of the explanatory variables in each observation.

The SCORE statement enables you to score new data sets and output the scored values and, optionally, the corresponding confidence limits into a SAS data set. If the response variable is included in the new data set, then you can request fit statistics for the data, which is especially useful for test or validation data. If the response is binary, you can also create a SAS data set containing the receiver operating characteristic (ROC) curve. You can specify multiple SCORE statements in the same invocation of PROC LOGISTIC.

By default, the posterior probabilities are based on implicit prior probabilities that are proportional to the frequencies of the response categories in the training data (the data used to fit the model). Explicit prior probabilities should be specified when the sample proportions of the response categories in the training data differ substantially from the operational data to be scored. For example, to detect a rare category, it is common practice to use a training set in which the rare categories are over-represented; without prior probabilities that reflect the true incidence rate, the predicted posterior probabilities for the rare category will be too high. By specifying the correct priors, the posterior probabilities are adjusted appropriately.

The model fit to the DATA= data set in the PROC LOGISTIC statement is the default model used for the scoring. Alternatively, you can save a fit model on one run of PROC LOGISTIC and use it to score new data on a subsequent run. The OUTMODEL= option in the PROC LOGISTIC statement saves the model information in a SAS data set. Specifying this data set in the INMODEL= option of a new PROC LOGISTIC run will score the DATA= data set in the SCORE statement without refitting the model.

The rest of this section provides some computational details about the scoring.

Posterior Probabilities and Confidence Limits

Let $F$ be the inverse link function. That is,

$$ F(t) = \begin{cases} \frac{1}{1+\exp(-t)}, & \text{logistic} \\ \Phi(t), & \text{normal} \\ 1 - \exp(-\exp(t)), & \text{complementary log-log} \end{cases} $$

The first derivative of $F$ is given by

$$ F'(t) = \begin{cases} \frac{\exp(-t)}{(1+\exp(-t))^2}, & \text{logistic} \\ \phi(t), & \text{normal} \\ \exp(t) \exp(-\exp(t)), & \text{complementary log-log} \end{cases} $$
Suppose there are $k + 1$ response categories. Let $Y$ be the response variable with levels $1, \ldots, k + 1$. Let $x = (x_0, x_1, \ldots, x_p)'$ be a $(p + 1)$-vector of covariates, with $x_0 \equiv 1$. Let $\theta$ be the vector of regression parameters.

Posterior probabilities are given by

$$P_n(i) = \frac{P_o(i) \tilde{p}_n(i)}{\sum_j P_o(j) \tilde{p}_n(j)}$$

$i = 1, \ldots, k + 1$

where the old posterior probabilities ($P_o$) are the conditional probabilities of the response categories given $x$, and the old priors ($p_o$) are the sample proportions of response categories of the training data. To simplify notation, absorb the old priors into the new priors; that is

$$p_n(i) = \frac{\tilde{p}_n(i)}{p_o(i)}$$

$i = 1, \ldots, k + 1$

The posterior probabilities are functions of $\theta$ and their estimates are obtained by substituting $\hat{\theta}$ by its MLE $\hat{\theta}$. The variances of the estimated posterior probabilities are given by the delta method as follows:

$$Var(\hat{P}_n(i)) = \left[ \frac{\partial P_n(i)}{\partial \theta} \right]' Var(\hat{\theta}) \left[ \frac{\partial P_n(i)}{\partial \theta} \right]$$

where

$$\frac{\partial P_n(i)}{\partial \theta} = \frac{\partial P_o(i) p_n(i)}{\sum_j P_o(j) p_n(j)} - \frac{P_o(i) p_n(i) \sum_j \frac{\partial P_o(j)}{\partial \theta} p_n(j)}{[\sum_j P_o(j) p_n(j)]^2}$$

A 100(1-$\alpha$) percent confidence interval for $P_n(i)$ is

$$\hat{P}_n(i) \pm z_{1-\alpha/2} \sqrt{Var(\hat{P}_n(i))}$$

where $z_\tau$ is the upper 100$\tau$ percentile of the standard normal distribution.

**Cumulative Response Model**

Let $\alpha_1, \ldots, \alpha_k$ be the intercept parameters and let $\beta$ be the vector of slope parameters. Denote $\theta = (\alpha_1, \ldots, \alpha_k, \beta)'$. Let

$$\eta_i = \eta_i(\theta) = \alpha_i + \mathbf{x}_i'\beta, \quad i = 1, \ldots, k$$

Estimates of $\eta_1, \ldots, \eta_k$ are obtained by substituting the maximum likelihood estimate $\hat{\theta}$ for $\theta$. 
The predicted probabilities of the responses are

\[ \hat{P}_o(i) = \hat{P}(Y = i) = \begin{cases} F(\hat{\eta}_1) & i = 1 \\ F(\hat{\eta}_i) - F(\hat{\eta}_{i-1}) & i = 2, \ldots, k \\ 1 - F(\hat{\eta}_k) & i = k + 1 \end{cases} \]

For \( i = 1, \ldots, k \), let \( \delta_i(x) \) be a \((k+1)\) column vector with \( i \)th entry equal to 1, \( k+1 \)th entry equal to \( x \), and all other entries 0. The derivative of \( P_o(i) \) with respect to \( \theta \) are

\[ \frac{\partial P_o(i)}{\partial \theta} = \begin{cases} F'(\alpha_1 + x'\beta) \delta_1(x) & i = 1 \\ F'(\alpha_i + x'\beta) \delta_i(x) - F'(\alpha_{i-1} + x'\beta) \delta_{i-1}(x) & i = 2, \ldots, k \\ -F'(\alpha_k + x'\beta) \delta_k(x) & i = k + 1 \end{cases} \]

**Generalized Logit Model**

Consider the last response level \( (Y=k+1) \) as the reference. Let \( \beta_1, \ldots, \beta_k \) be the parameter vectors for the first \( k \) logits, respectively. Denote \( \theta = (\beta_1', \ldots, \beta_k')' \). Let \( \eta = (\eta_1, \ldots, \eta_k)' \) with

\[ \eta_i = \eta_i(\theta) = x'\beta_i \quad i = 1, \ldots, k \]

Estimates of \( \eta_1, \ldots, \eta_k \) are obtained by substituting the maximum likelihood estimate \( \hat{\theta} \) for \( \theta \).

The predicted probabilities are

\[ \hat{P}_o(k + 1) \equiv \hat{P}(Y = k + 1|x) = \frac{1}{1 + \sum_{i=1}^{k} \exp(\hat{\eta}_i)} \]

\[ \hat{P}_o(i) \equiv \hat{P}(Y = i|x) = \hat{P}_o(k + 1) \exp(\hat{\eta}_i), \quad i = 1, \ldots, k \]

The derivative of \( P_o(i) \) with respect to \( \theta \) are

\[ \frac{\partial P_o(i)}{\partial \theta} = \frac{\partial \eta \cdot \partial P_o(i)}{\partial \theta} = \frac{\partial \eta}{\partial \theta} \left( \frac{\partial P_o(i)}{\partial \eta_1}, \ldots, \frac{\partial P_o(i)}{\partial \eta_k} \right)' \]

where

\[ \frac{\partial P_o(i)}{\partial \eta_j} = \begin{cases} P_o(i)(1 - P_o(i)) & j = i \\ -P_o(i)P_o(j) & \text{otherwise} \end{cases} \]
**Special Case of Binary Response Model with No Priors**

Let $\beta$ be the vector of regression parameters. Let

$$\eta = \eta(\beta) = x' \beta$$

The variance of $\hat{\eta}$ is given by

$$Var(\hat{\eta}) = x' Var(\hat{\beta}) x$$

A 100(1-$\alpha$) percent confidence interval for $\eta$ is

$$\hat{\eta} \pm z_{1-\alpha/2} \sqrt{\hat{Var}(\hat{\eta})}$$

Estimates of $P_\alpha(1)$ and confidence intervals for the $P_\alpha(1)$ are obtained by backtransforming $\hat{\eta}$ and the confidence intervals for $\eta$, respectively. That is,

$$\hat{P}_\alpha(1) = F(\hat{\eta})$$

and the confidence intervals are

$$F\left( \hat{\eta} \pm z_{1-\alpha/2} \sqrt{\hat{Var}(\hat{\eta})} \right)$$

**Conditional Logistic Regression**

The method of maximum likelihood described in the preceding sections relies on large-sample asymptotic normality for the validity of estimates and especially of their standard errors. When you do not have a large sample size compared to the number of parameters, this approach may be inappropriate resulting in biased inferences. This situation typically arises when your data are stratified and you fit intercepts to each stratum so that the number of parameters is of the same order as the sample size. For example, in a 1:1 matched pairs study with $n$ pairs and $p$ covariates, you would estimate $n - 1$ intercept parameters and $p$ slope parameters. Taking the stratification into account by “conditioning out” (and not estimating) the stratum-specific intercepts gives consistent and asymptotically normal MLEs for the slope coefficients. See Breslow and Day (1980) and Stokes, Davis, and Koch (2000) for more information. If your nuisance parameters are not just stratum-specific intercepts, you can perform an exact conditional logistic regression.

**Computational Details**

For each stratum $h$, $h = 1, \ldots, H$, number the observations as $i = 1, \ldots, n_h$ so that $hi$ indexes the $i$th observation in the $h$th stratum. Denote the $p$ covariates for observation $hi$ as $x_{hi}$ and its binary response as $y_{hi}$, let $y = (y_{11}, \ldots, y_{1n_1}, \ldots, y_{H1}, \ldots, y_{Hn_H})'$, $X_h = (x_{h1} \ldots x_{hn_h})'$, and $X = (X_1' \ldots X_H')'$. Let the dummy variables $z_h, h = 1, \ldots, H$, be indicator
functions for the strata \((z_h = 1\) if the observation is in stratum \(h)\), denote \(z_{hi} = (z_1, \ldots, z_H)\) for observation \(hi\), \(Z_h = (z_{h1} \ldots z_{hn_h})'\), and \(Z = (Z_1' \ldots Z_H')'\). Denote \(X^* = (Z|X)\) and \(x_{hi}' = (z_{hi}'|x_{hi}')'\). Arrange the observations in each stratum \(h\) so that \(y_{hi} = 1\) for \(i = 1, \ldots, m_h\), and \(y_{hi} = 0\) for \(i = m_{h+1}, \ldots, n_h\). Suppose all observations have unit frequency.

Consider the binary logistic regression model on page 2405 written as

\[
\logit(\pi) = X^* \theta
\]

where the parameter vector \(\theta = (\alpha', \beta')'\) consists of \(\alpha = (\alpha_1, \ldots, \alpha_H)'\), \(\alpha_h\) is the intercept for stratum \(h, h = 1, \ldots, H\), and \(\beta\) is the parameter vector for the \(p\) covariates.

From the “Determining Observations for Likelihood Contributions” section on page 2336, you can write the likelihood contribution of observation \(hi, i = 1, \ldots, n_h, h = 1, \ldots, H\), as

\[
L_{hi}(\theta) = \frac{e^{y_{hi}x_{hi}'\theta}}{1 + e^{x_{hi}'\theta}}
\]

where \(y_{hi} = 1\) when the response takes Ordered Value 1, and \(y_{hi} = 0\) otherwise.

The full likelihood is

\[
L(\theta) = \prod_{h=1}^{H} \prod_{i=1}^{n_h} L_{hi}(\theta) = \frac{e^{y'X^*\theta}}{\prod_{h=1}^{H} \prod_{i=1}^{n_h} \left(1 + e^{x_{hi}'\theta}\right)}
\]

Unconditional likelihood inference is based on maximizing this likelihood function.

When your nuisance parameters are the stratum-specific intercepts \((\alpha_1, \ldots, \alpha_H)'\), and \(\beta\) are your parameters of interest, “conditioning out” the nuisance parameters produces the following conditional likelihood (Lachin 2000)

\[
L(\beta) = \prod_{h=1}^{H} L_h(\beta) = \prod_{h=1}^{H} \frac{\prod_{i=1}^{n_h} \exp(x_{hi}'\beta)}{\sum_{j=1}^{m_h} \prod_{j'=j}^{m_h} \exp(x_{hj}'\beta)}
\]

where the summation is over all \(\binom{n_h}{m_h}\) subsets \(\{j_1, \ldots, j_{m_h}\}\) of \(m_h\) observations chosen from the \(n_h\) observations in stratum \(h\). Note that the nuisance parameters have been factored out of this equation.

For conditional asymptotic inference, maximum likelihood estimates \(\hat{\beta}\) of the regression parameters are obtained by maximizing the conditional likelihood, and asymptotic results are applied to the conditional likelihood function and the maximum likelihood estimators. A relatively fast method for computing this conditional likelihood and its derivatives is given by Gail, Lubin, and Rubinstein (1981) and Howard (1972). The default optimization techniques, which are the same as those implemented by the NLP procedure in SAS/OR software, are
Conditional Logistic Regression

- Newton-Raphson with ridging when the number of parameters $p < 40$
- quasi-Newton when $40 \leq p < 400$
- conjugate gradient when $p \geq 400$

Sometimes the log likelihood converges but the estimates diverge. This condition is flagged by having inordinately large standard errors for some of your parameter estimates, and can be monitored by specifying the ITPRINT option. Unfortunately, broad existence criteria such as those discussed in the “Existence of Maximum Likelihood Estimates” section on page 2338 do not exist for this model. It may be possible to circumvent such a problem by standardizing your independent variables before fitting the model.

Regression Diagnostic Details

Diagnostics are used to indicate observations that may have undue influence on the model fit, or which may be outliers. Further investigation should be performed before removing such an observation from the data set.

The derivations in this section follow Storer and Crowley’s (1985) method of augmenting the logistic regression model, which provides an estimate of the “one-step” DFBETAS estimates advocated by Pregibon (1984). The method also provides estimates of conditional stratum-specific predicted values, residuals, and leverage for each observation.

Following Storer and Crowley (1985), the log-likelihood contribution can be written as

$$ l_h = \log(L_h) = y_h' \gamma_h - a(\gamma_h) \quad \text{where} $$

$$ a(\gamma_h) = \log \left[ \sum_{j=j_1}^{j_{m_h}} \prod_{j=1}^j \exp(\gamma_{hj}) \right] $$

and the $h$ subscript on matrices indicates the submatrix for the stratum, $\gamma_h' = (\gamma_{h1}, \ldots, \gamma_{hn_h})$, and $\gamma_{hi} = x_{hi}' \beta$. Then the gradient and information matrix are

$$ g(\beta) = \left\{ \frac{\partial l_h}{\partial \beta} \right\}^H_{h=1} = X'(y - \pi) $$

$$ \Lambda(\beta) = \left\{ \frac{\partial^2 l_h}{\partial \beta^2} \right\}^H_{h=1} = X' \text{diag}(U_1, \ldots, U_H)X $$

where

$$ \pi_{hi} = \frac{\partial a(\gamma_h)}{\partial \gamma_{hi}} = \frac{\sum_{j(i)} \prod_{j=j_1}^{j_{m_h}} \exp(\gamma_{hj})}{\sum \prod_{j=j_1}^{j_{m_h}} \exp(\gamma_{hj})} $$

$$ \pi_h = (\pi_{h1}, \ldots, \pi_{hn_h}) $$
\[ \mathbf{U}_h = \frac{\partial^2 a(\gamma_h)}{\partial \gamma_h^2} = \left\{ \frac{\partial^2 a(\gamma_h)}{\partial \gamma_{hi} \partial \gamma_{hj}} \right\} = \{ a_{ij} \} \]

\[ a_{ij} = \frac{\sum_{k(i,j)} \prod_{k=m_h}^{k_{m_h}} \exp(\gamma_{hk})}{\sum \prod_{k=m_h}^{k_{m_h}} \exp(\gamma_{hk})} - \frac{\partial a(\gamma_h) \partial a(\gamma_h)}{\partial \gamma_{hi} \partial \gamma_{hj}} = \pi_{hi} - \pi_{hi} \pi_{hj} \]

where \( \pi_{hi} \) is the conditional stratum-specific probability that subject \( i \) in stratum \( h \) is a case, the summation on \( j(i) \) is over all subsets from \( \{1, \ldots, n_h\} \) of size \( m_h \) that contain the index \( i \), and the summation on \( k(i, j) \) is over all subsets from \( \{1, \ldots, n_h\} \) of size \( m_h \) that contain the indices \( i \) and \( j \).

To produce the true one-step estimate \( \beta^1_{hi} \), start at the MLE \( \hat{\beta} \), delete the \( h \)th observation, and take one-step of the Newton-Raphson algorithm using the reduced data set. Note that if there is only one event or one nonevent in a stratum, deletion of that single observation is equivalent to deletion of the entire stratum. The augmentation method does not take this into account.

The augmented model is

\[ \logit(Pr(y_{hi} = 1|x_{hi})) = \mathbf{x}'_{hi} \beta + \mathbf{z}'_{hi} \gamma \]

where \( \mathbf{z}_{hi} = (0, \ldots, 0, 1, 0, \ldots, 0)' \) has a 1 in the \( h \)th coordinate, and use \( \beta^0 = (\hat{\beta}, 0)' \) as the initial estimate for \( (\beta, \gamma)' \). The gradient and information matrix before the step are

\[ \mathbf{g}(\beta^0) = \left[ \begin{array}{c} \mathbf{x}'_{hi} \\ \mathbf{z}'_{hi} \end{array} \right] (\mathbf{y} - \pi) = \left[ \begin{array}{c} 0 \\ y_{hi} - \pi_{hi} \end{array} \right] \]

\[ \Lambda(\beta^0) = \left[ \begin{array}{c} \mathbf{x}'_{hi} \\ \mathbf{z}'_{hi} \end{array} \right] \mathbf{U} [\mathbf{x}_{hi} \mid \mathbf{z}_{hi}] = \left[ \begin{array}{c} \Lambda(\beta) \\ \mathbf{z}'_{hi} \mathbf{U} \mathbf{x} \\ \mathbf{z}'_{hi} \mathbf{U} \mathbf{z}_{hi} \end{array} \right] \]

Inserting the \( \beta^0 \) and \( (\mathbf{x}', \mathbf{z}'_{hi})' \) into the Gail, Lubin, and Rubinstein (1981) algorithm provides the appropriate estimates of \( \mathbf{g}(\beta^0) \) and \( \Lambda(\beta^0) \). Indicate these estimates with \( \tilde{\pi} = \pi(\tilde{\beta}), \tilde{\mathbf{U}} = \mathbf{U}(\tilde{\beta}), \tilde{\mathbf{g}}, \text{ and } \tilde{\Lambda} \).

DFBETA is computed from the information matrix as

\[ \Delta_{hi} \beta = \beta^0 - \beta^1_{hi} \]

\[ = -\tilde{\Lambda}^{-1} (\beta^0) \tilde{\mathbf{g}}(\beta^0) \]

\[ = -\tilde{\Lambda}^{-1} (\beta) (\mathbf{x}' \tilde{\mathbf{U}} \mathbf{z}_{hi}) \mathbf{M}^{-1} \mathbf{z}'_{hi} (\mathbf{y} - \tilde{\pi}) \quad \text{where} \]

\[ \mathbf{M} = (\mathbf{z}'_{hi} \tilde{\mathbf{U}} \mathbf{z}_{hi}) - (\mathbf{z}'_{hi} \tilde{\mathbf{U}} \mathbf{x}) \tilde{\Lambda}^{-1} (\beta) (\mathbf{x}' \tilde{\mathbf{U}} \mathbf{z}_{hi}) \]

For each observation in the dataset, a DFBETA statistic is computed for each parameter \( \beta_j, 1 \leq j \leq p \), and standardized by the standard error of \( \beta_j \) from the full data set to produce the estimate of DFBETAS.
The estimated residuals \( e_{hi} = y_{hi} - \hat{\pi}_{hi} \) are obtained from \( \hat{g}(\beta^0) \), and the weights, or predicted probabilities, are then \( \hat{\pi}_{hi} = y_{hi} - e_{hi} \). The residuals are standardized and reported as (estimated) Pearson residuals:

\[
\frac{r_{hi} - n_{hi}\hat{\pi}_{hi}}{\sqrt{n_{hi}\hat{\pi}_{hi}(1 - \hat{\pi}_{hi})}}
\]

where \( r_{hi} \) is the number of events in the observation and \( n_{hi} \) is the number of trials.

The estimated leverage is defined as

\[
h_{hi} = \frac{\text{trace}\{(z'_{hi}\hat{U}X\hat{\Lambda}\}^{-1}\beta)(X'\hat{U}z_{hi}\}}{\text{trace}\{z'_{hi}\hat{U}z_{hi}\}}
\]

This definition of leverage produces different values from those defined by Pregibon (1984), Moolgavkar, Lustbader, and Venzon (1985), and Hosmer and Lemeshow (2000); however, it has the advantage that no extra computations beyond those for the DFBETAS are required.

For events/trials MODEL syntax, treat each observation as two observations (the first for the nonevents and the second for the events) with frequencies \( f_{h,2i-1} = n_{hi} - r_{hi} \) and \( f_{h,2i} = r_{hi} \), and augment the model with a matrix \( Z_{hi} = [z'_{h,2i-1}z_{h,2i}] \) instead of a single \( z_{hi} \) vector. Writing \( \gamma_{hi} = x'_{hi}\beta f_{hi} \) in the preceding section results in the following gradient and information matrix.

\[
\begin{bmatrix}
0 \\
\hat{f}_{h,2i-1}(y_{h,2i-1} - \pi_{h,2i-1}) \\
\hat{f}_{h,2i}(y_{h,2i} - \pi_{h,2i})
\end{bmatrix}
\]

\[
\Lambda(\beta^0) = \begin{bmatrix}
\Lambda(\beta) & X'\text{diag}(f)U\text{diag}(f)Z_{hi} \\
Z'_{hi}\text{diag}(f)U\text{diag}(f)X & Z'_{hi}\text{diag}(f)U\text{diag}(f)Z_{hi}
\end{bmatrix}
\]

The predicted probabilities are then \( \hat{\pi}_{hi} = y_{h,2i} - e_{h,2i}/r_{h,2i} \), while the leverage and the DFBETAs are produced from \( \Lambda(\beta^0) \) in a similar fashion as for the preceding single-trial equations.

**Exact Conditional Logistic Regression**

The theory of exact conditional logistic regression analysis was originally laid out by Cox (1970), and the computational methods employed in PROC LOGISTIC are described in Hirji, Mehta, and Patel (1987), Hirji (1992), and Mehta, Patel, and Senchaudhuri (1992). Other useful references for the derivations include Cox and Snell (1989), Agresti (1990), and Mehta and Patel (1995).

Exact conditional inference is based on generating the conditional distribution for the sufficient statistics of the parameters of interest. This distribution is called the permutation or exact conditional distribution. Using the notation in the “Computational
Details” section on page 2365, follow Mehta and Patel (1995) and first note that the sufficient statistics $T = (T_1, \ldots, T_p)$ for $\theta$ are

$$T_j = \sum_{i=1}^{n} y_i x_{ij}, \quad j = 1, \ldots, p$$

Denote a vector of observable sufficient statistics as $t = (t_1, \ldots, t_p)'$.

The probability density function (pdf) for $T$ can be created by summing over all binary sequences $y$ that generate an observable $t$ and letting $C(t) = ||\{y : y'X = t\}||$ denote the number of sequences $y$ that generate $t$

$$Pr(T = t) = \frac{C(t)\exp(t'\theta)}{\prod_{i=1}^{p} [1 + \exp(x_i'\theta)]}$$

In order to condition out the stratum parameters, partition the parameter vector $\theta = (\theta_0', \theta_1')'$, where $\theta_0$ is a $p_0 \times 1$ vector of the nuisance parameters, and $\theta_1$ is the parameter vector for the remaining $p_1 = p - p_0$ parameters of interest. Likewise, partition $X$ into $X_0$ and $X_1$, $T$ into $T_0$ and $T_1$, and $t$ into $t_0$ and $t_1$. The nuisance parameters can be removed from the analysis by conditioning on their sufficient statistics to create the conditional likelihood of $T_1$ given $T_0 = t_0$

$$Pr(T_1 = t_1|T_0 = t_0) = \frac{Pr(T = t)}{Pr(T_0 = t_0)} = f_{\theta_1}(t_1|t_0) = \frac{C(t_0, t_1)\exp(t_1'\theta_1)}{\sum_u C(t_0, u)\exp(u'\theta_1)}$$

where $C(t_0, u)$ is the number of vectors $y$ such that $y'X_0 = t_0$ and $y'X_1 = u$. Note that the nuisance parameters have factored out of this equation, and that $C(t_0, t_1)$ is a constant.

The goal of the exact conditional analysis is to determine how likely the observed response $y_0$ is with respect to all $2^n$ possible responses $y = (y_1, \ldots, y_n)'$. One way to proceed is to generate every $y$ vector for which $y'X_0 = t_0$, and count the number of vectors $y$ for which $y'X_1$ is equal to each unique $t_1$. Generating the conditional distribution from complete enumeration of the joint distribution is conceptually simple; however, this method becomes computationally infeasible very quickly. For example, if you had only 30 observations, you’d have to scan through $2^{30}$ different $y$ vectors.

Several algorithms are available in PROC LOGISTIC to generate the exact distribution. All of the algorithms are based on the following observation. Given any $y = (y_1, \ldots, y_n)'$ and a design $X = (x_1, \ldots, x_n)'$, let $y_{(i)} = (y_1, \ldots, y_i)'$ and $X_{(i)} = (x_1, \ldots, x_i)'$ be the first $i$ rows of each matrix. Write the sufficient statistic based on these $i$ rows as $t_{(i)}' = y_{(i)}'X_{(i)}$. A recursion relation results: $t_{(i+1)} = t_{(i)} + y_{i+1}x_{i+1}$.
The following methods are available.

- The multivariate shift algorithm developed by Hirji, Mehta, and Patel (1987) steps through the recursion relation by adding one observation at a time and building an intermediate distribution at each step. If it determines that \( t(i) \) for the nuisance parameters could eventually equal \( t \), then \( t(i) \) is added to the intermediate distribution.

- Hirji (1992) extends the multivariate shift algorithm to generalized logit models. Since the generalized logit model fits a new set of parameters to each logit, the number of parameters in the model can easily get too large for this algorithm to handle. Note for these models that the hypothesis tests for each effect are computed across the logit functions, while individual parameters are estimated for each logit function.

- A network algorithm described in Mehta, Patel, and Senchaudhuri (1992) builds a network for each parameter that you are conditioning out in order to identify feasible \( y_i \) for the \( y \) vector. These networks are combined and the set of feasible \( y_i \) is further reduced, then the multivariate shift algorithm uses this knowledge to build the exact distribution without adding as many intermediate \( t(i+1) \) as the multivariate shift algorithm does.

- Mehta, Patel, and Senchaudhuri (2000) devised a hybrid Monte-Carlo and network algorithm that extends their 1992 algorithm by sampling from the combined network to build the exact distribution.

The bulk of the computation time and memory for these algorithms is consumed by the creation of the networks and the exact joint distribution. After the joint distribution for a set of effects is created, the computational effort required to produce hypothesis tests and parameter estimates for any subset of the effects is (relatively) trivial.

**Hypothesis Tests**

Consider testing the null hypothesis \( H_0: \beta_1 = 0 \) against the alternative \( H_A: \beta_1 \neq 0 \), conditional on \( T_0 = t_0 \). Under the null hypothesis, the test statistic for the exact probability test is just \( f_{\beta_1=0}(t_1|t_0) \), while the corresponding \( p \)-value is the probability of getting a less likely (more extreme) statistic,

\[
p(t_1|t_0) = \sum_{u \in \Omega_p} f_0(u|t_0)
\]

where \( \Omega_p = \{ u: \text{there exist } y \text{ with } y'X_1 = u, y'X_0 = t_0, \text{ and } f_0(u|t_0) \leq f_0(t_1|t_0) \} \).

For the exact conditional scores test, the conditional mean \( \mu_1 \) and variance matrix \( \Sigma_1 \) of the \( T_1 \) (conditional on \( T_0 = t_0 \)) are calculated, and the score statistic for the observed value,

\[
s = (t_1 - \mu_1)' \Sigma_1^{-1} (t_1 - \mu_1)
\]
is compared to the score for each member of the distribution

\[
S(T_1) = (T_1 - \mu_1)'\Sigma^{-1}_1(T_1 - \mu_1)
\]

The resulting \(p\)-value is

\[
p(t_1|t_0) = Pr(S \geq s) = \sum_{u \in \Omega_s} f_0(u|t_0)
\]

where \(\Omega_s = \{u: \text{there exist } y \text{ with } y'X_1 = u, y'X_0 = t_0, \text{ and } S(u) \geq s\}\).

The mid-\(p\) statistic, defined as

\[
p(t_1|t_0) - \frac{1}{2} f_0(t_1|t_0)
\]

was proposed by Lancaster (1961) to compensate for the discreteness of a distribution. Refer to Agresti (1992) for more information. However, to allow for more flexibility in handling ties, you can write the mid-\(p\) statistic as (based on a suggestion by LaMotte 2002 and generalizing Volset, Hirji, and Afifi 1991)

\[
\sum_{u \in \Omega_\prec} f_0(u|t_0) + \delta_1 f_0(t_1|t_0) + \delta_2 \sum_{u \in \Omega_=} f_0(u|t_0)
\]

where, for \(i \in \{p, s\}\), \(\Omega_\prec\) is \(\Omega_i\) using strict inequalities, and \(\Omega_=\) is \(\Omega_i\) using equalities with the added restriction that \(u \neq t_1\). Letting \((\delta_1, \delta_2) = (0.5, 1.0)\) yields Lancaster’s mid-\(p\).

**Caution:** When the exact distribution has ties and METHOD=NETWORKMC is specified, the Monte Carlo algorithm estimates \(p(t|t_0)\) with error, and hence it cannot determine precisely which values contribute to the reported \(p\)-values. For example, if the exact distribution has densities \(\{0.2, 0.2, 0.2, 0.4\}\) and if the observed statistic has probability 0.2, then the exact probability \(p\)-value is exactly 0.6. Under Monte Carlo sampling, if the densities after \(N\) samples are \(\{0.18, 0.21, 0.23, 0.38\}\) and the observed probability is 0.21, then the resulting \(p\)-value is 0.39. Therefore, the exact probability test \(p\)-value for this example fluctuates between 0.2, 0.4, and 0.6, and the reported \(p\)-values are actually lower bounds for the true \(p\)-values. If you need more precise values, you can specify the OUTDIST= option, determine appropriate cutoff values for the observed probability and score, then construct the true \(p\)-value estimates from the OUTDIST= data set using the following statements.

```plaintext
data _null_
  set outdist end=end;
  retain pvalueProb 0 pvalueScore 0;
  if prob < ProbCutOff then pvalueProb+prob;
  if score > ScoreCutOff then pvalueScore+prob;
  if end then put pvalueProb pvalueScore;
run;
```
Inference for a Single Parameter

Exact parameter estimates are derived for a single parameter $\beta_i$ by regarding all the other parameters $\beta_0 = (\beta_1, \ldots, \beta_{i-1}, \beta_{i+1}, \ldots, \beta_{p+q})'$ as nuisance parameters. The appropriate sufficient statistics are $T_1 = T_i$ and $T_0 = (T_1, \ldots, T_{i-1}, T_{i+1}, \ldots, T_{p+q})'$, with their observed values denoted by the lowercase $t$. Hence, the conditional pdf used to create the parameter estimate for $\beta_i$ is

$$f_{\beta_i}(t_i|t_0) = \frac{C(t_0, t_i) \exp(t_i\beta_i)}{\sum_{u \in \Omega} C(t_0, u) \exp(u\beta_i)}$$

for $\Omega = \{u: \text{there exist } y \text{ with } T_i = u \text{ and } T_0 = t_0\}$.

The maximum exact conditional likelihood estimate is the quantity $\hat{\beta}_i$, which maximizes the conditional pdf. A Newton-Raphson algorithm is used to perform this search. However, if the observed $t_i$ attains either its maximum or minimum value in the exact distribution (that is, either $t_i = \min\{u : u \in \Omega\}$ or $t_i = \max\{u : u \in \Omega\}$), then the conditional pdf is monotonically increasing in $\beta_i$ and cannot be maximized. In this case, a median unbiased estimate (Hirji, Tsiatis, and Mehta 1989) $\hat{\beta}_i$ is produced that satisfies $f_{\beta_i}(t_i|t_0) = 0.5$, and a Newton-Raphson-type algorithm is used to perform the search.

Likelihood ratio tests based on the conditional pdf are used to test the null $H_0: \beta_i = 0$ against the alternative $H_A: \beta_i > 0$. The critical region for this UMP test consists of the upper tail of values for $T_i$ in the exact distribution. Thus, the one-sided significance level $p_{+}(t_i; 0)$ is

$$p_{+}(t_i; 0) = \sum_{u \geq t_i} f_0(u|t_0)$$

Similarly, the one-sided significance level $p_{-}(t_i; 0)$ against $H_A: \beta_i < 0$ is

$$p_{-}(t_i; 0) = \sum_{u \leq t_i} f_0(u|t_0)$$

The two-sided significance level $p(t_i; 0)$ against $H_A: \beta_i \neq 0$ is calculated as

$$p(t_i; 0) = 2 \min[p_{-}(t_i; 0), p_{+}(t_i; 0)]$$

An upper $100(1 - 2\epsilon)$% exact confidence limit for $\hat{\beta}_i$ corresponding to the observed $t_i$ is the solution $\beta_U(t_i)$ of $\epsilon = p_{-}(t_i, \beta_U(t_i))$, while the lower exact confidence limit is the solution $\beta_L(t_i)$ of $\epsilon = p_{+}(t_i, \beta_L(t_i))$. Again, a Newton-Raphson procedure is used to search for the solutions.

Specifying the ONESIDED option displays only one $p$-value and one confidence interval, because small values of $p_{+}(t_i; 0)$ and $p_{-}(t_i; 0)$ support different alternative hypotheses and only one of these $p$-values can be less than 0.50.
The mid-p confidence limits are the solutions to \( \min \{ p(t_i, \beta(t_i)), p+(t_i, \beta(t_i)) \} - (1 - \delta_1) f_{\beta(t_i)}(u|t_0) = \epsilon \) for \( \epsilon = \alpha/2, 1 - \alpha/2 \) (Vollset, Hirji, and Afifi 1991). \( \delta_1 = 1 \) produces the usual exact (or \( \text{max-p} \)) confidence interval, \( \delta_1 = 0.5 \) yields the mid-p interval, and \( \delta_1 = 0 \) gives the \( \text{min-p} \) interval. The mean of the endpoints of the \( \text{max-p} \) and \( \text{min-p} \) intervals provides the \( \text{mean-p} \) interval as defined by Hirji, Mehta, and Patel (1988).

Estimates and confidence intervals for the odds-ratios are produced by exponentiating the estimates and interval endpoints for the parameters.

### OUTEST= Output Data Set

The OUTEST= data set contains one observation for each BY group containing the maximum likelihood estimates of the regression coefficients. If you also use the COVOUT option in the PROC LOGISTIC statement, there are additional observations containing the rows of the estimated covariance matrix. If you use the FORWARD, BACKWARD, or STEPWISE selection method, only the estimates of the parameters and covariance matrix for the final model are output to the OUTEST= data set.

#### Variables in the OUTEST= Data Set

The OUTEST= data set contains the following variables:

- any BY variables specified
- _LINK_, a character variable of length 8 with four possible values: CLOGLOG for the complementary log-log function, LOGIT for the logit function, NORMIT for the probit (alias normit) function, and GLOGIT for the generalized logit function.
- _TYPE_, a character variable of length 8 with two possible values: PARMS for parameter estimates or COV for covariance estimates. If an EXACT statement is also specified, then two other values are possible: EPARMMLE for the exact maximum likelihood estimates and EPARMMUE for the exact median unbiased estimates.
- _NAME_, a character variable containing the name of the response variable when _TYPE_=PARMS, EPARMMLE, and EPARMMUE, or the name of a model parameter when _TYPE_=COV
- _STATUS_, a character variable that indicates whether the estimates have converged
- one variable for each intercept parameter
- one variable for each slope parameter and one variable for the offset variable if the OFFSET= option if specified. If an effect is not included in the final model in a model building process, the corresponding parameter estimates and covariances are set to missing values.
- _LNLIKE_, the log likelihood
Parameter Names in the OUTEST= Data Set

If there are only two response categories in the entire data set, the intercept parameter is named Intercept. If there are more than two response categories in the entire data set, the intercept parameters are named Intercept–xxx, where xxx is the value (formatted if a format is applied) of the corresponding response category.

For continuous explanatory variables, the names of the parameters are the same as the corresponding variables. For class variables, the parameter names are obtained by concatenating the corresponding CLASS variable name with the CLASS category; see the PARAM= option in the CLASS statement and the “CLASS Variable Parameterization” section on page 2331 for more details. For interaction and nested effects, the parameter names are created by concatenating the names of each effect.

For the generalized logit model, names of parameters corresponding to each nonreference category contain _xxx as the suffix, where xxx is the value (formatted if a format is applied) of the corresponding nonreference category. For example, suppose the variable Net3 represents the television network (ABC, CBS, and NBC) viewed at a certain time. The following code fits a generalized logit model with Age and Gender (a CLASS variable with values Female and Male) as explanatory variables.

```
proc logistic;
  class Gender;
  model Net3 = Age Gender / link=glogit;
run;
```

There are two logit functions, one contrasting ABC with NBC and the other contrasting CBS with NBC. For each logit, there are three parameters: an intercept parameter, a slope parameter for Age, and a slope parameter for Gender (since there are only two gender levels and the EFFECT parameterization is used by default). The names of the parameters and their descriptions are as follows.

<table>
<thead>

</table>
INEST= Input Data Set

You can specify starting values for the iterative algorithm in the INEST= data set. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set.

The INEST= data set must contain the intercept variables (named Intercept for binary response models and Intercept, Intercept2, Intercept3, and so forth, for ordinal and nominal response models) and all explanatory variables in the MODEL statement. If BY processing is used, the INEST= data set should also include the BY variables, and there must be one observation for each BY group. If the INEST= data set also contains the _TYPE_ variable, only observations with _TYPE_ value ‘PARMS’ are used as starting values.

OUT= Output Data Set in the OUTPUT Statement

The OUT= data set in the OUTPUT statement contains all the variables in the input data set along with statistics you request using keyword=name options or the PREDPROBS= option in the OUTPUT statement. In addition, if you use the single-trial syntax and you request any of the XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= options, the OUT= data set contains the automatic variable _LEVEL_. The value of _LEVEL_ identifies the response category upon which the computed values of XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= are based.

When there are more than two response levels, only variables named by the XBETA=, STDXBETA=, PREDICTED=, LOWER=, and UPPER= options and the variables given by PREDPROBS=(INDIVIDUAL CUMULATIVE) have their values computed; the other variables have missing values. If you fit a generalized logit model, the cumulative predicted probabilities are not computed.

When there are only two response categories, each input observation produces one observation in the OUT= data set.

If there are more than two response categories and you only specify the PREDPROBS= option, then each input observation produces one observation in the OUT= data set. However, if you fit an ordinal (cumulative) model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as one fewer than the number of response levels, and the predicted probabilities and their confidence limits correspond to the cumulative predicted probabilities. If you fit a generalized logit model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as the number of response categories; the predicted probabilities and their confidence limits correspond to the probabilities of individual response categories.

For observations in which only the response variable is missing, values of the XBETA=, STDXBETA=, PREDICTED=, UPPER=, LOWER=, and the PREDPROBS= options are computed even though these observations do not affect the model fit. This enables, for instance, predicted probabilities to be computed for new observations.
OUT= Output Data Set in a SCORE Statement

The OUT= data set in a SCORE statement contains all the variables in the data set being scored. The data set being scored can be either the input DATA= data set in the PROC LOGISTIC statement or the DATA= data set in the SCORE statement. The DATA= data set in the SCORE statement may not contain a response variable.

If the data set being scored contains a response variable, then denote the normalized levels (left justified formatted values of 16 characters or less) of your response variable Y by Y\(_1\), ..., Y\(_{k+1}\). For each response level, the OUT= data set also contains:

- F\(_{-Y}\), the normalized levels of the response variable Y in the data set being scored. If the events/trials syntax is used, the F\(_{-Y}\) variable is not created.
- I\(_{-Y}\), the normalized levels that the observations are classified into. Note that an observation is classified into the level with the largest probability. If the events/trials syntax is used, the _INTO_ variable is created instead and it contains the values EVENT and NONEVENT.
- P\(_{-Y}\)_\(_i\), the posterior probabilities of the normalized response level Y\(_i\).
- If the CLM option is specified in the SCORE statement, the OUT= data set also includes:
  - LCL\(_{-Y}\)_\(_i\), the lower 100(1-\(\alpha\))% confidence limits for P\(_{-Y}\)_\(_i\)
  - UCL\(_{-Y}\)_\(_i\), the upper 100(1-\(\alpha\))% confidence limits for P\(_{-Y}\)_\(_i\)

OUTDIST= Output Data Set

The OUTDIST= data set contains every exact conditional distribution necessary to process the EXACT statement. For example, the following statements create one distribution for the x1 parameter and another for the x2 parameters, and produces the data set dist shown in Figure 42.7:

```
proc logistic;
  class x2 / param=ref;
  model y=x1 x2;
  exact x1 x2/ outdist=dist;
proc print data=dist;
run;
```
Figure 42.7. OUTDIST

The first nine observations in the dist data set contain an exact distribution for the parameters of the x2 effect (hence the values for the x1 parameter are missing), and the remaining five observations are for the x1 parameter. If a joint distribution was created, there would be observations with values for both the x1 and x2 parameters. For CLASS variables, the corresponding parameters in the dist data set are identified by concatenating the variable name with the appropriate classification level.

The data set contains the possible sufficient statistics of the parameters for the effects specified in the EXACT statement, and the Count variable contains the number of different responses that yield these statistics. For example, there were 6 possible response vectors y for which the dot product $y'x_1$ was equal to 2, and for which $y'x_{20}$, $y'x_{21}$, and $y'1$ were equal to their actual observed values (displayed in the “Sufficient Statistics” table). When hypothesis tests are performed on the parameters, the Prob variable contains the probability of obtaining that statistic (which is just the count divided by the total count), and the Score variable contains the score for that statistic. For more information, see the section “EXACT Statement Examples” on page 2302.

OUTROC= Output Data Set

The OUTROC= data set contains data necessary for producing the ROC curve, and can be created by specifying the OUTROC= option in the MODEL statement or the OUTROC= option in the SCORE statement: It has the following variables:

- any BY variables specified
- _STEP_, the model step number. This variable is not included if model selection is not requested.
- _PROB_, the estimated probability of an event. These estimated probabilities serve as cutpoints for predicting the response. Any observation with an estimated event probability that exceeds or equals _PROB_ is predicted to be an event; otherwise, it is predicted to be a nonevent. Predicted probabilities
that are close to each other are grouped together, with the maximum allowable
difference between the largest and smallest values less than a constant that is
specified by the ROCEPS= option. The smallest estimated probability is used
to represent the group.

- _POS_, the number of correctly predicted event responses
- _NEG_, the number of correctly predicted nonevent responses
- _FALPOS_, the number of falsely predicted event responses
- _FALNEG_, the number of falsely predicted nonevent responses
- _SENSIT_, the sensitivity, which is the proportion of event observations that
  were predicted to have an event response
- _1MSPEC_, one minus specificity, which is the proportion of nonevent ob-
  servations that were predicted to have an event response

Note that none of these statistics are affected by the bias-correction method discussed
in the “Classification Table” section on page 2352. An ROC curve is obtained by
plotting _SENSIT_ against _1MSPEC_. For more information, see the section
“Receiver Operating Characteristic Curves” on page 2357.

**Computational Resources**

The memory needed to fit an unconditional model is approximately $24(p + 2)^2$ bytes,
where $p$ is the number of parameters estimated. For cumulative response models
with more than two response levels, a test of the parallel lines assumption requires an
additional memory of approximately $4k^2(m + 1)^2 + 24(m + 2)^2$ bytes, where $k$ is the
number of response levels and $m$ is the number of slope parameters. However, if this
additional memory is not available, the procedure skips the test and finishes the other
computations. You may need more memory if you use the SELECTION= option for
model building.

The data that consist of relevant variables (including the design variables for model
effects) and observations for fitting the model are stored in the utility file. If sufficient
memory is available, such data will also be kept in memory; otherwise, the data
are reread from the utility file for each evaluation of the likelihood function and its
derivatives, with the resulting execution time of the procedure substantially increased.

If a conditional logistic regression is performed, then approximately

$$4(m^2 + m + 4) \max_h(m_h) + (8s_H + 36)H + 12s_H$$

additional bytes of memory are needed, where $m_h$ is the number of events in stratum $h$, $H$ is the total number of strata, and $s_H$ is
the number of variables used to define the strata.

**Computational Resources for Exact Conditional Logistic Regression**

Many problems require a prohibitive amount of time and memory for exact computa-
tions, depending on the speed and memory available on your computer. For such
problems, consider whether exact methods are really necessary. Stokes, Davis, and
Koch (2000) suggest looking at exact $p$-values when the sample size is small and the
approximate $p$-values from the unconditional analysis are less than 0.10, and they
provide rules of thumb for determining when various models are valid.
A formula does not exist that can predict the amount of time and memory necessary to generate the exact conditional distributions for a particular problem. The time and memory required depends on several factors, including the total sample size, the number of parameters of interest, the number of nuisance parameters, and the order in which the parameters are processed. To provide a feel for how these factors affect performance, 19 data sets containing \( N_{\text{obs}} \in \{10, \ldots , 500\} \) observations consisting of up to 10 independent uniform binary covariates (\( X_1, \ldots , X_N \)) and a binary response variable (\( Y \)), are generated and exact conditional distributions are created for \( X_1 \) conditional on the other covariates using the default METHOD=NETWORK. Figure 42.8 displays results obtained on a 400Mhz PC with 768MB RAM running Microsoft Windows NT.

```plaintext
data one;
  do obs=1 to HalfNobs;
    do Y=0 to 1;
      X1=round(ranuni(0));
      ...
      XN=round(ranuni(0));
      output;
    end;
  end;
options fullstimer;
proc logistic exactonly exactoptions(method=network maxtime=1200);
  class X1 ... XN / param=ref;
  model Y=X1 ... XN;
  exact X1 / outdist=dist;
run;
```

![Figure 42.8. Mean Time and Memory Required](image)
At any time while PROC LOGISTIC is deriving the distributions, you can terminate the computations by pressing the system interrupt key sequence (refer to the SAS Companion for your system) and choosing to stop computations. If you run out of memory, refer to the SAS Companion for your system to see how to allocate more.

You can use the EXACTOPTIONS option `MAXTIME=` to limit the total amount of time PROC LOGISTIC uses to derive all of the exact distributions. If PROC LOGISTIC does not finish within that time, the procedure terminates.

Calculation of frequencies are performed in the log-scale by default. This reduces the need to check for excessively large frequencies but can be slower than not scaling. You can turn off the log-scaling by specifying the `NOLOGSCALE` option in the `MODEL` statement. If a frequency in the exact distribution is larger than the largest integer that can be held in double-precision, a warning is printed to the LOG, but since inaccuracies due to adding small numbers to these large frequencies may have little-or-no effect on the statistics, the exact computations continue.

You can monitor the progress of the procedure by submitting your program with the `EXACTOPTIONS` option `STATUSTIME=`. If the procedure is too slow, you can try another method by specifying the `EXACTOPTIONS` option `METHOD=`, you can try reordering the variables in the `MODEL` statement (note that CLASS variables are always processed before continuous covariates), or you can try reparameterizing your classification variables, for example:

```plaintext
class class-variables / param=ref ref=first order=freq;
```

**Displayed Output**

If you use the NOPRINT option in the PROC LOGISTIC statement, the procedure does not display any output. Otherwise, the displayed output of the LOGISTIC procedure includes the following:

- “Model Information” table, which gives
  - name of the input Data Set
  - name and label of the Response Variable, if the `single-trial` syntax is used
  - number of Response Levels, if the `single-trial` syntax is used
  - name of the Events Variable, if the `events/trials` syntax is used
  - name of the Trials Variable, if the `events/trials` syntax is used
  - name of the Offset Variable, if the `OFFSET=` option is specified
  - name of the Frequency Variable, if the `FREQ` statement is specified
  - name of the Weight Variable, if the `WEIGHT` statement is specified
  - Number of Strata, if the `STRATA` statement is specified
  - Number of Strata Ignored and the total Frequency Ignored, if the `STRATA` statement is specified and at least one stratum has no events or no nonevents
  - Link Function
- Optimization Technique
- seed, if METHOD=NETWORKMC is specified

- “Number of Observations” table, which gives
  - Number of Observations read from the input data set
  - Number of Observations used in the analysis
  - Sum of Frequencies of all the observations read from the input data set
  - Sum of Frequencies of all the observations used in the analysis
  - Sum of Weights of all the observations read from the input data set
  - Sum of Weights of all the observations used in the analysis
  - Normalized Sum of Weights of all the observations used in the analysis, if the SCALE=WILLIAMS option is specified in the MODEL statement or the NORMALIZE option is specified in the WEIGHT statement.

An ODS OUTPUT data set created from this table contains all of the information in every row.

- “Response Profile” table, which gives, for each response level, the ordered value (an integer between one and the number of response levels, inclusive); the value of the response variable if the single-trial syntax is used or the values “Event” and “Nonevent” if the events/trials syntax is used; the count or frequency; and the sum of weights if the WEIGHT statement is specified

- “Class Level Information” table, which gives the level and the design variables for each CLASS explanatory variable

- “Descriptive Statistics for Continuous Explanatory Variables” table for continuous explanatory variables, the “Frequency Distribution of Class Variables,” and the “Weight Distribution of Class Variables” tables (if the WEIGHT statement is specified), if you specify the SIMPLE option in the PROC LOGISTIC statement. The “Descriptive Statistics for Continuous Explanatory Variables” table contains the mean, standard deviation, maximum and minimum of each continuous variable specified in the MODEL statement.

- “Maximum Likelihood Iterative Phase” table, if you use the ITPRINT option in the MODEL statement. This table gives the iteration number, the step size (in the scale of 1.0, .5, .25, and so on) or the ridge value, $-2 \log$ likelihood, and parameter estimates for each iteration. Also displayed are the last evaluation of the gradient vector and the last change in the $-2 \log$ likelihood.

- Pearson and deviance goodness-of-fit statistics, if you use the SCALE= option in the MODEL statement

- score test result for testing the parallel lines assumption, if an ordinal response model is fitted. If LINK=CLOGLOG or LINK=PROBIT, this test is labeled “Score Test for the Parallel Slopes Assumption.” The proportion odds assumption is a special case of the parallel lines assumption when LINK=LOGIT. In this case, the test is labeled “Score Test for the Proportional Odds Assumption”.

- “Model Fit Statistics” and “Testing Global Null Hypothesis: BETA=0” tables, which give the various criteria ($-2 \log$ L, AIC, SC) based on the likelihood
for fitting a model with intercepts only and for fitting a model with intercepts and explanatory variables. If you specify the NOINT option, these statistics are calculated without considering the intercept parameters. The third column of the table gives the chi-square statistics and p-values for the $-2 \log L$ statistic and for the Score statistic. These test the joint effect of the explanatory variables included in the model. The Score criterion is always missing for the models identified by the first two columns of the table. Note also that the first two rows of the Chi-Square column are always missing, since tests cannot be performed for AIC and SC.

- generalized $R^2$ measures for the fitted model, if you specify the RSQUARE option in the MODEL statement
- “Type 3 Analysis of Effects” table, if the model contains an effect involving a CLASS variable. This table gives the Wald Chi-square statistic, the degrees of freedom, and the p-value for each effect in the model
- “Analysis of Maximum Likelihood Estimates” table, which includes
  - parameter name, which also identifies the CLASS variable level and, for generalized logit models, a response variable column to identify the corresponding logit by displaying the nonreference level of the logit
  - maximum likelihood estimate of the parameter
  - estimated standard error of the parameter estimate, computed as the square root of the corresponding diagonal element of the estimated covariance matrix
  - Wald chi-square statistic, computed by squaring the ratio of the parameter estimate divided by its standard error estimate
  - p-value of the Wald chi-square statistic with respect to a chi-square distribution with one degree of freedom
  - standardized estimate for the slope parameter, if you specify the STB option in the MODEL statement. This estimate is given by $\hat{\beta}_i / (s/s_i)$, where $s_i$ is the total sample standard deviation for the $i$th explanatory variable and

$$ s = \begin{cases} \pi / \sqrt{3} & \text{Logistic} \\ 1 & \text{Normal} \\ \pi / \sqrt{6} & \text{Extreme-value} \end{cases} $$

Standardized estimates of the intercept parameters are set to missing.
- $e^{\hat{\beta}_i}$ for each slope parameter $\beta_i$, if you specify the EXPB option in the MODEL statement. For continuous variables, this is equivalent to the estimated odds ratio for a 1 unit change.
- label of the variable, if you specify the PARMLABEL option in the MODEL statement and if space permits. Due to constraints on the line size, the variable label may be suppressed in order to display the table in one panel. Use the SAS system option LINESIZE= to specify a larger line size to accommodate variable labels. A shorter line size can break the table into two panels allowing labels to be displayed.
• “Odds Ratio Estimates” table, which contains the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

• “Association of Predicted Probabilities and Observed Responses” table, which includes a breakdown of the number of pairs with different responses, and four rank correlation indexes: Somers’ D, Goodman-Kruskal Gamma, and Kendall’s Tau-a, and c

• confidence intervals for all the parameters, if you use the CLPARM= option in the MODEL statement

• confidence intervals for all the odds ratios, if you use the CLODDS= option in the MODEL statement

• a summary of the model-building process, if you use a FORWARD, BACKWARD, or STEPWISE selection method. This summary gives the step number, the explanatory variables entered or removed at each step, the chi-square statistic, and the corresponding p-value on which the entry or removal of the variable is based (the score chi-square is used to determine entry; the Wald chi-square is used to determine removal)

• “Analysis of Variables Removed by Fast Backward Elimination” table, if you specify the FAST option in the MODEL statement. This table gives the approximate chi-square statistic for the variable removed, the corresponding p-value with respect to a chi-square distribution with one degree of freedom, the residual chi-square statistic for testing the joint significance of the variable and the preceding ones, the degrees of freedom, and the p-value of the residual chi-square with respect to a chi-square distribution with the corresponding degrees of freedom

• “Analysis of Effects not in the Model” table, if you specify the DETAILS option in the MODEL statement. This table gives the score chi-square statistic for testing the significance of each variable not in the model after adjusting for the variables already in the model, and the p-value of the chi-square statistic with respect to a chi-square distribution with one degree of freedom

• classification table, if you use the CTABLE option in the MODEL statement. For each prior event probability (labeled “Prob Event”) specified by the PEVENT= option and each cutpoint specified in the PPROB= option, the table gives the four entries of the $2 \times 2$ table of observed and predicted responses and the percentages of correct classification, sensitivity, specificity, false positive, and false negative. The columns labeled “Correct” give the number of correctly classified events and nonevents. “Incorrect Event” gives the number of nonevents incorrectly classified as events. “Incorrect Nonevent” gives the number of nonevents incorrectly classified as events.

• estimated covariance matrix of the parameter estimates, if you use the COVB option in the MODEL statement

• estimated correlation matrix of the parameter estimates, if you use the CORRB option in the MODEL statement

• “Contrast Test Results” table, if you specify a CONTRAST statement. This table gives the result of the Wald test for each CONTRAST specified. If you
specify the E option in the CONTRAST statement, then the contrast matrix is displayed. If you specify the ESTIMATE= option in the CONTRAST statement, then estimates and Wald tests for each contrast (row of the contrast matrix) or exponentiated contrast are produced.

- “Linear Hypothesis Testing” table, if you specify a TEST statement. This table gives the result of the Wald test for each TEST statement specified. If you specify the PRINT option in the TEST statement, then matrices used in the intermediate calculations are also displayed.

- results of the Hosmer and Lemeshow test for the goodness of fit of the fitted model, if you use the LACKFIT option in the MODEL statement

- “Regression Diagnostics” table, if you use the INFLUENCE option in the MODEL statement. This table gives, for each observation, the case number (which is the observation number), the values of the explanatory variables included in the model, the Pearson residual, the deviance residual, the diagonal element of the hat matrix, the standardized difference in the estimate for each parameter (name DFBETA, where name is either Intercept or the name of an explanatory variable), two confidence interval displacement diagnostics (C and CBAR), the change in the Pearson chi-square statistic (DIFCHISQ), and the change in the deviance (DIFDEV)

If you also specify the STRATA statement, then this table contains the case number (which is the observation number), the values of the explanatory variables included in the model, the estimated one-step Pearson residual, the estimated one-step diagonal element of the hat matrix, and the estimated one-step standardized difference in the estimate for each parameter.

- index plots of regression diagnostics, if you specify the IPLOTS option in the MODEL statement. These include plots of
  - Pearson residuals
  - deviance residuals
  - diagonal elements of the hat matrix
  - standardized differences in parameter estimates, DFBETA0 for the intercept estimate, DFBETA1 for the slope estimate of the first explanatory variable in the MODEL statement, and so on
  - confidence interval displacement diagnostics C
  - confidence interval displacement diagnostics CBAR
  - changes in the Pearson chi-square statistic
  - changes in the deviance

- if you specify a STRATA statement
  - “Strata Summary” table, which displays a pattern of the number of events and the number of non-events in a stratum, the number of strata having that pattern, and the total number of observations contained in those strata
  - “Strata Information” table, if you specify the INFO option on the STRATA statement. This table displays each stratum, its frequency, and the number of events and non-events in that stratum.
if you specify an EXACT statement

- “Sufficient Statistics” table, if you request an OUTDIST= data set. This table is displayed before printing any of the exact analysis results and lists the parameters and their observed sufficient statistics.

- “Conditional Exact Tests” table, which provides two tests for the null hypothesis that the parameters for the specified effects are zero: the Exact Probability Test and the Exact Conditional Scores test. For each test, the test statistic, an exact $p$-value (the probability of obtaining a more extreme statistic than the observed, assuming the null hypothesis), and a mid $p$-value (which adjusts for the discreteness of the distribution) are displayed.

- “Exact Parameter Estimates” table, if you specify the ESTIMATE, ESTIMATE=PARM, or ESTIMATE=BOTH options. This table gives individual parameter estimates for each variable (conditional on the values of all the other parameters in the model), confidence limits, and a two-sided $p$-value (twice the one-sided $p$-value) for testing that the parameter is zero.

- “Exact Odds Ratios” table, if you specify the ESTIMATE=ODDS or ESTIMATE=BOTH options. This table gives odds ratio estimates for the individual parameters, confidence limits, and a two-sided $p$-value for testing that the odds ratio is 1.

**ODS Table Names**

PROC LOGISTIC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**ODS Graphics (Experimental)**

This section describes the use of ODS for creating graphics with the LOGISTIC procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement in addition to options on the MODEL or GRAPHICS statement as described in the following sections. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

**MODEL Statement Options**

If the INFLUENCE or IPlots option is specified in the MODEL statement, then the lineprinter plots are suppressed and ODS GRAPHICS versions of the plots are produced.

If you specify the OUTROC= option, and if ROCEPS= is not specified, then ROC curves are produced. If you also specify a SELECTION= method then an overlaid plot of all the ROC curves for each step of the selection process is displayed.
GRAPHICS Statement and Options

GRAPHICS options ;

The GRAPHICS statement provides options for requesting and modifying certain graphical displays. This statement has no effect unless ODS GRAPHICS ON has been specified. The functionality of this statement may be replaced by alternative syntax in a future release.

The following options are available.

DFBETAS displays the DFBETAS versus Case Number plots. This acts like DFBETAS=_ALL_ in the OUTPUT statement. These plots are produced by default when the GRAPHICS statement is specified.

HATDIAG displays plots of DIFCHISQ, DIFDEV, and DFBETAS (when the DFBETAS option is specified) versus the hat diagonals.

INFLUENCE | INDEX displays the INFLUENCE plots with no DFBETAS. These plots are produced by default when the GRAPHICS statement is specified.

PHAT displays plots of DIFCHISQ, DIFDEV, and DFBETAS (when the DFBETAS option is specified) versus the predicted event probability.

ALL invokes the DFBETAS, HATDIAG, INFLUENCE, and PHAT options.

NOINFLUENCE suppresses the default INFLUENCE and DFBETAS plots.

NOPANELS unpanels the graphical displays and produces a series of plots which form the panelled display.

ROC displays the ROC curve. If the ROCEPS= option is specified on the MODEL statement then it must be equal to zero, otherwise no ROC curve is produced. If you also specify a SELECTION= method then an overlaid plot of all the ROC curves for each step of the selection process is displayed.

ESTPROB(\(fit\)-options) displays the fit curves for the model when only one continuous covariate is specified in the model. If you use events/trials syntax, then this displays the estimated event probability and the prediction limits versus the covariate with the observed proportions overlaid on the graph. If you use single-trial syntax, this displays the estimated event probability and the prediction limits versus the covariate with the observed responses overlaid on the graph. If you specify a polytomous logit model, then the estimated probabilities for each possible response level are graphed. If you have an OFFSET= variable with more than one value, then the prediction curves are replaced with error bars and the estimated probabilities are displayed at the observed covariate values.

The following \(fit\)-options are available with the ESTPROB option.
**ALPHA=** specifies the size of the prediction interval. The ALPHA= value specified on the PROC statement is the default. If neither ALPHA= value is specified, then ALPHA=0.05 by default.

**GRIDSIZE=** specifies the number of equally-spaced points at which the fit curve is computed. By default, GRIDSIZE=50.

**OBSERVE** specifies that the fit curve should be computed at the observed values only.

See Example 42.6 on page 2422 and Example 42.7 on page 2429 for examples of the ODS graphical displays.

**ODS Graph Names**

PROC LOGISTIC assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 42.3.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 42.3. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

Table 42.3. ODS Graphics Produced by PROC LOGISTIC
Examples

Example 42.1. Stepwise Logistic Regression and Predicted Values

Consider a study on cancer remission (Lee 1974). The data, consisting of patient characteristics and whether or not cancer remission occurred, are saved in the data set Remission.

data Remission;
  input remiss cell smear infil li blast temp;
  label remiss='Complete Remission';
datalines;
1 .8 .83 .66 1.9 1.1 .996
1 .9 .36 .32 1.4 .74 .992
0 .8 .88 .7 .8 .176 .982
0 1 .87 .87 .7 1.053 .986
1 .9 .75 .68 1.3 .519 .98
0 1 .65 .65 .6 .519 .982
1 .95 .97 .92 1 1.23 .992
0 .95 .87 .83 1.9 1.354 1.02
0 1 .45 .45 .8 .322 .999
0 .95 .36 .34 .5 0 1.038
0 .85 .39 .33 .7 .279 .988
0 .7 .76 .53 1.2 .146 .982
0 .8 .46 .37 .4 .38 1.006
0 .2 .39 .08 .8 .114 .99
0 1 .9 .9 1.1 1.037 .99
1 1 .84 .84 1.9 2.064 1.02
0 .65 .42 .27 .5 .114 1.014
0 1 .75 .75 1 1.322 1.004
0 .5 .44 .22 .6 .114 .99
1 1 .63 .63 1.1 1.072 .986
0 1 .33 .33 .4 .176 1.01
0 .9 .93 .84 .6 1.591 1.02
1 1 .58 .58 1 .531 1.002
0 .95 .32 .3 1.6 .886 .988
1 1 .6 .6 1.7 .964 .99
The data set *Remission* contains seven variables. The variable *remiss* is the cancer remission indicator variable with a value of 1 for remission and a value of 0 for nonremission. The other six variables are the risk factors thought to be related to cancer remission.

The following invocation of PROC LOGISTIC illustrates the use of stepwise selection to identify the prognostic factors for cancer remission. A significance level of 0.3 (SLENTRY=0.3) is required to allow a variable into the model, and a significance level of 0.35 (SLSTAY=0.35) is required for a variable to stay in the model. A detailed account of the variable selection process is requested by specifying the DETAILS option. The Hosmer and Lemeshow goodness-of-fit test for the final selected model is requested by specifying the LACKFIT option. The OUTTEST= and COVOUT options in the PROC LOGISTIC statement create a data set that contains parameter estimates and their covariances for the final selected model. The response variable option EVENT= sets *remiss*=1 (remission) to be Ordered Value 1 so that the probability of remission is modeled. The OUTPUT statement creates a data set that contains the cumulative predicted probabilities and the corresponding confidence limits, and the individual and cross validated predicted probabilities for each observation.

```latex
title 'Stepwise Regression on Cancer Remission Data';
proc logistic data=Remission outest=betas covout;
   model remiss(event='1')=cell smear infil li blast temp
       / selection=stepwise
       slentry=0.3
       slstay=0.35
       details
       lackfit;
   output out=pred p=phat lower=lcl upper=ucl
       predprob=(individual crossvalidate);
run;

proc print data=betas;
   title2 'Parameter Estimates and Covariance Matrix';
run;

proc print data=pred;
   title2 'Predicted Probabilities and 95% Confidence Limits';
run;
```

In stepwise selection, an attempt is made to remove any insignificant variables from the model before adding a significant variable to the model. Each addition or deletion of a variable to or from a model is listed as a separate step in the displayed output, and at each step a new model is fitted. Details of the model selection steps are shown in Output 42.1.1 – Output 42.1.5.

Prior to the first step, the intercept-only model is fitted and individual score statistics for the potential variables are evaluated (Output 42.1.1). In Step 1 (Output 42.1.2), variable li is selected into the model since it is the most significant variable among those to be chosen ($p = 0.0049 < 0.3$). The intermediate model that contains an intercept and li is then fitted. Li remains significant ($p = 0.0146 < 0.35$) and is not removed. In Step 2 (Output 42.1.3), variable temp is added to the model. The model then contains an intercept and variables li and temp. Both li and temp remain significant at 0.035 level; therefore, neither li nor temp is removed from the model. In Step 4 (Output 42.1.4), variable cell is added to the model. The model then contains an intercept and variables li, temp, and cell. None of these variables are removed from the model since all are significant at the 0.35 level. Finally, none of the remaining variables outside the model meet the entry criterion, and the stepwise selection is terminated. A summary of the stepwise selection is displayed in Output 42.1.5.

The data set betas created by the OUTEST= and COVOUT options is displayed in Output 42.1.7. The data set contains parameter estimates and the covariance matrix for the final selected model. Note that all explanatory variables listed in the MODEL statement are included in this data set; however, variables that are not included in the final model have all missing values.
The data set pred created by the OUTPUT statement is displayed in Output 42.1.8. It contains all the variables in the input data set, the variable phat for the (cumulative) predicted probability, the variables lcl and ucl for the lower and upper confidence limits for the probability, and four other variables (viz., IP – 1, IP – 0, XP – 1, and XP – 0) for the PREDPROBS= option. The data set also contains the variable _LEVEL_, indicating the response value to which phat, lcl, and ucl refer. For instance, for the first row of the OUTPUT data set, the values of _LEVEL_ and phat, lcl, and ucl are 1, 0.72265, 0.16892 and 0.97093, respectively; this means that the estimated probability that remiss ≤ 1 is 0.723 for the given explanatory variable values, and the corresponding 95% confidence interval is (0.16892, 0.97093). The variables IP – 1 and IP – 0 contain the predicted probabilities that remiss = 1 and remiss = 0, respectively. Note that values of phat and IP – 1 are identical since they both contain the probabilities that remiss = 1. The variables XP – 1 and XP – 0 contain the cross validated predicted probabilities that remiss = 1 and remiss = 0, respectively.
Next, a different variable selection method is used to select prognostic factors for cancer remission, and an efficient algorithm is employed to eliminate insignificant variables from a model. The following SAS statements invoke PROC LOGISTIC to perform the backward elimination analysis.

```sas
title 'Backward Elimination on Cancer Remission Data';
proc logistic data=Remission;
   model remiss(event='1')=temp cell li smear blast
       / selection=backward fast slstay=0.2 ctable;
run;
```

The backward elimination analysis (SELECTION=BACKWARD) starts with a model that contains all explanatory variables given in the MODEL statement. By specifying the FAST option, PROC LOGISTIC eliminates insignificant variables without refitting the model repeatedly. This analysis uses a significance level of 0.2 (SLSTAY=0.2) to retain variables in the model, which is different from the previous stepwise analysis where SLSTAY=.35. The CTABLE option is specified to produce classifications of input observations based on the final selected model.

Results of the fast elimination analysis are shown in Output 42.1.9 and Output 42.1.10. Initially, a full model containing all six risk factors is fit to the data (Output 42.1.9). In the next step (Output 42.1.10), PROC LOGISTIC removes blast, smear, cell, and temp from the model all at once. This leaves li and the intercept as the only variables in the final model. Note that in this analysis, only parameter estimates for the final model are displayed because the DETAILS option has not been specified.

Note that you can also use the FAST option when SELECTION=STEPWISE. However, the FAST option operates only on backward elimination steps. In this example, the stepwise process only adds variables, so the FAST option would not be useful.
Results of the CTABLE option are shown in Output 42.1.11. Each row of the “Classification Table” corresponds to a cutpoint applied to the predicted probabilities, which is given in the Prob Level column. The $2 \times 2$ frequency tables of observed and predicted responses are given by the next four columns. For example, with a cutpoint of 0.5, 4 events and 16 nonevents were classified correctly. On the other hand, 2 nonevents were incorrectly classified as events and 5 events were incorrectly classi-
Example 42.2. Logistic Modeling with Categorical Predictors

Consider a study of the analgesic effects of treatments on elderly patients with neuralgia. Two test treatments and a placebo are compared. The response variable is whether the patient reported pain or not. Researchers recorded age and gender of the patients and the duration of complaint before the treatment began. The data, consisting of 60 patients, are contained in the data set Neuralgia.

Data Neuralgia;
  input Treatment $ Sex $ Age Duration Pain $ @@;

;

The data set Neuralgia contains five variables: Treatment, Sex, Age, Duration, and Pain. The last variable, Pain, is the response variable. A specification of Pain=Yes indicates there was pain, and Pain=No indicates no pain. The variable Treatment is a categorical variable with three levels: A and B represent the two test treatments, and P represents the placebo treatment. The gender of the patients is given by the categorical variable Sex. The variable Age is the age of the patients, in years, when treatment began. The duration of complaint, in months, before the treatment began is given by the variable Duration. The following statements use the LOGISTIC procedure to fit a two-way logit with interaction model for the effect of Treatment and Sex, with Age and Duration as covariates. The categorical variables Treatment and Sex are declared in the CLASS statement.
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain= Treatment Sex Treatment*Sex Age Duration / expb;
run;

In this analysis, PROC LOGISTIC models the probability of no pain (Pain=No). By default, effect coding is used to represent the CLASS variables. Two design variables are created for Treatment and one for Sex, as shown in Output 42.2.1.

**Output 42.2.1. Effect Coding of CLASS Variables**

<table>
<thead>

<td>-1</td>
</tr>
</tbody>
</table>

PROC LOGISTIC displays a table of the Type 3 analysis of effects based on the Wald test (Output 42.2.2). Note that the Treatment*Sex interaction and the duration of complaint are not statistically significant (p =0.9318 and p =0.8752, respectively). This indicates that there is no evidence that the treatments affect pain differently in men and women, and no evidence that the pain outcome is related to the duration of pain.

**Output 42.2.2. Wald Tests of Individual Effects**

</tbody>
</table>

Parameter estimates are displayed in Output 42.2.3. The Exp(Est) column contains the exponentiated parameter estimates requested with the EXPB option. These values may, but do not necessarily, represent odds ratios for the corresponding variables. For continuous explanatory variables, the Exp(Est) value corresponds to the odds ratio for a unit increase of the corresponding variable. For CLASS variables using the effect coding, the Exp(Est) values have no direct interpretation as a comparison of levels.
However, when the reference coding is used, the Exp(Est) values represent the odds ratio between the corresponding level and the last level. Following the parameter estimates table, PROC LOGISTIC displays the odds ratio estimates for those variables that are not involved in any interaction terms. If the variable is a CLASS variable, the odds ratio estimate comparing each level with the last level is computed regardless of the coding scheme. In this analysis, since the model contains the Treatment*Sex interaction term, the odds ratios for Treatment and Sex were not computed. The odds ratio estimates for Age and Duration are precisely the values given in the Exp(Est) column in the parameter estimates table.

</tbody>
</table>

The following PROC LOGISTIC statements illustrate the use of forward selection on the data set Neuralgia to identify the effects that differentiate the two Pain responses. The option **SELECTION=FORWARD** is specified to carry out the forward selection. The term **Treatment|Sex@2** illustrates another way to specify main effects and two-way interaction as is available in other procedures such as PROC GLM. (Note that, in this case, the “@2” is unnecessary because no interactions besides the two-way interaction are possible).

```plaintext
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain=Treatment|Sex@2 Age Duration /selection=forward expb;
run;
```

Results of the forward selection process are summarized in **Output 42.2.4**. The variable Treatment is selected first, followed by Age and then Sex. The results are consistent with the previous analysis (**Output 42.2.2**) in which the Treatment*Sex interaction and Duration are not statistically significant.
Chapter 42. The LOGISTIC Procedure

Output 42.2.4. Effects Selected into the Model

<table>
<thead>
<tr>
<th>Step</th>
<th>Effect Entered</th>

<tr>
<td>3</td>
<td>Sex</td>
<td>1</td>
<td>3</td>
<td>5.9959</td>
<td>0.0143</td>
</tr>
</tbody>
</table>

Output 42.2.5 shows the Type 3 analysis of effects, the parameter estimates, and the odds ratio estimates for the selected model. All three variables, Treatment, Age, and Sex, are statistically significant at the 0.05 level ($p = 0.0011$, $p = 0.0011$, and $p = 0.0143$, respectively). Since the selected model does not contain the Treatment*Sex interaction, odds ratios for Treatment and Sex are computed. The estimated odds ratio is 24.022 for treatment A versus placebo, 41.528 for Treatment B versus placebo, and 6.194 for female patients versus male patients. Note that these odds ratio estimates are not the same as the corresponding values in the Exp(Est) column in the parameter estimates table because effect coding was used. From Output 42.2.5, it is evident that both Treatment A and Treatment B are better than the placebo in reducing pain; females tend to have better improvement than males; and younger patients are faring better than older patients.

Finally, PROC LOGISTIC is invoked to refit the previously selected model using reference coding for the CLASS variables. Two CONTRAST statements are specified. The one labeled 'Pairwise' specifies three rows in the contrast matrix, L, for all the pairwise comparisons between the three levels of Treatment. The contrast labeled 'Female vs Male' compares female to male patients. The option ESTIMATE=EXP is specified in both CONTRAST statements to exponentiate the estimates of $L\hat{\beta}$. With the given specification of contrast coefficients, the first row of the 'Pairwise' CONTRAST statement corresponds to the odds ratio of A versus P, the second row corresponds to B versus P, and the third row corresponds to A versus B. There is only one row in the 'Female vs Male' CONTRAST statement, and it corresponds to the odds ratio comparing female to male patients.

```
proc logistic data=Neuralgia;
   class Treatment Sex /param=ref;
   model Pain= Treatment Sex age;
   contrast 'Pairwise' Treatment 1 0,
       Treatment 0 1,
       Treatment 1 -1 / estimate=exp;
   contrast 'Female vs Male' Sex 1 / estimate=exp;
run;
```
Output 42.2.6. Reference Coding of CLASS Variables

The LOGISTIC Procedure

Class Level Information

<td>M</td>
<td>0</td>
</tr>
</tbody>
</table>

The reference coding is shown in Output 42.2.6. The Type 3 analysis of effects, the parameter estimates for the reference coding, and the odds ratio estimates are displayed in Output 42.2.7. Although the parameter estimates are different (because of the different parameterizations), the “Type 3 Analysis of Effects” table and the “Odds Ratio” table remain the same as in Output 42.2.5. With effect coding, the treatment A parameter estimate (0.8772) estimates the effect of treatment A compared to the average effect of treatments A, B, and placebo. The treatment A estimate (3.1790) under the reference coding estimates the difference in effect of treatment A and the placebo treatment.

Output 42.2.8 contains two tables: the “Contrast Test Results” table and the “Contrast Rows Estimation and Testing Results” table. The former contains the overall Wald test for each CONTRAST statement. Although three rows are specified in the ‘Pairwise’ CONTRAST statement, there are only two degrees of freedom, and the Wald test result is identical to the Type 3 analysis of Treatment in Output 42.2.7. The latter table contains estimates and tests of individual contrast rows. The estimates for the first two rows of the ‘Pairwise’ CONTRAST statement are the same as those given in the “Odds Ratio Estimates” table (in Output 42.2.7). Both treatments A and B are highly effective over placebo in reducing pain. The third row estimates the odds ratio comparing A to B. The 95% confidence interval for this odds ratio is (0.0932, 3.5889), indicating that the pain reduction effects of these two test treatments are not that different. Again, the ‘Female vs Male’ contrast shows that female patients fared better in obtaining relief from pain than male patients.

Example 42.3. Ordinal Logistic Regression

Consider a study of the effects on taste of various cheese additives. Researchers tested four cheese additives and obtained 52 response ratings for each additive. Each response was measured on a scale of nine categories ranging from strong dislike (1) to excellent taste (9). The data, given in McCullagh and Nelder (1989, p. 175) in the form of a two-way frequency table of additive by rating, are saved in the data set Cheese.

```plaintext
data Cheese;
   do Additive = 1 to 4;
      do y = 1 to 9;
         input freq @@;
         output;
      end;
   end;
   label y='Taste Rating';
datalines;
0 0 1 7 8 8 19 8 1
6 9 12 11 7 6 1 0 0
1 1 6 8 23 7 5 1 0
0 0 0 1 3 7 14 16 11
;```
The data set Cheese contains the variables y, Additive, and freq. The variable y contains the response rating. The variable Additive specifies the cheese additive (1, 2, 3, or 4). The variable freq gives the frequency with which each additive received each rating.

The response variable y is ordinarily scaled. A cumulative logit model is used to investigate the effects of the cheese additives on taste. The following SAS statements invoke PROC LOGISTIC to fit this model with y as the response variable and three indicator variables as explanatory variables, with the fourth additive as the reference level. With this parameterization, each Additive parameter compares an additive to the fourth additive. The COVB option produces the estimated covariance matrix.

```
proc logistic data=Cheese;
  freq freq;
  class Additive (param=ref ref=’4’);
  model y=Additive / covb;
  title1 ’Multiple Response Cheese Tasting Experiment’;
run;
```

Results of the analysis are shown in Output 42.3.1, and the estimated covariance matrix is displayed in Output 42.3.2.

Since the strong dislike (y=1) end of the rating scale is associated with lower Ordered Values in the Response Profile table, the probability of disliking the additives is modeled.

The score chi-square for testing the proportional odds assumption is 17.287, which is not significant with respect to a chi-square distribution with 21 degrees of freedom (p = 0.694). This indicates that the proportional odds model adequately fits the data. The positive value (1.6128) for the parameter estimate for Additive1 indicates a tendency towards the lower-numbered categories of the first cheese additive relative to the fourth. In other words, the fourth additive is better in taste than the first additive. Each of the second and the third additives is less favorable than the fourth additive. The relative magnitudes of these slope estimates imply the preference ordering: fourth, first, third, second.

Example 42.4. Nominal Response Data: Generalized Logits Model

Over the course of one school year, third graders from three different schools are exposed to three different styles of mathematics instruction: a self-paced computer-learning style, a team approach, and a traditional class approach. The students are asked which style they prefer, and their responses are classified by the type of program they are in (a regular school day versus a regular day supplemented with an afternoon school program). The data are displayed in Table 42.4. The data set is from Stokes, Davis, and Koch (2000), and is also analyzed in the “Generalized Logits Model” section on page 824 of Chapter 22, “The CATMOD Procedure.”

</tbody>
</table>
The levels of the response variable (self, team, and class) have no essential ordering, so a logistic regression is performed on the generalized logits. The model to be fit is

$$\log \left( \frac{\pi_{hij}}{\pi_{hir}} \right) = \alpha_j + x_{hi}^T \beta_j$$

where $\pi_{hij}$ is the probability that a student in school $h$ and program $i$ prefers teaching style $j$, $j \neq r$, and style $r$ is the baseline style (in this case, class). There are separate sets of intercept parameters $\alpha_j$ and regression parameters $\beta_j$ for each logit, and the matrix $x_{hi}$ is the set of explanatory variables for the $hi$th population. Thus, two logits are modeled for each school and program combination: the logit comparing self to class and the logit comparing team to class.

The following statements create the data set school and request the analysis. The LINK=GLOGIT option forms the generalized logits. The response variable option ORDER=DATA means that the response variable levels are ordered as they exist in the data set: self, team, and class; thus, the logits are formed by comparing self to class and by comparing team to class. The ODS statement suppresses the display of the maximum likelihood estimates. The results of this analysis are shown in Output 42.4.1 through Output 42.4.4.

The “Type 3 Analysis of Effects” table in Output 42.4.3 shows that the interaction effect is clearly nonsignificant, so a main effects model is fit with the following statements.

```
proc logistic data=school;
  freq Count;
  class School Program(ref=first);
  model Style(order=data)=School Program / link=glogit;
run;
```

All of the global fit tests in Output 42.4.5 suggest the model is significant, and the Type 3 tests show that the school and program effects are also significant.
Example 42.5. Stratified Sampling

Consider the hypothetical example in Fleiss (1981, pp. 6–7) in which a test is applied to a sample of 1,000 people known to have a disease and to another sample of 1,000 people known not to have the same disease. In the diseased sample, 950 test positive; in the nondiseased sample, only 10 test positive. If the true disease rate in the population is 1 in 100, specifying `PEVENT=0.01` results in the correct false positive and negative rates for the stratified sampling scheme. Omitting the `PEVENT=` option is equivalent to using the overall sample disease rate (1000/2000 = 0.5) as the value of the `PEVENT=` option, which would ignore the stratified sampling.

The SAS code is as follows:

```sas
data Screen;
do Disease='Present','Absent';
do Test=1,0;
    input Count @@;
    output;
end;
end;
datalines;
950 50
10 990
;```

The parameter estimates, tests for individual parameters, and odds ratios are displayed in Output 42.4.6. The `Program` variable has nearly the same effect on both logits, while `School=1` has the largest effect of the schools.
The response variable option EVENT= indicates that Disease='Present' is the event. The CTABLE option is specified to produce a classification table. Specifying PPROB=0.5 indicates a cutoff probability of 0.5. A list of two probabilities, 0.5 and 0.01, is specified for the PEVENT= option; 0.5 corresponds to the overall sample disease rate, and 0.01 corresponds to a true disease rate of 1 in 100.

The classification table is shown in Output 42.5.1.

Output 42.5.1. False Positive and False Negative Rates

<table>
<thead>
<tr>
<th>Prob Event</th>
<th>Prob Level</th>
<th>Correct Event</th>
<th>Incorrect Event</th>
<th>Percentages</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.500</td>
<td>0.500</td>
<td>950</td>
<td>990</td>
<td>97.0</td>
</tr>
<tr>
<td>0.010</td>
<td>0.500</td>
<td>950</td>
<td>990</td>
<td>99.0</td>
</tr>
</tbody>
</table>

In the classification table, the column “Prob Level” represents the cutoff values (the settings of the PPROB= option) for predicting whether an observation is an event. The “Correct” columns list the numbers of subjects that are correctly predicted as events and nonevents, respectively, and the “Incorrect” columns list the number of nonevents incorrectly predicted as events and the number of events incorrectly predicted as nonevents, respectively. For PEVENT=0.5, the false positive rate is 1% and the false negative rate is 4.8%. These results ignore the fact that the samples were stratified and incorrectly assume that the overall sample proportion of disease (which is 0.5) estimates the true disease rate. For a true disease rate of 0.01, the false positive rate and the false negative rate are 51% and 0.1%, respectively, as shown on the second line of the classification table.

Example 42.6. Logistic Regression Diagnostics

In a controlled experiment to study the effect of the rate and volume of air inspired on a transient reflex vaso-constriction in the skin of the digits, 39 tests under various combinations of rate and volume of air inspired were obtained (Finney 1947). The end point of each test is whether or not vaso-constriction occurred. Pregibon (1981) uses this set of data to illustrate the diagnostic measures he proposes for detecting influential observations and to quantify their effects on various aspects of the maximum likelihood fit.

The vaso-constriction data are saved in the data set vaso:
data vaso;
    length Response $12;
    input Volume Rate Response @@;
    LogVolume=log(Volume);
    LogRate=log(Rate);
datalines;
3.70 0.825 constrict 3.50 1.09 constrict  
1.25 2.50 constrict 0.75 1.50 constrict  
0.80 3.20 constrict 0.70 3.50 constrict  
0.60 0.75 no_constrict 1.10 1.70 no_constrict  
0.90 0.75 no_constrict 0.90 0.45 no_constrict  
0.80 0.57 no_constrict 0.55 2.75 no_constrict  
0.60 3.00 no_constrict 1.40 2.33 constrict  
0.75 3.75 constrict 2.30 1.64 constrict  
3.20 1.60 constrict 0.85 1.415 constrict  
1.70 1.06 no_constrict 1.80 1.80 constrict  
0.40 2.00 no_constrict 0.95 1.36 no_constrict  
1.35 1.35 no_constrict 1.50 1.36 no_constrict  
1.60 1.78 constrict 0.60 1.50 no_constrict  
1.80 1.50 constrict 0.95 1.90 no_constrict  
1.90 0.95 constrict 1.60 0.40 no_constrict  
2.70 0.75 constrict 2.35 0.03 no_constrict  
1.10 1.83 no_constrict 1.10 2.20 constrict  
1.20 2.00 constrict 0.80 3.33 constrict  
0.95 1.90 no_constrict 0.75 1.90 no_constrict  
1.30 1.625 constrict ;

In the data set vaso, the variable Response represents the outcome of a test. The variable LogVolume represents the log of the volume of air intake, and the variable LogRate represents the log of the rate of air intake.

The following SAS statements invoke PROC LOGISTIC to fit a logistic regression model to the vaso-constriction data, where Response is the response variable, and LogRate and LogVolume are the explanatory variables. The INFLUENCE option and the IPLOTS option are specified to display the regression diagnostics and the index plots.

ods html;
ods graphics on;
title 'Occurrence of Vaso-Constriction';
proc logistic data=vaso;
    model Response=LogRate LogVolume/influence iplots;
run;
ods graphics off;
ods html close;

Results of the model fit are shown in Output 42.6.1. Both LogRate and LogVolume are statistically significant to the occurrence of vaso-constriction ($p = 0.0131$ and $p = 0.0055$, respectively). Their positive parameter estimates indicate that a higher
inspiration rate or a larger volume of air intake is likely to increase the probability of vaso-constriction.

The INFLUENCE option displays the values of the explanatory variables (LogRate and LogVolume) for each observation, a column for each diagnostic produced, and the case number which represents the sequence number of the observation (Output 42.6.2). Also produced (but not shown here) is a lineprinter plot where the vertical axis represents the case number and the horizontal axis represents the value of the diagnostic statistic.

The index plots produced by the IPLOTS option are essentially the same lineprinter plots as those produced by the INFLUENCE option with a 90-degree rotation and perhaps on a more refined scale. This version of the plots are not displayed here. The vertical axis of an index plot represents the value of the diagnostic and the horizontal axis represents the sequence (case number) of the observation. The index plots are useful for identification of extreme values.

Since the experimental ODS GRAPHICS statement is also specified, the lineprinter plots from the INFLUENCE and IPLOTS options are suppressed and graphical displays are produced as shown in Output 42.6.3 through Output 42.6.5. For general
information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the LOGISTIC procedure, see the “ODS Graphics” section on page 2388.

Output 42.6.3.  Residuals, Hat Matrix, and CI Displacement C (Experimental)

Output 42.6.4.  CI Displacement CBar, Change in Deviance and Pearson $\chi^2$, and DFBETAS for the Intercept (Experimental)
Output 42.6.5. DFBETAS for LogRate and LogVolume (Experimental)

The index plots of the Pearson residuals and the deviance residuals (Output 42.6.3) indicate that case 4 and case 18 are poorly accounted for by the model. The index plot of the diagonal elements of the hat matrix (Output 42.6.3) suggests that case 31 is an extreme point in the design space. The index plots of DFBETAS (Output 42.6.4 and Output 42.6.5) indicate that case 4 and case 18 are causing instability in all three parameter estimates. The other four index plots in Output 42.6.3 and Output 42.6.4 also point to these two cases as having a large impact on the coefficients and goodness of fit.

Example 42.7. ROC Curve, Customized Odds Ratios, Goodness-of-Fit Statistics, R-Square, and Confidence Limits

This example plots an ROC curve, estimates a customized odds ratio, produces the traditional goodness-of-fit analysis, displays the generalized $R^2$ measures for the fitted model, calculates the normal confidence intervals for the regression parameters, and produces an experimental display of the probability function and prediction curves for the fitted model. The data consist of three variables: $n$ (number of subjects in a sample), disease (number of diseased subjects in the sample), and age (age for the sample). A linear logistic regression model is used to study the effect of age on the probability of contracting the disease.
The SAS statements are as follows:

```sas
data Data1;
  input disease n age;
datalines;
  0 14 25
  0 20 35
  0 19 45
  7 18 55
  6 12 65
  17 17 75;
ods html;
ods graphics on;
proc logistic data=Data1;
  model disease/n=age / scale=none
    clparm=wald
    clodds=pl
    rsquare
    outroc=roc1;
  units age=10;
run;
ods graphics off;
ods html close;
```

The option SCALE=NONE is specified to produce the deviance and Pearson goodness-of-fit analysis without adjusting for overdispersion. The RSQUARE option is specified to produce generalized $R^2$ measures of the fitted model. The CLPARM=WALD option is specified to produce the Wald confidence intervals for the regression parameters. The UNITS statement is specified to produce customized odds ratio estimates for a change of 10 years in the age variable, and the CLODDS=PL option is specified to produce profile likelihood confidence limits for the odds ratio. The OUTROC= option outputs the data for the ROC curve to the SAS data set, roc1.

Results are shown in Output 42.7.1 and Output 42.7.2.

Since the experimental ODS GRAPHICS statement is specified, a graphical display of the ROC curve is produced as shown in Output 42.7.3. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the LOGISTIC procedure, see the “ODS Graphics” section on page 2388.
Output 42.7.3. Receiver Operating Characteristic Curve (Experimental)

Note that the area under the ROC curve is given by the statistic $c$ in the “Association of Predicted Probabilities and Observed Responses” table. In this example, the area under the ROC curve is 0.953.

The ROC curve may also be displayed with the GPLOT procedure by using the following code.

```latex
symbol i=join v=none c=black;
proc gplot data=roc1;
  title 'ROC Curve';
  plot _sensit_*_1mspec_=1 / vaxis=0 to 1 by .1 cframe=white;
run;
```
Because there is only one continuous covariate, if the experimental ODS GRAPHICS statement and the experimental GRAPHICS option ESTPROB are specified, then a graphical display of the estimated probability curve with bounding 95% prediction limits is displayed as shown in Output 42.7.4.

```sas
ods html;
ods graphics on;

proc logistic data=Data1;
   model disease/n=age / scale=none
       clparm=wald
       clodds=pl
       rsquare
       outroc=roc1;
   units age=10;
   graphics estprob;
run;

ods graphics off;
ods html close;
```

**Output 42.7.4.** Estimated Probability and 95% Prediction Limits (Experimental)
Example 42.8. Goodness-of-Fit Tests and Subpopulations

A study is done to investigate the effects of two binary factors, \( A \) and \( B \), on a binary response, \( Y \). Subjects are randomly selected from subpopulations defined by the four possible combinations of levels of \( A \) and \( B \). The number of subjects responding with each level of \( Y \) is recorded and entered into data set \( A \).

```sas
data a;
  do A=0,1;
    do B=0,1;
      do Y=1,2;
        input F @@;
        output;
      end;
    end;
  end;
  datalines;
  23 63 31 70 67 100 70 104;
;
A full model is fit to examine the main effects of \( A \) and \( B \) as well as the interaction effect of \( A \) and \( B \).

```sas
proc logistic data=a;
  freq F;
  model Y=A B A*B;
run;
```

### Association of Predicted Probabilities and Observed Responses

- Percent Concordant: 42.2
- Somers’ D: 0.118
- Percent Discordant: 30.4
- Gamma: 0.162
- Percent Tied: 27.3
- Tau-a: 0.054
- Pairs: 64367
- c: 0.559

Pearson and Deviance goodness-of-fit tests cannot be obtained for this model since a full model containing four parameters is fit, leaving no residual degrees of freedom. For a binary response model, the goodness-of-fit tests have \( m - q \) degrees of freedom, where \( m \) is the number of subpopulations and \( q \) is the number of model parameters. In the preceding model, \( m = q = 4 \), resulting in zero degrees of freedom for the tests.

Results of the model fit are shown in Output 42.8.1. Notice that neither the A*B interaction nor the B main effect is significant. If a reduced model containing only the A effect is fit, two degrees of freedom become available for testing goodness of fit. Specifying the SCALE=NONE option requests the Pearson and deviance statistics. With single-trial syntax, the AGGREGATE= option is needed to define the subpopulations in the study. Specifying AGGREGATE=(A B) creates subpopulations of the four combinations of levels of A and B. Although the B effect is being dropped from the model, it is still needed to define the original subpopulations in the study. If AGGREGATE=(A) were specified, only two subpopulations would be created from the levels of A, resulting in \( m = q = 2 \) and zero degrees of freedom for the tests.

```bash
proc logistic data=a;
   freq F;
   model Y=A / scale=none aggregate=(A B);
run;
```

The goodness-of-fit tests (Output 42.8.2) show that dropping the B main effect and the A*B interaction simultaneously does not result in significant lack of fit of the model. The tests’ large p-values indicate insufficient evidence for rejecting the null hypothesis that the model fits.

Example 42.9. Overdispersion

In a seed germination test, seeds of two cultivars were planted in pots of two soil conditions. The following SAS statements create the data set `seeds`, which contains the observed proportion of seeds that germinated for various combinations of cultivar and soil condition. Variable `n` represents the number of seeds planted in a pot, and variable `r` represents the number germinated. The indicator variables `cult` and `soil` represent the cultivar and soil condition, respectively.

```sas
data seeds;
  input pot n r cult soil;
  datalines;
  1 16 8 0 0
  2 51 26 0 0
  3 45 23 0 0
  4 39 10 0 0

Results of fitting the full factorial model are shown in Output 42.9.1. Both Pearson $\chi^2$ and deviance are highly significant ($p < 0.0001$), suggesting that the model does not fit well. If the link function and the model specification are correct and if there are no outliers, then the lack of fit may be due to overdispersion. Without adjusting for the overdispersion, the standard errors are likely to be underestimated, causing the Wald tests to be too sensitive. In PROC LOGISTIC, there are three SCALE= options to accommodate overdispersion. With unequal sample sizes for the observations, SCALE=WILLIAMS is preferred. The Williams model estimates a scale parameter $\phi$ by equating the value of Pearson $\chi^2$ for the full model to its approximate expected value. The full model considered here is the model with cultivar, soil condition, and their interaction. Using a full model reduces the risk of contaminating $\phi$ with lack of fit due to incorrect model specification.

```plaintext
proc logistic data=seeds;
  model r/n=cult soil cult*soil / scale=williams;
  title 'Full Model With SCALE=WILLIAMS';
run;
```

Results using Williams’ method are shown in Output 42.9.2. The estimate of $\phi$ is 0.075941 and is given in the formula for the Weight Variable at the beginning of the displayed output. Since neither cult nor cult $\times$ soil is statistically significant ($p = 0.5290$ and $p = 0.9274$, respectively), a reduced model that contains only the soil condition factor is fitted, with the observations weighted by $1/(1+0.075941(N-1))$. This can be done conveniently in PROC LOGISTIC by including the scale estimate in the SCALE=WILLIAMS option as follows:

```
proc logistic data=seeds;
    model r/n=soil / scale=williams(0.075941);
    title 'Reduced Model With SCALE=WILLIAMS(0.075941)';
run;
```
Example 42.10. Conditional Logistic Regression for Matched Pairs Data

Output 42.9.3. Reduced Model with Overdispersion Controlled

<table>

<tr>
<td>soil</td>
<td>1</td>
<td>0.7910</td>
<td>0.2902</td>
<td>7.4284</td>
<td>0.0064</td>
</tr>
</tbody>
</table>

Results of the reduced model fit are shown in Output 42.9.3. Soil condition remains a significant factor ($p = 0.0064$) for the seed germination.

Example 42.10. Conditional Logistic Regression for Matched Pairs Data

In matched pairs, or case-control, studies, conditional logistic regression is used to investigate the relationship between an outcome of being an event (case) or a nonevent (control) and a set of prognostic factors.

The data in this example are a subset of the data from the Los Angeles Study of the Endometrial Cancer Data in Breslow and Day (1980). There are 63 matched pairs, each consisting of a case of endometrial cancer (Outcome=1) and a control (Outcome=0). The case and corresponding control have the same ID. Two prognostic factors are included: Gall (an indicator variable for gall bladder disease) and Hyper (an indicator variable for hypertension). The goal of the case-control analysis is to determine the relative risk for gall bladder disease, controlling for the effect of hypertension.

```plaintext
data Data1;
do ID=1 to 63;
do Outcome = 1 to 0 by -1;
   input Gall Hyper @@;
   output;
endo;
datalines;
0 0 0 0 0 0 0 0 0 1 0 1 0 0 1 0 0 1 0 0 1
0 1 0 0 1 0 0 1 1 0 1 0 0 0 0 0 0 0 0 0
1 0 0 0 0 0 1 1 0 1 1 0 1 1 0 0 1 1 1 0
0 1 0 0 0 0 1 1 0 1 0 0 0 0 0 0 0 0 0 0
0 0 1 1 0 1 0 1 0 1 0 0 0 0 0 0 0 0 0 0
0 0 0 1 1 0 1 0 1 0 0 0 0 0 0 0 0 0 0 0
0 1 0 0 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0
0 0 0 1 0 1 0 0 0 1 0 1 0 1 0 1 0 0 0 0
0 0 0 0 0 1 1 0 0 0 1 0 0 0 0 0 0 0 1 0
0 0 0 0 0 0 1 0 0 0 1 0 0 0 1 0 0 0 1 0
```
There are several ways to approach this problem with PROC LOGISTIC.

- Specify the STRATA statement to perform a conditional logistic regression.
- Specify EXACT and STRATA statements to perform an exact conditional logistic regression on the original data set, if you believe the data set is too small or too sparse for the usual asymptotics to hold.
- Transform each matched pair into a single observation then specify a PROC LOGISTIC statement on this transformed data without a STRATA statement; this also performs a conditional logistic regression and produces essentially the same results.
- Specify an EXACT statement on the transformed data.

SAS statements and selected results for these four approaches are given in the remainder of this example.

**Conditional Analysis Using the STRATA Statement**

In the following SAS statements, PROC LOGISTIC is invoked with the ID variable declared in the STRATA statement to obtain the conditional logistic model estimates. Two models are fitted. The first model contains Gall as the only predictor variable, and the second model contains both Gall and Hyper as predictor variables. Because the option CLODDS=Wald is specified, PROC LOGISTIC computes a 95% Wald confidence interval for the odds ratio for each predictor variable.

```
proc logistic data=Data1;
  strata ID;
  model outcome(event='1')=Gall / clodds=Wald;
run;

proc logistic data=Data1;
  strata ID;
  model outcome(event='1')=Gall Hyper /clodds=Wald;
run;
```

Results from the two conditional logistic analyses are shown in Output 42.10.1 and Output 42.10.2. Note that there is only one response level listed in the “Response Profile” tables, and there is no intercept term in the “Analysis of Maximum Likelihood Estimates” tables.

Probability modeled is Outcome=1.

Strata Summary
Outcome  Number of Strata Frequency
Response Pattern
0 1 63 126
1 1 63 126
In the first model, where Gall is the only predictor variable (Output 42.10.1), the odds ratio estimate for Gall is 2.60, which is marginally significant ($p=0.0694$) and which is an estimate of the relative risk for gall bladder disease. A 95% confidence interval for this relative risk is (0.927, 7.293).

In the second model, where both Gall and Hyper are present (Output 42.10.2), the odds ratio estimate for Gall is 2.639, which is an estimate of the relative risk for gall bladder disease adjusted for the effects of hypertension. A 95% confidence interval for this adjusted relative risk is (0.933, 7.468). Note that the adjusted values (accounting for hypertension) for gall bladder disease are not very different from the unadjusted values (ignoring hypertension). This is not surprising since the prognostic factor Hyper is highly statistically insignificant. The 95% Wald confidence interval for the odds ratio for Hyper is (0.677, 2.965), which contains unity with a $p$-value greater than 0.3.
Exact Analysis Using the STRATA Statement

When you believe there is not enough data or that the data are too sparse, you can perform a stratified exact conditional logistic regression. The following statements perform stratified exact conditional logistic regressions on the original data set by specifying both the STRATA and EXACT statements.

```
proc logistic data=Data1 exactonly;
   strata ID;
   model outcome(event='1')=Gall;
   exact Gall / estimate=both;
run;
```

```
proc logistic data=Data1 exactonly;
   strata ID;
   model outcome(event='1')=Gall Hyper;
   exact Gall Hyper / jointonly estimate=both;
run;
```

Note that the score statistics in the “Conditional Exact Tests” tables in Output 42.10.3 and Output 42.10.4 are identical to the score statistics in the conditional analyses in Output 42.10.1 and Output 42.10.2, respectively. The exact odds ratio confidence intervals are much wider than their conditional analysis counterparts, but the parameter estimates are similar. The exact analyses confirm the marginal significance of Gall and the insignificance of Hyper as predictor variables.

Conditional Analysis Using Transformed Data

When each matched set consists of one event and one nonevent, the conditional likelihood is given by

$$\prod_i (1 + \exp(-\beta' (x_{i1} - x_{i0})))^{-1}$$

where $x_{i1}$ and $x_{i0}$ are vectors representing the prognostic factors for the event and nonevent, respectively, of the $i$th matched set. This likelihood is identical to the likelihood of fitting a logistic regression model to a set of data with constant response, where the model contains no intercept term and has explanatory variables given by $d_i = x_{i1} - x_{i0}$ (Breslow 1982).
To apply this method, each matched pair is transformed into a single observation, where the variables $G_{all}$ and $Hyper$ contain the differences between the corresponding values for the case and the control (case $-$ control). The variable $Outcome$, which will be used as the response variable in the logistic regression model, is given a constant value of 0 (which is the $Outcome$ value for the control, although any constant, numeric or character, will do).

```sas
data Data2;
    set Data1;
    drop id1 gall1 hyper1;
    retain id1 gall1 hyper1 0;
    if (ID = id1) then do;
        Gall=gall1-Gall; Hyper=hyper1-Hyper;
        output;
    end;
    else do;
        id1=ID; gall1=Gall; hyper1=Hyper;
    end;
run;
```

Note that there are 63 observations in the data set, one for each matched pair. The variable $Outcome$ has a constant value of 0.

In the following SAS statements, PROC LOGISTIC is invoked with the NOINT option to obtain the conditional logistic model estimates. Because the option CLODDS=PL is specified, PROC LOGISTIC computes a 95% profile likelihood confidence interval for the odds ratio for each predictor variable; note that profile likelihood confidence intervals are not currently available when a STRATA statement is specified.

```sas
proc logistic data=Data2;
    model outcome=Gall / noint clodds=PL;
run;
```

```sas
proc logistic data=Data2;
    model outcome=Gall Hyper / noint clodds=PL;
run;
```

The results are not displayed here.

**Exact Analysis Using Transformed Data**

Sometimes the original data set in a matched-pairs study may be too large for the exact methods to handle. In such cases it may be possible to use the transformed data set. The following code performs exact conditional logistic regressions on the transformed data set. The results are not displayed here.
Example 42.11. Complementary Log-Log Model for Infection Rates

Antibodies produced in response to an infectious disease like malaria remain in the body after the individual has recovered from the disease. A serological test detects the presence or absence of such antibodies. An individual with such antibodies is termed seropositive. In areas where the disease is endemic, the inhabitants are at fairly constant risk of infection. The probability of an individual never having been infected in $Y$ years is $\exp(-\mu Y)$, where $\mu$ is the mean number of infections per year (refer to the appendix of Draper, Voller, and Carpenter 1972). Rather than estimating the unknown $\mu$, it is of interest to epidemiologists to estimate the probability of a person living in the area being infected in one year. This infection rate $\gamma$ is given by

$$\gamma = 1 - e^{-\mu}$$

The following statements create the data set `sero`, which contains the results of a serological survey of malarial infection. Individuals of nine age groups (`Group`) were tested. Variable `A` represents the midpoint of the age range for each age group. Variable `N` represents the number of individuals tested in each age group, and variable `R` represents the number of individuals that are seropositive.

```plaintext
data sero;
  input Group A N R;
  X=log(A);
  label X='Log of Midpoint of Age Range';
datalines;
1  1.5 123 8
2  4.0 132 6
3  7.5 182 18
4 12.5 140 14
5 17.5 138 20
6 25.0 161 39
7 35.0 133 19
8 47.0 92 25
9 60.0 74 44
;```

For the $i$th group with age midpoint $A_i$, the probability of being seropositive is $p_i = 1 - \exp(-\mu A_i)$. It follows that

$$\log(-\log(1 - p_i)) = \log(\mu) + \log(A_i)$$
By fitting a binomial model with a complementary log-log link function and by using $X=\log(A)$ as an offset term, you can estimate $\beta_0 = \log(\mu)$ as an intercept parameter. The following SAS statements invoke PROC LOGISTIC to compute the maximum likelihood estimate of $\beta_0$. The `LINK=CLOGLOG` option is specified to request the complementary log-log link function. Also specified is the `CLPARM=PL` option, which requests the profile likelihood confidence limits for $\beta_0$.

```
proc logistic data=sero;
   model R/N= / offset=X
       link=cloglog
       clparm=pl
       scale=none;
   title 'Constant Risk of Infection';
run;
```

Results of fitting this constant risk model are shown in Output 42.11.1. The maximum likelihood estimate of $\beta_0 = \log(\mu)$ and its estimated standard error are $\hat{\beta}_0 = -4.6605$ and $\hat{\sigma}_{\beta_0} = 0.0725$, respectively. The infection rate is estimated as

$$\hat{\gamma} = 1 - e^{-\hat{\mu}} = 1 - e^{-e^{\hat{\beta}_0}} = 1 - e^{-e^{-4.6605}} = 0.00942$$

The 95% confidence interval for $\gamma$, obtained by back-transforming the 95% confidence interval for $\beta_0$, is (0.0082, 0.0108); that is, there is a 95% chance that, in repeated sampling, the interval of 8 to 11 infections per thousand individuals contains the true infection rate. 

The goodness of fit statistics for the constant risk model are statistically significant ($p < 0.0001$), indicating that the assumption of constant risk of infection is not correct. You can fit a more extensive model by allowing a separate risk of infection for each age group. Suppose $\mu_i$ is the mean number of infections per year for the $i$th age group. The probability of seropositive for the $i$th group with age midpoint $A_i$ is $p_i = 1 - \exp(-\mu_i A_i)$, so that

$$\log(-\log(1 - p_i)) = \log(\mu_i) + \log(A_i)$$

In the following statements, a complementary log-log model is fit containing Group as an explanatory classification variable with the GLM coding (so that a dummy variable is created for each age group), no intercept term, and $X=\log(A)$ as an offset.
term. The ODS OUTPUT statement saves the estimates and their 95% profile likelihood confidence limits to ClparmPL data set. Note that \( \log(\mu_i) \) is the regression parameter associated with Group = \( i \).

</table>

Results of fitting the model with a separate risk of infection are shown in **Output 42.11.2**. For the first age group (Group=1), the point estimate of \( \log(\mu_1) \) is \(-3.1048\), which transforms into an infection rate of \( 1 - \exp(-\exp(-3.1048)) = 0.0438 \). A 95% confidence interval for this infection rate is obtained by transforming the 95% confidence interval for \( \log(\mu_1) \). For the first age group, the lower and upper confidence limits are \( 1 - \exp(-\exp(-3.8880)) = 0.0203 \) and \( 1 - \exp(-\exp(-2.4833)) = 0.0801 \), respectively; that is, there is a 95% chance that, in repeated sampling, the interval of 20 to 80 infections per thousand individuals contains the true infection rate.
The following statements perform this transformation on the estimates and confidence limits saved in the ClparmPL data set; the resulting estimated infection rates in one year’s time for each age group are displayed in Table 42.5. Note that the infection rate for the first age group is high compared to the other age groups.

```sas
data ClparmPL;
    set ClparmPL;
    Estimate=round( 1000*( 1-exp(-exp(Estimate)) ) );
    LowerCL =round( 1000*( 1-exp(-exp(LowerCL)) ) );
    UpperCL =round( 1000*( 1-exp(-exp(UpperCL)) ) );
run;
```

Table 42.5. Infection Rate in One Year

Example 42.12. Complementary Log-Log Model for Interval-Censored Survival Times

Often survival times are not observed more precisely than the interval (for instance, a day) within which the event occurred. Survival data of this form are known as grouped or interval-censored data. A discrete analogue of the continuous proportional hazards model (Prentice and Gloeckler 1978; Allison 1982) is used to investigate the relationship between these survival times and a set of explanatory variables.

Suppose \( T_i \) is the discrete survival time variable of the \( i \)th subject with covariates \( \mathbf{x}_i \). The discrete-time hazard rate \( \lambda_{it} \) is defined as

\[
\lambda_{it} = \Pr(T_i = t \mid T_i \geq t, \mathbf{x}_i), \quad t = 1, 2, \ldots
\]

Using elementary properties of conditional probabilities, it can be shown that

\[
\Pr(T_i = t) = \lambda_{it} \prod_{j=1}^{t-1} (1 - \lambda_{ij}) \quad \text{and} \quad \Pr(T_i > t) = \prod_{j=1}^{t} (1 - \lambda_{ij})
\]
Suppose \( t_i \) is the observed survival time of the \( i \)th subject. Suppose \( \delta_i = 1 \) if \( T_i = t_i \) is an event time and 0 otherwise. The likelihood for the grouped survival data is given by

\[
L = \prod_i \left[ \Pr(T_i = t_i) \delta_i \right] \left[ \Pr(T_i > t_i) \right]^{1-\delta_i} \\
= \prod_i \left( \frac{\lambda_{it_i}}{1 - \lambda_{it_i}} \right)^{\delta_i} \prod_j (1 - \lambda_{ij}) \\
= \prod_i \prod_j \left( \frac{\lambda_{ij}}{1 - \lambda_{ij}} \right)^{y_{ij}} (1 - \lambda_{ij})
\]

where \( y_{ij} = 1 \) if the \( i \)th subject experienced an event at time \( T_i = j \) and 0 otherwise.

Note that the likelihood \( L \) for the grouped survival data is the same as the likelihood of a binary response model with event probabilities \( \lambda_{ij} \). If the data are generated by a continuous-time proportional hazards model, Prentice and Gloeckler (1978) have shown that

\[
\lambda_{ij} = 1 - \exp(-\exp(\alpha_j + \beta' x_i))
\]

where the coefficient vector \( \beta \) is identical to that of the continuous-time proportional hazards model, and \( \alpha_j \) is a constant related to the conditional survival probability in the interval defined by \( T_i = j \) at \( x_i = 0 \). The grouped data survival model is therefore equivalent to the binary response model with complementary log-log link function. To fit the grouped survival model using PROC LOGISTIC, you must treat each discrete time unit for each subject as a separate observation. For each of these observations, the response is dichotomous, corresponding to whether or not the subject died in the time unit.

Consider a study of the effect of insecticide on flour-beetles. Four different concentrations of an insecticide were sprayed on separate groups of flour-beetles. The numbers of male and female flour-beetles dying in successive intervals were saved in the data set beetles.

```plaintext
data beetles(keep=time sex conc freq);
  input time m20 f20 m32 f32 m50 f50 m80 f80;
  conc=.20;

14 101 126 19 47 7 17 2 4
;

The data set beetles contains four variables: time, sex, conc, and freq. time represents the interval death time; for example, time=2 is the interval between day 1 and day 2. Insects surviving the duration (13 days) of the experiment are given a time value of 14. The variable sex represents the sex of the insects (1=male, 2=female), conc represents the concentration of the insecticide (mg/cm²), and freq represents the frequency of the observations.

To use PROC LOGISTIC with the grouped survival data, you must expand the data so that each beetle has a separate record for each day of survival. A beetle that died in the third day (time=3) would contribute three observations to the analysis, one for each day it was alive at the beginning of the day. A beetle that survives the 13-day duration of the experiment (time=14) would contribute 13 observations.

A new data set days that contains the beetle-day observations is created from the data set beetles. In addition to the variables sex, conc and freq, the data set contains an outcome variable y and 13 indicator variables day1, day2, ..., day13. y has a value of 1 if the observation corresponds to the day that the beetle died and a value of 0 otherwise. An observation for the first day will have a value of 1 for day1 and a value of 0 for day2–day13; an observation for the second day will have a value of 1 for day2 and a value of 0 for day1 and day2–day13. For instance, Output 42.12.1 shows an observation in the beetles data set with time=3, and Output 42.12.2 shows the corresponding beetle-day observations in the data set days.
Example 42.12. Complementary Log-Log Model for Interval-Censored Survival Times

```sas
data days;
    retain day1-day13 0;
    array dd[13] day1-day13;
    set beetles;
    if time = 14 then do day=1 to 13;
        y=0; dd[day]=1;
        output;
        dd[day]=0;
    end;
    else do day=1 to time;
        if day=time then y=1;
        else y=0;
        dd[day]=1;
        output;
        dd[day]=0;
    end;

The following SAS statements invoke PROC LOGISTIC to fit a complementary log-log model for binary data with response variable Y and explanatory variables day1–day13, sex, and conc. Specifying the EVENT= option ensures that the event (Y=1) probability is modeled. The coefficients of day1–day13 can be used to estimate the baseline survival function. The NOINT option is specified to prevent any redundancy in estimating the coefficients of day1–day13. The Newton-Raphson algorithm is used for the maximum likelihood estimation of the parameters.

```sas
proc logistic data=days outest=est1;
    model y(event='1')= day1-day13 sex conc
        / noint link=cloglog technique=newton;
    freq freq;
run;
```

</table>

Results of the model fit are given in Output 42.12.3. Both sex and conc are statistically significant for the survival of beetles sprayed by the insecticide. Female beetles are more resilient to the chemical than male beetles, and increased concentration increases the effectiveness of the insecticide.

The coefficients of day1−day13 are the maximum likelihood estimates of $\alpha_1, \ldots, \alpha_{13}$, respectively. The baseline survivor function $S_0(t)$ is estimated by

$$\hat{S}_0(t) = \bar{F}(T > t) = \prod_{j \leq t} \exp(-\exp(\hat{\alpha}_j))$$

and the survivor function for a given covariate pattern (sex=$x_1$ and conc=$x_2$) is estimated by

$$y\hat{S}(t) = [\hat{S}_0(t)]^{\exp(-0.5651x_1 + 3.0918x_2)}$$
The following statements compute the survivor curves for male and female flour-beetles exposed to the insecticide of concentrations 0.20 mg/cm² and 0.80 mg/cm². The GPLOT procedure in SAS/GRAPH software is used to plot the survival curves. Instead of plotting them as step functions, the SPLINE option is used to smooth the curves. These smoothed survival curves are displayed in Output 42.12.4.

```
proc gplot data=one;
  plot (s_m20 s_f20 s_m80 s_f80) * day
    / overlay legend=legend1 vaxis=axis1;
  symbol1 v=circle i=spline c=black height=.8;
  symbol2 v=diamond i=spline c=black height=.8;
  symbol3 v=triangle i=spline c=black height=.8;
  symbol4 v=square i=spline c=black height=.8;
run;
```

The probability of survival is displayed on the vertical axis. Notice that most of the insecticide effect occurs by day 6 for both the high and low concentrations.

**Output 42.12.4.** Predicted Survival at Concentrations of 0.20 and 0.80 mg/cm²
Example 42.13. Scoring Data Sets with the SCORE Statement

This example first illustrates the syntax used for scoring data sets, then uses a previously scored data set to score a new data set. A generalized logit model is fit to the remote-sensing data set used in Example 25.4 on page 1231 of Chapter 25, “The DISCRIM Procedure,” to illustrate discrimination and classification methods. The response variable is Crop and the prognostic factors are x1 through x4.

```sas
data Crops;
  length Crop $ 10;
  infile datalines truncover;
  input Crop $ @@;
  do i=1 to 3;
    input x1-x4 @@;
    if (x1 ^= .) then output;
  end;
  input;
  datalines;
Corn    16 27 31 33 15 23 30 30 16 27 27 26
Corn    18 20 25 23 15 15 31 32 15 32 32 15
Corn    12 15 16 73
Soybeans 20 23 23 25 24 24 25 32 21 25 23 24
Soybeans 27 45 24 12 12 13 15 42 22 32 31 43
Cotton   31 32 33 34 29 24 26 28 34 32 28 45
Cotton   26 25 23 24 53 48 75 26 34 35 25 78
Sugarbeets 22 23 25 42 25 25 24 26 34 25 16 52
Sugarbeets 54 23 21 54 25 43 32 15 26 54 2 54
Clover   12 45 32 54 24 58 25 34 87 54 61 21
Clover   51 31 31 16 96 48 54 62 31 31 11 11
Clover   56 13 13 71 32 13 27 32 36 26 54 32
Clover   53 08 06 54 32 32 62 16;
```

You can specify a SCORE statement to score the Crops data using the fitted model. The data together with the predicted values are saved into the data set Score1.

```sas
proc logistic data=Crops;
  model Crop=x1-x4 / link=glogit;
  score out=Score1;
run;
```

The OUTMODEL= option saves the fitted model information in a data set. In the following statements, the model is again fit, the data and the predicted values are saved into the data set Score2, and the model information is saved in the permanent SAS data set sasuser.CropModel.

```sas
proc logistic data=Crops outmodel=sasuser.CropModel;
  model Crop=x1-x4 / link=glogit;
  score data=Crops out=Score2;
run;
```
Example 42.13. Scoring Data Sets with the SCORE Statement ♦ 2463

To score data without refitting the model, specify the INMODEL= option to identify a previously saved SAS data set of model information. In the following statements, the model is read from the `sasuser.CropModel` data set, and the data and the predicted values are saved into the data set `Score3`.

```
proc logistic inmodel=sasuser.CropModel;
   score data=Crops out=Score3;
run;
```

To set prior probabilities on the responses, specify the PRIOR= option to identify a SAS data set containing the response levels and their priors. In the following statements, the `Prior` data set contains the values of the response variable (because this example uses single-trial MODEL syntax) and a `_PRIOR_` variable containing values proportional to the default priors. The model is fit, then the data and the predicted values are saved into the data set `Score4`.

```
data Prior;
   input Crop $ 1-10 _PRIOR_;
   datalines;
      Clover 11
      Corn 7
      Cotton 6
      Soybeans 6
      Sugarbeets 6
;  
proc logistic inmodel=sasuser.CropModel;
   score data=Crops prior=prior out=Score4;
run;
```

The data sets `Score1`, `Score2`, `Score3`, and `Score4` are identical. The following statements display the results of scoring the `Crops` data set in Output 42.13.1.

```
proc freq data=Score1;
   table F_Crop*I_Crop / nocol nocum nopercent;
run;
```

Chapter 43
The MDS Procedure

Overview

Multidimensional scaling (MDS) is a class of methods that estimates the coordinates of a set of objects in a space of specified dimensionality that come from data measuring the distances between pairs of objects. A variety of models can be used that include different ways of computing distances and various functions relating the distances to the actual data. The MDS procedure fits two- and three-way, metric and nonmetric multidimensional scaling models. PROC MDS shares many of the features of the ALSCAL procedure (Young, Lewyckyj, and Takane 1986; Young 1982), as well as some features of the MLSCALE procedure (Ramsay 1986). Both PROC ALSCAL and PROC MLSCALE are described in the SUGI Supplemental Library User’s Guide, Version 5 Edition.

The data for the MDS procedure consist of one or more square symmetric or asymmetric matrices of similarities or dissimilarities between objects or stimuli (Kruskal and Wish 1978, pp. 7–11). Such data are also called proximity data. In psychometric applications, each matrix typically corresponds to a subject, and models that fit different parameters for each subject are called individual difference models.

Missing values are allowed. In particular, if the data are all missing except within some off-diagonal rectangle, the analysis is called unfolding. There are, however, many difficulties intrinsic to unfolding models (Heiser, 1981). PROC MDS does not perform external unfolding; for analyses requiring external unfolding, use the TRANSREG procedure instead.

The MDS procedure estimates the following parameters by nonlinear least squares:

- **configuration**: the coordinates of each object in a Euclidean (Kruskal and Wish 1978, pp. 17–19) or weighted Euclidean space (Kruskal and Wish 1978, pp. 61–63) of one or more dimensions

- **dimension coefficients**: for each data matrix, the coefficients that multiply each coordinate of the common or group weighted Euclidean space to yield the individual unweighted Euclidean space. These coefficients are the square roots of the subject weights (Kruskal and Wish 1978, pp. 61–63). A plot of the dimension coefficients is directly interpretable in that it shows how a unit square in the group space is transformed to a rectangle in each individual space. A plot of subject weights has no such simple interpretation. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).
transformation parameters

Depending on the LEVEL= option, PROC MDS fits either a regression model of the form

\[
fit(datum) = fit(trans(distance)) + error
\]

or a measurement model of the form

\[
fit(trans(datum)) = fit(distance) + error
\]

where

- \(fit\) is a predetermined power or logarithmic transformation specified by the FIT= option.
- \(trans\) is an estimated (“optimal”) linear, affine, power, or monotone transformation specified by the LEVEL= option.
- \(datum\) is a measure of the similarity or dissimilarity of two objects or stimuli.
- \(distance\) is a distance computed from the estimated coordinates of the two objects and estimated dimension coefficients in a space of one or more dimensions. If there are no dimension coefficients (COEF=IDENTITY), this is an unweighted Euclidean distance. If dimension coefficients are used (COEF=DIAGONAL), this is a weighted Euclidean distance where the weights are the squares of the dimension coefficients; alternatively, you can multiply each dimension by its coefficient and compute an unweighted Euclidean distance.
- \(error\) is an error term assumed to have an approximately normal distribution and to be independently and identically distributed for all data. Under these assumptions, least-squares estimation is statistically appropriate.

For an introduction to multidimensional scaling, refer to Kruskal and Wish (1978) and Arabie, Carroll, and DeSarbo (1987). A more advanced treatment is given by Young (1987). Many practical issues of data collection and analysis are discussed in Schiffman, Reynolds, and Young (1981). The fundamentals of psychological measurement, including both unidimensional and multidimensional scaling, are expounded by Torgerson (1958). Nonlinear least-squares estimation of PROC MDS models is discussed in Null and Sarle (1982).
The simplest application of PROC MDS is to reconstruct a map from a table of distances between points on the map (Kruskal and Wish 1978, pp. 7–9). For example, the following DATA step reads a table of flying mileages between ten U.S. cities:

```plaintext
data city;
  title 'Analysis of Flying Mileages Between Ten U.S. Cities';
  input (atlanta chicago denver houston losangeles miami newyork sanfran seattle washdc) (5.) @56 city $15.;
  datalines;
    0 Atlanta
    587 0 Chicago
   1212 920 0 Denver
    701 940 879 0 Houston
   1936 1745 831 1374 0 Los Angeles
    604 1188 1726 968 2339 0 Miami
    748 713 1631 1420 2451 1092 0 New York
   2139 1858 949 1645 347 2594 2571 0 San Francisco
   2182 1737 1021 1891 959 2734 2408 678 0 Seattle
    543 597 1494 1220 2300 923 205 2442 2329 0 Washington D.C.
;```

Since the flying mileages are very good approximations to Euclidean distance, no transformation is needed to convert distances from the model to data. The analysis can therefore be done at the absolute level of measurement, as displayed in the following PROC MDS step (LEVEL=ABSOLUTE). An output data set containing the estimated configuration (coordinates on the map) is created with the OUT= option and then used to display the map using the %PLOTIT macro. The ID statement copies the names of the cities to the OUT= data set so that they can be used on the plot. The following statements produce Figure 43.1:

```plaintext
proc mds data=city level=absolute out=out;
  id city;
run;
```

By default, PROC MDS displays only the iteration history. In this example, only one iteration is required. The badness-of-fit criterion 0.001689 indicates that the data fit the model extremely well.
Analysis of Flying Mileages Between Ten U.S. Cities

Multidimensional Scaling:

Convergence criterion is satisfied.

Figure 43.1. Iteration History from PROC MDS

In order for the plot to represent the geometry of the configuration correctly, the axes must be scaled so that a given physical distance on one axis represents the same number of units as the same physical distance on the other axis. You can use the %PLOTIT macro to obtain such a scaling by specifying the VTOH= option. The VTOH= option indicates the ratio of the vertical distance between lines to the horizontal distance between characters; obtaining a suitable value may require some experimentation. The %PLOTIT macro can create graphical scatter plots with iteratively derived optimal label placement. See Appendix B, “Using the %PLOTIT Macro,” for more information on the %PLOTIT macro.

The following statements produce Figure 43.2:

```
%plotit(data=out, datatype=mds, labelvar=city,
       vtoh=1.75, labfont=swissb);
run;
```

While PROC MDS can recover the relative positions of the cities, it cannot determine absolute location or orientation. In this case, north is toward the bottom of the plot.
You can specify the following statements with the MDS procedure:

```
PROC MDS < options > ;
   VAR variables ;
   INVAR variables ;
   ID | OBJECT variable ;
   MATRIX | SUBJECT variable ;
   WEIGHT variables ;
   BY variables ;
```

The PROC MDS statement is required. All other statements are optional.
PROC MDS Statement

PROC MDS < options > ;

By default, the only result produced by the MDS procedure is the iteration history. Hence, you should always specify one or more options for output data sets (OUT=, OUTFIT=, and OUTRES=) or displayed output (such as PFINAL). PROC MDS does not produce any plots; to produce plots, use the output data sets with PROC PLOT or PROC GPLOT.

The types of estimates written to the OUT= data set are determined by the OCONFIG, OCOEF, OTRANS, and OCRIT options. If you do not specify any of these four options, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion appear in the OUT= data set. If you specify one or more of these options, only the information requested by the specified options appear in the OUT= data set. Also, the OITER option causes these statistics to be written to the OUT= data set after initialization and on each iteration, as well as after the iterations have terminated.

Displayed output is controlled by the interaction of the PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options with the PININ, PINIT, PITER, and PFINAL options. The PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options specify which estimates and fit statistics are to be displayed. The PININ, PINIT, PITER, and PFINAL options specify when the estimates and fit statistics are to be displayed. If you specify at least one of the PCONFIG, PCOEF, PTRANS, PFIT and PFITROW options but none of the PININ, PINIT, PITER, and PFINAL options, the final results (PFINAL) are displayed. If you specify at least one of the PININ, PINIT, PITER, and PFINAL options but none of the PCONFIG, PCOEF, PTRANS, PFIT and PFITROW options, all estimates (PCONFIG, PCOEF, PTRANS) and the fit statistics for each matrix and for the entire sample (PFIT) are displayed. If you do not specify any of these nine options, no estimates or fit statistics are displayed (except the badness-of-fit criterion in the iteration history).

**ALTERNATE | ALT=NONE | NO | N**
**ALTERNATE | ALT=MATRIX | MAT | M | SUBJECT | SUB | S**
**ALTERNATE | ALT=ROW | R <n>**

determines what form of alternating-least-squares algorithm is used. The default depends on the amount of memory available. The following ALTERNATE= options are listed in order of decreasing memory requirements:

ALT=NONE causes all parameters to be adjusted simultaneously on each iteration. This option is usually best for a small number of subjects and objects.

ALT=MATRIX adjusts all the parameters for the first subject, then all the parameters for the second subject, and so on, and finally adjusts all parameters that do not correspond to a subject, such as coordinates and unconditional transformations. This option usually works best for a large number of subjects with a small number of objects.
ALT=ROW treats subject parameters the same way as the ALTERNATE=MATRIX option but also includes separate stages for unconditional parameters and for subsets of the objects. The ALT=ROW option usually works best for a large number of objects.

Specifying ALT=ROW=n divides the objects into subsets of n objects each, except possibly for one subset when n does not divide the number of objects evenly. If you omit =n, the number of objects in the subsets is determined from the amount of memory available. The smaller the value of n, the less memory is required.

When you specify the LEVEL=ORDINAL option, the monotone transformation is always computed in a separate stage and is listed as a separate iteration in the iteration history. In this case, estimation is done by iteratively reweighted least squares. The weights are recomputed according to the FORMULA= option on each monotone iteration; hence, it is possible for the badness-of-fit criterion to increase after a monotone iteration.

COEF=IDENTITY | IDEN | I
COEF=DIAGONAL | DIAG | D
specifies the type of matrix for the dimension coefficients.

COEF=IDENTITY is the default, which yields Euclidean distances.
COEF=DIAGONAL produces weighted Euclidean distances, in which each subject is allowed differential weights for the dimensions. The dimension coefficients that PROC MDS outputs are related to the square roots of what are called subject weights in PROC ALSCAL; the normalization in PROC MDS also differs from that in PROC ALSCAL. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).

CONDITION | COND=UN | U
CONDITION | COND=MATRIX | MAT | M | SUBJECT | SUB | S
CONDITION | COND=ROW | R
specifies the conditionality of the data (Young 1987, pp. 60–63). The default is CONDITION=MATRIX.

The data are divided into disjoint subsets called partitions. Within each partition, a separate transformation is applied, as specified by the LEVEL= option.

COND=UN puts all the data into a single partition.
COND=MATRIX makes each data matrix a partition.
COND=ROW makes each row of each data matrix a partition.
The CONDITION= option also determines the default value for the SHAPE= option. If you specify the CONDITION=ROW option and omit the SHAPE= option, each data matrix is stored as a square and possibly asymmetric matrix. If you specify the CONDITION=UN or CONDITION=MATRIX option and omit the SHAPE= option, only one triangle is stored. See the SHAPE= option on page 2484 for details.

**CONVERGE | CONV=p**

Sets both the gradient convergence criterion and the monotone convergence criterion to \( p \), where \( 0 \leq p \leq 1 \). The default is CONVERGE=0.01; smaller values may greatly increase the number of iterations required. Values less than .0001 may be impossible to satisfy because of the limits of machine precision. See the GCONVERGE= (page 2480) and MCONVERGE= (page 2481) options.

**CUTOFF=n**

Causes data less than \( n \) to be replaced by missing values. The default is CUTOFF=0.

**DATA=SAS-data-set**

Specifies the SAS data set containing one or more square matrices to be analyzed. In typical psychometric data, each matrix contains judgments from one subject, so there is a one-to-one correspondence between data matrices and subjects.

The data matrices contain similarity or dissimilarity measurements to be modeled and, optionally, weights for these data. The data are generally assumed to be dissimilarities unless you use the SIMILAR option. However, if there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values, the data are assumed to be similarities and are treated as if the SIMILAR option is specified. The diagonal elements are not otherwise used in fitting the model.

Each matrix must have exactly the same number of observations as the number of variables specified by the VAR statement or determined by defaults. This number is the number of objects or stimuli.

The first observation and variable are assumed to contain data for the first object, the second observation and variable are assumed to contain data for the second object, and so on.

When there are two or more matrices, the observations in each matrix must correspond to the same objects in the same order as in the first matrix.

The matrices can be symmetric or asymmetric, as specified by the SHAPE= option.

**DECIMALS | DEC=n**

Specifies how many decimal places to use when displaying the parameter estimates and fit statistics. The default is DECIMALS=2, which is generally reasonable except in conjunction with the LEVEL=ABSOLUTE option and very large or very small data.

**DIMENSION | DIMENS | DIM=n TO m BY=i >**

Specifies the number of dimensions to use in the MDS model, where \( 1 \leq n, m < \text{number of objects} \). The parameter \( i \) can be either positive or negative but not zero. If you specify different values for \( n \) and \( m \), a separate model is fitted for each requested dimension. If you specify only DIMENSION=n, then only \( n \) dimensions are
fitted. The default is DIMENSION=2 if there are three or more objects; otherwise, DIMENSION=1 is the only valid specification. The analyses for each number of dimensions are done independently. For information on choosing the dimensionality, refer to Kruskal and Wish (1978, pp. 48–60).

**EPSILON | EPS=n**

specifies a number \( n, \ 0 < n < 1 \), that determines the amount added to squared distances computed from the model to avoid numerical problems such as division by 0. This amount is computed as \( \epsilon \) equal to \( n \) times the mean squared distance in the initial configuration. The distance in the MDS model is thus computed as

\[
\text{distance} = \sqrt{\text{sqdist} + \epsilon}
\]

where \( \text{sqdist} \) is the squared Euclidean distance or the weighted squared Euclidean distance.

The default is EPSILON=1E−12, which is small enough to have no practical effect on the estimates unless the FIT= value is nonpositive and there are dissimilarities that are very close to 0. Hence, when the FIT= value is nonpositive, dissimilarities less than \( n \) times 100 times the maximum dissimilarity are disallowed.

**FIT=DISTANCE | DIS | D**

**FIT=SQUARED | SQU | S**

**FIT=LOG | L**

**FIT=n**

specifies a predetermined (not estimated) transformation to apply to both sides of the MDS model before the error term is added.

The default is FIT=DISTANCE or, equivalently, FIT=1, which fits data to distances.

The option FIT=SQUARED or FIT=2 fits squared data to squared distances. This gives greater importance to large data and distances and lesser importance to small data and distances in fitting the model.

The FIT=LOG or FIT=0 option fits log data to log distances. This gives lesser importance to large data and distances and greater importance to small data and distances in fitting the model.

In general, the FIT=n option fits \( n \)th-power data to \( n \)th-power distances. Values of \( n \) that are large in absolute value can cause floating-point overflows.

If the FIT= value is 0 or negative, the data must be strictly positive (see the EPSILON= option). Negative data may produce strange results with any value other than FIT=1.

**FORMULA | FOR=0 | OLS | O**

**FORMULA | FOR=1 | USS | U**

**FORMULA | FOR=2 | CSS | C**

determines how the badness-of-fit criterion is standardized in correspondence with stress formulas 1 and 2 (Kruskal and Wish 1978, pp. 24–26). The default is FORMULA=1 unless you specify FIT=LOG, in which case the default is FORMULA=2. Data partitions are defined by the CONDITION= option.
**FORMULA=0**
fits a regression model by ordinary least squares (Null and Sarle 1982) without standardizing the partitions; this option cannot be used with the LEVEL=ORDINAL option. The badness-of-fit criterion is the square root of the error sum of squares.

**FORMULA=1**
standardizes each partition by the uncorrected sum of squares of the (possibly transformed) data; this option should not be used with the FIT=LOG option. With the FIT=DISTANCE and LEVEL=ORDINAL options, this is equivalent to Kruskal’s stress formula 1 or an obvious generalization thereof. With the FIT=SQUARED and LEVEL=ORDINAL options, this is equivalent to Young’s s-stress formula 1 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where $R$ is a multiple correlation about the origin.

**FORMULA=2**
standardizes each partition by the corrected sum of squares of the (possibly transformed) data; this option is the recommended method for unfolding. With the FIT=DISTANCE and LEVEL=ORDINAL options, this is equivalent to Kruskal’s stress formula 2 or an obvious generalization thereof. With the FIT=SQUARED and LEVEL=ORDINAL options, this is equivalent to Young’s s-stress formula 2 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where $R$ is a multiple correlation computed with a denominator corrected for the mean.

**GCONV,** **GCONVERGE**
sets the gradient convergence criterion to $p$, where $0 \leq p \leq 1$. The default is GCONVERGE=0.01; smaller values may greatly increase the number of iterations required. Values less than 0.0001 may be impossible to satisfy because of the limits of machine precision.

The gradient convergence measure is the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean. See the CONVERGE= (page 2478) and MCONVERGE= (page 2481) options.

**INAV=DATA | D**
**INAV=SSCP | S**
affects the computation of initial coordinates. The default is INAV=DATA.

**INAV=DATA**
computes a weighted average of the data matrices. Its value is estimated only if an element is missing from every data matrix. The weighted average of the data matrices with missing values filled in is then converted to a scalar products matrix (or what would be a scalar products matrix if the fit were perfect), from which the initial coordinates are computed.

**INAV=SSCP**
estimates missing values in each data matrix and converts each data matrix to a scalar products matrix. The initial coordinates are computed from the unweighted average of the scalar products matrices.
INITIAL | IN=SAS-data-set
specifies a SAS data set containing initial values for some or all of the parameters of the MDS model. If the INITIAL= option is omitted, the initial values are computed from the data.

LEVEL=ABSOLUTE | ABS | A
LEVEL=RATIO | RAT | R
LEVEL=INTERVAL | INT | I
LEVEL=LOGINTERVAL | LOG | L
LEVEL=ORDINAL | ORD | O
specifies the measurement level of the data and hence the type of estimated (optimal) transformations applied to the data or distances (Young 1987, pp. 57–60; Krantz et. al. 1971, pp. 9–12) within each partition as specified by the CONDITION= option. LEVEL=ORDINAL specifies a nonmetric analysis, while all other LEVEL= options specify metric analyses. The default is LEVEL=ORDINAL.

LEVEL=ABSOLUTE allows no optimal transformations. Hence, the distinction between regression and measurement models is irrelevant.

LEVEL=RATIO fits a regression model in which the distances are multiplied by a slope parameter in each partition (a linear transformation). In this case, the regression model is equivalent to the measurement model with the slope parameter reciprocated.

LEVEL=INTERVAL fits a regression model in which the distances are multiplied by a slope parameter and added to an intercept parameter in each partition (an affine transformation). In this case, the regression and measurement models differ if there is more than one partition.

LEVEL=LOGINTERVAL fits a regression model in which the distances are raised to a power and multiplied by a slope parameter in each partition (a power transformation).

LEVEL=ORDINAL fits a measurement model in which a least-squares monotone increasing transformation is applied to the data in each partition. At the ordinal measurement level, the regression and measurement models differ.

MAXITER | ITER=n
specifies the maximum number of iterations, where $n \geq 0$. The default is MAXITER=100.

MCONVERGE | MCONV=p
sets the monotone convergence criterion to $p$, where $0 \leq p \leq 1$, for use with the LEVEL=ORDINAL option. The default is MCONVERGE=0.01; if you want greater precision, MCONVERGE=0.001 is usually reasonable, but smaller values may greatly increase the number of iterations required.
The monotone convergence criterion is the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions defined by the CONDITION= option. See the CONVERGE= (page 2478) and GCONVERGE= (page 2480) options.

**MINCRIT | CRITMIN=n**
causes iteration to terminate when the badness-of-fit criterion is less than or equal to \( n \), where \( n \geq 0 \). The default is MINCRIT=1E-6.

**NEGATIVE**
allows slopes or powers to be negative with the LEVEL=RATIO, INTERVAL, or LOGINTERVAL option.

**NONORM**
suppresses normalization of the initial and final estimates.

**NOPHIST | NOPRINT | NOP**
suppresses the output of the iteration history.

**NOULB**
causes missing data to be estimated during initialization by the average nonmissing value, where the average is computed according to the FIT= option. Otherwise, missing data are estimated by interpolating between the Rabinowitz (1976) upper and lower bounds.

**OCOEF**
writes the dimension coefficients to the OUT= data set. See the OUT= option for interactions with other options.

**OCONFIG**
writes the coordinates of the objects to the OUT= data set. See the OUT= option for interactions with other options.

**OCRIT**
writes the badness-of-fit criterion to the OUT= data set. See the OUT= option for interactions with other options.

**OITER | OUTITER**
writes current values to the output data sets after initialization and on every iteration. Otherwise, only the final values are written to any output data sets. See the OUT=, OUTFIT=, and OUTRES= options.

**OTRANS**
writes the transformation parameter estimates to the OUT= data set if any such estimates are computed. There are no transformation parameters with the LEVEL=ORDINAL option. See the OUT= option for interactions with other options.

**OUT=SAS-data-set**
creates a SAS data set containing, by default, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion. However, if you specify one or more of the OCONFIG, OCOEF, OTRANS, and OCRIT options, only
the information requested by the specified options appears in the OUT= data set. See also the OITER option.

**OUTFIT=SAS-data-set**
creates a SAS data set containing goodness-of-fit and badness-of-fit measures for each partition as well as for the entire data set. See also the OITER option.

**OUTRES=SAS-data-set**
creates a SAS data set containing one observation for each nonmissing datum from the DATA= data set. Each observation contains the original datum, the estimated distance computed from the MDS model, transformed data and distances, and the residual. See also the OITER option.

**OVER=n**
specifies the maximum overrelaxation factor, where \( n \geq 1 \). Values between 1 and 2 are generally reasonable. The default is OVER=2 with the LEVEL=ORDINAL, ALTERNATE=_MATRIX, or ALTERNATE=ROW option; otherwise, the default is OVER=1. Use this option only if you have convergence problems.

**PCOEFF**
produces the estimated dimension coefficients.

**PCONFIG**
produces the estimated coordinates of the objects in the configuration.

**PDATA**
displays each data matrix.

**PFNFINAL**
displays final estimates.

**PFIT**
displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each data matrix, as well as for the entire sample.

**PFITROW**
displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each row as well as for each data matrix and for the entire sample. This option works only with the CONDITION=ROW option.

**PNAVADATA**
displays the sum of the weights and the weighted average of the data matrices computed during initialization with the INAV=DATA option.

**PINEIGVAL**
displays the eigenvalues computed during initialization.

**PINEIGVEC**
displays the eigenvectors computed during initialization.
Chapter 43. The MDS Procedure

PININ displays values read from the INITIAL= data set. Since these values may be incomplete, the PFIT and PFITROW options do not apply.

PINIT displays initial values.

PITER displays estimates on each iteration.

PTRANS displays the estimated transformation parameters if any are computed. There are no transformation parameters with the LEVEL=ORDINAL option.

RANDOM <seed> causes initial coordinate values to be pseudorandom numbers. In one dimension, the pseudorandom numbers are uniformly distributed on an interval. In two or more dimensions, the pseudorandom numbers are uniformly distributed on the circumference of a circle or the surface of a (hyper)sphere.

RIDGE=n specifies the initial ridge value, where n ≥ 0. The default is RIDGE=1E−4.

If you get a floating-point overflow in the first few iterations, specify a larger value such as RIDGE=0.01 or RIDGE=1 or RIDGE=100.

If you know that the initial estimates are very good, using RIDGE=0 may speed convergence.

SHAPE=TRIANGULAR | TRIANGLE | TRI | T SHAPE=SQUARE | SQU | S determines whether the entire data matrix for each subject or only one triangle of the matrix is stored and analyzed. If you specify the CONDITION=ROW option, the default is SHAPE=SQUARE. Otherwise, the default is SHAPE=TRIANGLE.

SHAPE=SQUARE causes the entire matrix to be stored and analyzed. The matrix can be asymmetric.

SHAPE=TRIANGLE causes only one triangle to be stored. However, PROC MDS reads both upper and lower triangles to look for nonmissing values and to symmetrize the data if needed. If corresponding elements in the upper and lower triangles both contain nonmissing values, only the average of the two values is stored and analyzed (Kruskal and Wish 1978, p. 74). Also, if an OUTRES= data set is requested, only the average of the two corresponding elements is output.

SIMILAR | SIM<max> causes the data to be treated as similarity measurements rather than dissimilarities. If =max is not specified, each datum is converted to a dissimilarity by subtracting it from the maximum value in the data set or BY group. If =max is specified, each...
datum is subtracted from the maximum of \( \text{max} \) and the data. The diagonal data are included in computing these maxima.

By default, the data are assumed to be dissimilarities unless there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values. In this case, the data are assumed to be similarities and are treated as if the SIMILAR option is specified.

\[ \text{BY Statement} \]

SINGULAR=\( p \)

specifies the singularity criterion \( p, 0 \leq p \leq 1 \). The default is SINGULAR=1E−8.

UNTIE

allows tied data to be assigned different optimally scaled values with the LEVEL=ORDINAL option. Otherwise, tied data are assigned equal optimally scaled values. The UNTIE option has no effect with values of the LEVEL= option other than LEVEL=ORDINAL.

**BY Statement**

\[ \text{BY variables ;} \]

You can specify a BY statement with PROC MDS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MDS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

If the INITIAL= data set contains the BY variables, the BY groups must appear in the same order as in the DATA= data set. If the BY variables are not in the INITIAL= data set, the entire data set is used to provide initial values for each BY group in the DATA= data set.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*. 
ID Statement

```
ID | OBJECT | OBJ  variable ;
```

The ID statement specifies a variable in the DATA= data set that contains descriptive labels for the objects. The labels are used in the output and are copied to the OUT= data set. If there is more than one data matrix, only the ID values from the observations containing the first data matrix are used.

The ID variable is not used to establish any correspondence between observations and variables.

If the ID statement is omitted, the variable labels or names are used as object labels.

INVAR Statement

```
INVAR  variables ;
```

The INVAR statement specifies the numeric variables in the INITIAL= data set that contain initial parameter estimates. The first variable corresponds to the first dimension, the second variable to the second dimension, and so on.

If the INVAR statement is omitted, the variables DIM1, . . . , DIMm are used, where m is the maximum number of dimensions.

MATRIX Statement

```
MATRIX | MAT | SUBJECT | SUB  variable ;
```

The MATRIX statement specifies a variable in the DATA= data set that contains descriptive labels for the data matrices or subjects. The labels are used in the output and are copied to the OUT= and OUTRES= data sets. Only the first observation from each data matrix is used to obtain the label for that matrix.

If the MATRIX statement is omitted, the matrices are labeled 1, 2, 3, and so on.

VAR Statement

```
VAR  variables ;
```

The VAR statement specifies the numeric variables in the DATA= data set that contain similarity or dissimilarity measurements on a set of objects or stimuli. Each variable corresponds to one object.

If the VAR statement is omitted, all numeric variables that are not specified in another statement are used.

To analyze a subset of the objects in a data set, you can specify the variable names corresponding to the columns in the subset, but you must also use a DATA step or a WHERE clause to specify the rows in the subset. PROC MDS expects to read one or more square matrices, and you must ensure that the rows in the data set correctly correspond to the columns in number and order.
WEIGHT Statement

```WEIGHT variables ;
```

The WEIGHT statement specifies numeric variables in the DATA= data set that contain weights for each similarity or dissimilarity measurement. These weights are used to compute weighted least-squares estimates. The number of WEIGHT variables must be the same as the number of VAR variables, and the variables in the WEIGHT statement must be in the same order as the corresponding variables in the VAR statement.

If the WEIGHT statement is omitted, all data within a partition are assigned equal weights.

Data with 0 or negative weights are ignored in fitting the model but are included in the OUTRES= data set and in monotone transformations.

Details

Formulas

The following notation is used:

- \( A_p \) intercept for partition \( p \)
- \( B_p \) slope for partition \( p \)
- \( C_p \) power for partition \( p \)
- \( D_{rcs} \) distance computed from the model between objects \( r \) and \( c \) for subject \( s \)
- \( F_{rcs} \) data weight for objects \( r \) and \( c \) for subject \( s \) obtained from the \( c \)th WEIGHT variable, or 1 if there is no WEIGHT statement
- \( f \) value of the FIT= option
- \( N \) number of objects
- \( O_{rcs} \) observed dissimilarity between objects \( r \) and \( c \) for subject \( s \)
- \( P_{rcs} \) partition index for objects \( r \) and \( c \) for subject \( s \)
- \( Q_{rcs} \) dissimilarity after applying any applicable estimated transformation for objects \( r \) and \( c \) for subject \( s \)
- \( R_{rcs} \) residual for objects \( r \) and \( c \) for subject \( s \)
- \( S_p \) standardization factor for partition \( p \)
- \( T_p(\cdot) \) estimated transformation for partition \( p \)
- \( V_{sd} \) coefficient for subject \( s \) on dimension \( d \)
- \( X_{nd} \) coordinate for object \( n \) on dimension \( d \)

Summations are taken over nonmissing values.
Distances are computed from the model as
\[ D_{rcs} = \sqrt{\sum_d (X_{rd} - X_{cd})^2} \]
for COEF=IDENTITY:
Euclidean distance
\[ = \sqrt{\sum_d v_{sd}^2 (X_{rd} - X_{cd})^2} \]
for COEF=DIAGONAL:
weighted Euclidean distance

Partition indexes are
\[ P_{rcs} = \begin{cases} 1 & \text{for CONDITION=UN} \\ s & \text{for CONDITION=MATRIX} \\ (s - 1)N + r & \text{for CONDITION=ROW} \end{cases} \]

The estimated transformation for each partition is
\[ T_p(d) = \begin{cases} d & \text{for LEVEL=ABSOLUTE} \\ B_p d & \text{for LEVEL=RATIO} \\ A_p + B_p d & \text{for LEVEL=INTERVAL} \\ B_p d c_p & \text{for LEVEL=LOGINTERVAL} \end{cases} \]

For LEVEL=ORDINAL, \( T_p(\cdot) \) is computed as a least-squares monotone transformation.

For LEVEL=ABSOLUTE, RATIO, or INTERVAL, the residuals are computed as
\[
\begin{align*}
Q_{rcs} &= O_{rcs} \\
R_{rcs} &= Q^f_{rca} - [T_{P_{rcs}}(D_{rcs})]^f
\end{align*}
\]

For LEVEL=ORDINAL, the residuals are computed as
\[
\begin{align*}
Q_{rcs} &= T_{P_{rcs}}(O_{rcs}) \\
R_{rcs} &= Q^f_{rca} - D^f_{rcs}
\end{align*}
\]

If \( f \) is 0, then natural logarithms are used in place of the \( f \)th powers.

For each partition, let
\[
U_p = \frac{\sum_{r,c,s} F_{rcs}}{\sum_{r,c,s | P_{rcs}=p} F_{rcs}}
\]

and
\[
\overline{Q}_p = \frac{\sum_{r,c,s | P_{rcs}=p} Q_{rcs} F_{rcs}}{\sum_{r,c,s | P_{rcs}=p} F_{rcs}}
\]
Then the standardization factor for each partition is

\[
S_p = \begin{cases} 
  1 & \text{for FORMULA=0} \\
  U_p \sum_{r,c,s | P_{rcs}=p} Q_{rcs}^2 F_{rcs} & \text{for FORMULA=1} \\
  U_p \sum_{r,c,s | P_{rcs}=p} (Q_{rcs} - Q_p)^2 F_{rcs} & \text{for FORMULA=2}
\end{cases}
\]

The badness-of-fit criterion that the MDS procedure tries to minimize is

\[
\sqrt{\sum_{r,c,s} \frac{R_{rcs}^2 F_{rcs}}{S_{P_{rcs}}}}
\]

**OUT= Data Set**

The OUT= data set contains the following variables:

- **BY** variables, if any
- **_.ITER_.** (if the OUTITER option is specified), a numeric variable containing the iteration number
- **_.DIMENS_.**, a numeric variable containing the number of dimensions
- **_.MATRIX_.** or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains. This variable contains a missing value for observations that pertain to the data set as a whole and not to a particular matrix, such as the coordinates (**_.TYPE_.**='CONFIG').
- **_.TYPE_.**, a character variable of length 10 identifying the type of information in the observation

The values of **_.TYPE_.** are as follows:

- **CONFIG** the estimated coordinates of the configuration of objects
- **DIAGCOEF** the estimated dimension coefficients for COEF=DIAGONAL
- **INTERCEPT** the estimated intercept parameters
- **SLOPE** the estimated slope parameters
- **POWER** the estimated power parameters
- **CRITERION** the badness-of-fit criterion
- **_.LABEL_.** or the variable in the ID statement, containing the variable label or value of the ID variable of the object to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- **_.NAME_.**, a character variable of length 8 containing the variable name of the object or dimension to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- **DIM1, . . . , DIMm**, where m is the maximum number of dimensions
OUTFIT= Data Set

The OUTFIT= data set contains various measures of goodness and badness of fit. There is one observation for the entire sample plus one observation for each matrix. For the CONDITION=ROW option, there is also one observation for each row.

The OUTFIT= data set contains the following variables:

- BY variables, if any
- _ITER_, (if the OUTITER option is specified), a numeric variable containing the iteration number
- _DIMENS_, a numeric variable containing the number of dimensions
- _MATRIX_ or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains
- _LABEL_ or the variable in the ID statement, containing the variable label or value of the ID variable of the object to which the observation pertains when CONDITION=ROW
- _NAME_, a character variable of length 8 containing the variable name of the object or dimension to which the observation pertains when CONDITION=ROW
- N, the number of nonmissing data
- WEIGHT, the weight of the partition
- CRITER, the badness-of-fit criterion
- DISCORR, the correlation between the transformed data and the distances for LEVEL=ORDINAL or the correlation between the data and the transformed distances otherwise
- UDISCORR, the correlation uncorrected for the mean between the transformed data and the distances for LEVEL=ORDINAL or the correlation between the data and the transformed distances otherwise
- FITCORR, the correlation between the fit-transformed data and the fit-transformed distances
- UFITCORR, the correlation uncorrected for the mean between the fit-transformed data and the fit-transformed distances

OUTRES= Data Set

The OUTRES= data set has one observation for each nonmissing datum. It contains the following variables:

- BY variables, if any
- _ITER_, (if the OUTITER option is specified), a numeric variable containing the iteration number
- _DIMENS_, a numeric variable containing the number of dimensions
• _MATRIX_ or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains
• _ROW_, containing the variable label or value of the ID variable of the row to which the observation pertains
• _COL_, containing the variable label or value of the ID variable of the column to which the observation pertains
• DATA, the original datum
• TRANDATA, the optimally transformed datum when LEVEL=ORDINAL
• DISTANCE, the distance computed from the PROC MDS model
• TRANSDIST, the optimally transformed distance when the LEVEL= option is not ORDINAL or ABSOLUTE
• FITDATA, the datum further transformed according to the FIT= option
• FITDIST, the distance further transformed according to the FIT= option
• WEIGHT, the combined weight of the datum based on the WEIGHT variable(s), if any, and the standardization specified by the FORMULA= option
• RESIDUAL, FITDATA minus FITDIST

To cause a datum to appear in the OUTRES= data set, yet be ignored in fitting the model, give the datum a nonmissing value but a 0 weight (see “WEIGHT Statement”).

INITIAL= Data Set

The INITIAL= data set has the same structure as the OUT= data set but is not required to have all of the variables or observations that appear in the OUT= data set. You can use an OUT= data set previously created by PROC MDS (without the OUTITER option) as an INITIAL= data set in a subsequent invocation of the procedure.

The only variables that are required are DIM1, . . . , DIMm (where m is the maximum number of dimensions) or equivalent variables specified in the INVAR statement. If these are the only variables, then all the observations are assumed to contain coordinates of the configuration; you cannot read dimension coefficients or transformation parameters.

To read initial values for the dimension coefficients or transformation parameters, the INITIAL= data set must contain the _TYPE_ variable and either the variable specified in the ID statement or, if no ID statement is used, the variable _NAME_. In addition, if there is more than one data matrix, either the variable specified in the MATRIX statement or, if no MATRIX statement is used, the variable _MATRIX_ or _MATNUM_ is required.

If the INITIAL= data set contains the variable _DIMENS_, initial values are obtained from observations with the corresponding number of dimensions. If there is no _DIMENS_ variable, the same observations are used for each number of dimensions analyzed.
If you want PROC MDS to read initial values from some but not all of the observa-
tions in the INITIAL= data set, use the WHERE= data set option to select the desired
observations.

**Missing Values**

Missing data in the similarity or dissimilarity matrices are ignored in fitting the model
and are omitted from the OUTRES= data set. Any matrix that is completely missing
is omitted from the analysis.

Missing weights are treated as 0.

Missing values are also allowed in the INITIAL= data set, but a large number of
missing values may yield a degenerate initial configuration.

**Normalization of the Estimates**

In multidimensional scaling models, the parameter estimates are not uniquely de-
termined; the estimates can be transformed in various ways without changing their
badness of fit. The initial and final estimates from PROC MDS are, therefore, normal-
ized (unless you specify the NONORM option) to make it easier to compare results
from different analyses.

The configuration always has a mean of 0 for each dimension.

With the COEF=IDENTITY option, the configuration is rotated to a principal-axis
orientation. Unless you specify the LEVEL=ABSOLUTE option, the entire config-
uration is scaled so that the root-mean-square element is 1, and the transformations
are adjusted to compensate.

With the COEF=DIAGONAL option, each dimension is scaled to a root-mean-square
value of 1, and the dimension coefficients are adjusted to compensate. Unless you
specify the LEVEL=ABSOLUTE option, the dimension coefficients are normal-
ized as follows. If you specify the CONDITION=UN option, all of the dimension
coefficients are scaled to a root-mean-square value of 1. For other values of the
CONDITION= option, the dimension coefficients are scaled separately for each sub-
ject to a root-mean-square value of 1. In either case, the transformations are adjusted
to compensate.

Each dimension is reflected to give a positive rank correlation with the order of the
objects in the data set.

For the LEVEL=ORDINAL option, if the intercept, slope, or power parameters are
fitted, the transformed data are normalized to eliminate these parameters if possible.
Comparison with the ALSCAL Procedure

The MDS procedure generally produces results similar to those from the ALSCAL procedure (Young, Lewyckyj, and Takane 1986; Young 1982) if you use the following options in PROC MDS:

- FIT=SQUARED
- FORMULA=1 except for unfolding data, which require FORMULA=2
- PFINAL to get output similar to that from PROC ALSCAL

Unlike PROC ALSCAL, PROC MDS produces no plots, so you must use output data sets and PROC PLOT or PROC GPLOT.

The MDS and ALSCAL procedures may sometimes produce different results for the following reasons:

- With the LEVEL=INTERVAL option, PROC MDS fits a regression model while PROC ALSCAL fits a measurement model. These models are not equivalent if there is more than one partition, although the differences in the parameter estimates are usually minor.
- PROC MDS and PROC ALSCAL use different algorithms for initialization and optimization. Hence, different local optima may be found by PROC MDS and PROC ALSCAL for some data sets with poor fit. Using the INAV=SSCP option causes the initial estimates from PROC MDS to be more like those from PROC ALSCAL.
- The default convergence criteria in PROC MDS are more strict than those in PROC ALSCAL. The convergence measure in PROC ALSCAL may cause PROC ALSCAL to stop iterating because progress is slow rather than because a local optimum has been reached. Even if you run PROC ALSCAL with a very small convergence criterion and a very large iteration limit, PROC ALSCAL may never achieve the same degree of precision as PROC MDS. For most applications, this problem is of no practical consequence since two- or three-digit precision is sufficient. If the model does not fit well, obtaining higher precision may require hundreds of iterations.

PROC MDS accepts some PROC ALSCAL options as synonyms for the preceding options, as displayed in Table 43.1.

Comparison with the MLSCALE Procedure

Running the MDS procedure with the options

```
proc mds fit=log level=loginterval ... ;
```

generally produces results similar to using the MLSCALE procedure (Ramsay 1986) with the options
proc mlscale stvarnce=constant suvarnce=constant ... ;

Alternatively, using the FIT=DISTANCE option in the PROC MDS statement produces results similar to specifying the NORMAL option in the PROC MLSCALE statement.

The MDS procedure uses the least-squares method of estimation. The least-squares method is equivalent to the maximum-likelihood method if the error terms are assumed to be independent and identically distributed normal random variables. Unlike PROC MLSCALE, PROC MDS does not provide any options for unequal error variances.

PROC MDS accepts some PROC MLSCALE options as synonyms for the options described previously, as displayed in Table 43.2.

Displayed Output

Unless you specify the NOPHIST option, PROC MDS displays the iteration history containing

- Iteration number
- Type of iteration:
  - Initial: initial configuration
  - Monotone: monotone transformation
  - Gau-New: Gauss-Newton step
  - Lev-Mar: Levenberg-Marquardt step
- Badness-of-Fit Criterion
- Change in Criterion
- Convergence Measures:
  - Monotone: the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions
  - Gradient: the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean

Depending on what options are specified, PROC MDS may also display the following tables:

- Data Matrix and possibly Weight Matrix for each subject
- Eigenvalues from the computation of the initial coordinates
- Sum of Data Weights and Pooled Data Matrix computed during initialization with INAV=DATA
• Configuration, the estimated coordinates of the objects
• Dimension Coefficients
• A table of transformation parameters, including one or more of the following:
  - Intercept
  - Slope
  - Power
• A table of fit statistics for each matrix and possibly each row, including
  - Number of Nonmissing Data
  - Weight of the matrix or row, allowing for both observation weights and standardization factors
  - Badness-of-Fit Criterion
  - Distance Correlation computed between the distances and data with optimal transformation
  - Uncorrected Distance Correlation not corrected for the mean
  - Fit Correlation computed after applying the FIT= transformation to both distances and data
  - Uncorrected Fit Correlation not corrected for the mean

**ODS Table Names**

PROC MDS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Example

Example 43.1. Jacobowitz Body Parts Data from Children and Adults

Jacobowitz (1975) collected conditional rank-order data regarding perceived similarity of parts of the body from children of ages 6, 8, and 10 years and from college sophomores. The following analysis includes data from 15 children (6-year-olds) and 15 sophomores. The method of data collection and some results of an analysis are also described by Young (1987, pp. 4–10). A portion of the data is included below. See “Mds Documentation Examples” in the SAS/STAT Sample Program Library for the complete data set.

data body;
  title 'Jacobowitz Body Parts Data from 6 Yr Olds and Adults';

The data are analyzed as row conditional (CONDITION=ROW) at the ordinal level of measurement (LEVEL=ORDINAL) using the weighted Euclidean model (COEF=DIAGONAL) in three dimensions (DIMENSION=3). The final estimates are displayed (PFINAL). The estimates (OUT=OUT) and fitted values (OUTRES=RES) are saved in output data sets. The following statements produce Output 43.1.1:

```plaintext
options ps=60;
proc mds data=body
   condition=row
   level=ordinal
   coef=diagonal
   dimension=3
   pfinal
   out=out
   outres=res
;
subject subject;
title5 'Nonmetric Weighted MDS';
run;
```

The OUTRES= data set is used to produce a plot showing the overall fit of the model, with the transformed data on the vertical axis and the distances from the model on the horizontal axis. If the model fits perfectly, all points lie on a diagonal line from lower left to upper right. The vertical departure of each point from this diagonal line represents the residual of the corresponding observation. The HAXIS and VAXIS options in the PLOT statement specify that the horizontal and vertical axes use the definitions AXIS2 and AXIS1, respectively. The identical ORDER= options in each of these AXIS statements make physical distances on each axis comparable.

The following statements produce Output 43.1.2:

```plaintext
   title1 'Plot of Over-All Fit';
   axis1 label=(angle=90 rotate=0) minor=none
```
Example 43.1. Jacobowitz Body Parts Data from Children and Adults ♦ 2503

```sas
order=(0 to 5 by 1);
axis2 minor=none order=(0 to 5 by 1);

proc gplot data=res;
    plot fitdata*fitdist/vaxis=axis1 haxis=axis2
        frame cframe=ligr;
run;
```

**Output 43.1.2.** Plot of Over-All Fit for Body Parts Data

The OUT= data set is used to plot the configuration and dimension coefficients using the %PLOTIT macro. Again it is necessary to use the VTOH= option to make the axes commensurable. The configuration is plotted by selecting observations having _TYPE_='CONFIG' with a WHERE statement and by using the _NAME_ variable to identify each body part on the plot.

The dimension coefficients are plotted by selecting observations having _TYPE_='DIAGCOEF' and by using the Subject variable to distinguish children from adults on the plot. The following statements produce **Output 43.1.3:**

```sas
title1 'Plot of configuration';
%plotit(data=out(where=(_type_='CONFIG')), datatype=mds,
    labelvar=_name_, vtoh=1.75);
%plotit(data=out(where=(_type_='CONFIG')), datatype=mds,
    plotvars=dim3 dim1, labelvar=_name_, vtoh=1.75);
run;
```

```sas
title1 'Plot of Dimension Coefficients for Each Subject';
%plotit(data=out(where=(_type_='DIAGCOEF')), symtype=vector,
    symbols='', datatype=mds, place=0, labelvar=subject,
```
vechead=, ls=100, plotopts=hzero vzero);

%plotit(data=out(where=(_type_='DIAGCOEF')), plotvars=dim3 dim1, symtype=vector, symbols='', datatype=mds, place=0, labelvar=subject, ls=100, vechead=, plotopts=hzero vzero);
run;

The configuration displayed in Output 43.1.3 has a tripodal shape with Body at the apex. The three legs of the tripod can be distinguished in the plot of dimension 2 by dimension 1, which shows three distinct clusters with Body in the center. Dimension 1 separates head parts from arm and leg parts. Dimension 2 separates arm parts from leg parts. The plot of dimension 3 by dimension 1 shows the tripod from the side. Dimension 3 distinguishes the more inclusive body parts (at the top) from the less inclusive body parts (at the bottom).

**Output 43.1.3.** Plot of Configuration for Body Parts Data
The plots of dimension coefficients in Output 43.1.4 show that children differ from adults primarily in the emphasis given to dimension 2. Children give about the same weight (approximately 1) to each dimension. Adults are much more variable than children, but all have coefficients less than 1.0 for dimension 2, with an average of about 0.7. Referring back to the configuration plot, you can see that adults consider arm parts to be more similar to leg parts than do children. Many adults also give a high weight to dimension 1, indicating that they consider head parts to be more dissimilar from arm and leg parts than do children. Dimension 3 shows considerable variability for both children and adults.
Output 43.1.4. Plot of Dimension Coefficients for Body Parts Data

Chapter 44
The MI Procedure

Overview

The MI procedure performs multiple imputation of missing data. Missing values are an issue in a substantial number of statistical analyses. Most SAS statistical procedures exclude observations with any missing variable values from the analysis. These observations are called incomplete cases. While analyzing only complete cases has its simplicity, the information contained in the incomplete cases is lost. This approach also ignores possible systematic differences between the complete cases and the incomplete cases, and the resulting inference may not be applicable to the population of all cases, especially with a small number of complete cases.

Some SAS procedures use all the available cases in an analysis, that is, cases with useful information. For example, the CORR procedure estimates a variable mean by using all cases with nonmissing values for this variable, ignoring the possible missing values in other variables. PROC CORR also estimates a correlation by using all cases with nonmissing values for this pair of variables. This makes better use of the available data than use only the complete cases, but the resulting correlation matrix may not be positive definite.

Another strategy for handling missing data is single imputation, which substitutes a value for each missing value. Standard statistical procedures for complete data analysis can then be used with the filled-in data set. For example, each missing value can be imputed with the variable mean of the complete cases, or it can be imputed with the mean conditional on observed values of other variables. This approach treats missing values as if they were known in the complete-data analysis. However, single imputation does not reflect the uncertainty about the predictions of the unknown missing values, and the resulting estimated variances of the parameter estimates will be biased toward zero (Rubin 1987, p. 13).

Instead of filling in a single value for each missing value, multiple imputation (Rubin 1976; 1987) replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute. The multiply imputed data sets are then analyzed by using standard procedures for complete data and combining the results from these analyses. No matter which complete-data analysis is used, the process of combining results from different data sets is essentially the same.

Multiple imputation does not attempt to estimate each missing value through simulated values. Instead, it draws a random sample of the missing values from its distribution. This process results in valid statistical inferences that properly reflect the uncertainty due to missing values; for example, confidence intervals with the correct probability coverage.
Multiple imputation inference involves three distinct phases:

1. The missing data are filled in \( m \) times to generate \( m \) complete data sets.
2. The \( m \) complete data sets are analyzed using standard statistical analyses.
3. The results from the \( m \) complete data sets are combined to produce inferential results.

The MI procedure creates multiply imputed data sets for incomplete multivariate data. It uses methods that incorporate appropriate variability across the \( m \) imputations. The method of choice depends on the patterns of missingness.

For data sets with monotone missing patterns, either a parametric method that assumes multivariate normality or a nonparametric method is appropriate. Parametric methods available include the regression method (Rubin 1987, pp. 166–167) and the predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996). The nonparametric method is the propensity score method (Rubin 1987, pp. 124, 158; Lavori, Dawson, and Shera 1995).

For data sets with arbitrary missing patterns, a Markov Chain Monte Carlo (MCMC) method (Schafer 1997) that assumes multivariate normality is used to impute all missing values or just enough missing values to make the imputed data sets have monotone missing patterns.

Once the \( m \) complete data sets are analyzed using standard SAS procedures, the MIANALYZE procedure can be used to generate valid statistical inferences about these parameters by combining results from the \( m \) analyses.

Often, as few as three to five imputations are adequate in multiple imputation (Rubin 1996, p. 480). The relative efficiency of the small \( m \) imputation estimator is high for cases with little missing information (Rubin 1987, p. 114). Also see the “Multiple Imputation Efficiency” section on page 2562.

Multiple imputation inference assumes that the model (variables) you used to analyze the multiply imputed data (the analyst’s model) is the same as the model used to impute missing values in multiple imputation (the imputer’s model). But in practice, the two models may not be the same. The consequences for different scenarios (Schafer 1997, pp. 139–143) are discussed in the “Imputer’s Model Versus Analyst’s Model” section on page 2563.

In SAS 9, an experimental CLASS statement has been added to specify classification variables, which can be used either as covariates for imputed variables or as imputed variables for data sets with monotone missing patterns. The CLASS statement must be used in conjunction with the MONOTONE statement.

Experimental graphics using ODS are now available with the MI procedure. For more information, see the “ODS Graphics” section on page 2567.
Consider the following Fitness data set that has been altered to contain an arbitrary pattern of missingness:

```
*----------------- Data on Physical Fitness -----------------*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University. |
| Only selected variables of |
| Oxygen (oxygen intake, ml per kg body weight per minute), |
| Runtime (time to run 1.5 miles in minutes), and |
| RunPulse (heart rate while running) are used. |
| Certain values were changed to missing for the analysis. |
*------------------------------------------------------------*
```

```plaintext
data FitMiss;
  input Oxygen RunTime RunPulse @@;
datalines;
  44.609 11.37 178
  54.297 8.65 156
  49.874 9.22 176
  . 11.95 176
  39.442 13.08 174
  50.541 . .
  44.754 11.12 176
  51.855 10.33 166
  40.836 10.95 168
  46.774 10.25 168
  39.407 12.63 174
  45.441 9.63 164
  45.118 11.08 .
  45.790 10.47 186
  48.673 9.40 186
  47.467 10.50 170
;
```

Suppose that the data are multivariate normally distributed and the missing data are missing at random (MAR). That is, the probability that an observation is missing can depend on the observed variable values of the individual, but not on the missing variable values of the individual. See the “Statistical Assumptions for Multiple Imputation” section on page 2537 for a detailed description of the MAR assumption.

The following statements invoke the MI procedure and impute missing values for the FitMiss data set.

```
proc mi data=FitMiss seed=501213 mu0=50 10 180 out=outmi;
  var Oxygen RunTime RunPulse;
run;
```

Figure 44.1. Model Information

The “Model Information” table displayed in Figure 44.1 describes the method used in the multiple imputation process. By default, the procedure uses the Markov Chain Monte Carlo (MCMC) method with a single chain to create five imputations. The posterior mode, the highest observed-data posterior density, with a noninformative prior, is computed from the EM algorithm and is used as the starting value for the chain.

The MI procedure takes 200 burn-in iterations before the first imputation and 100 iterations between imputations. In a Markov chain, the information in the current iteration has influence on the state of the next iteration. The burn-in iterations are iterations in the beginning of each chain that are used both to eliminate the series of dependence on the starting value of the chain and to achieve the stationary distribution. The between-imputation iterations in a single chain are used to eliminate the series of dependence between the two imputations.
Figure 44.2. Missing Data Patterns

The “Missing Data Patterns” table displayed in Figure 44.2 lists distinct missing data patterns with corresponding frequencies and percents. Here, an “X” means that the variable is observed in the corresponding group and a “.” means that the variable is missing. The table also displays group-specific variable means. The MI procedure sorts the data into groups based on whether an individual’s value is observed or missing for each variable to be analyzed. For a detailed description of missing data patterns, see the “Missing Data Patterns” section on page 2538.

Figure 44.3. Variance Information
After the completion of \( m \) imputations, the “Multiple Imputation Variance Information” table shown in Figure 44.3 displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency (in units of variance) for each variable are also displayed. A detailed description of these statistics is provided in the “Combining Inferences from Multiply Imputed Data Sets” section on page 2561.

The following “Multiple Imputation Parameter Estimates” table shown in Figure 44.4 displays the estimated mean and standard error of the mean for each variable. The inferences are based on the \( t \) distribution. The table also displays a 95% confidence interval for the mean and a \( t \) statistic with the associated \( p \)-value for the hypothesis that the population mean is equal to the value specified with the MU0= option. A detailed description of these statistics is provided in the “Combining Inferences from Multiply Imputed Data Sets” section on page 2561.

#### Figure 44.4. Parameter Estimates

In addition to the output tables, the procedure also creates a data set with imputed values. The imputed data sets are stored in the outmi data set, with the index variable _Imputation_ indicating the imputation numbers. The data set can now be analyzed using standard statistical procedures with _Imputation_ as a BY variable.

The following statements list the first ten observations of data set outmi.

```sas
proc print data=outmi (obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Figure 44.5. Imputed Data Set

The table displayed in Figure 44.5 shows that the precision of the imputed values differs from the precision of the observed values. You can use the ROUND= option to make the imputed values consistent with the observed values.

Syntax

The following statements are available in PROC MI.

```plaintext
PROC MI < options > ;
   BY variables ;
   CLASS variables ;
   EM < options > ;
   FREQ variable ;
   MCMC < options > ;
   MONOTONE < options > ;
   TRANSFORM transform ( variables < / options > )
      < . . . transform ( variables < / options > ) > ;
   VAR variables ;
```

The BY statement specifies groups in which separate multiple imputation analyses are performed.

The CLASS statement lists the classification variables in the VAR statement. Classification variables can be either character or numeric.

The EM statement uses the EM algorithm to compute the maximum likelihood estimate (MLE) of the data with missing values, assuming a multivariate normal distribution for the data.

The FREQ statement specifies the variable that represents the frequency of occurrence for other values in the observation.
The MCMC statement uses a Markov chain Monte Carlo method to impute values for a data set with an arbitrary missing pattern, assuming a multivariate normal distribution for the data.

The MONOTONE statement specifies monotone methods to impute continuous and CLASS variables for a data set with a monotone missing pattern. Note that you can use either an MCMC statement or a MONOTONE statement, but not both. When neither of these two statements is specified, the MCMC method with its default options is used.

The TRANSFORM statement lists the variables to be transformed before the imputation process. The imputed values of these transformed variables will be reverse-transformed to the original forms before the imputation.

The VAR statement lists the numeric variables to be analyzed. If you omit the VAR statement, all numeric variables not listed in other statements are used.

The PROC MI statement is the only required statement for the MI procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MI statement. The remaining statements are in alphabetical order.

### PROC MI Statement

```latex
PROC MI < options > ;
```

The following table summarizes the options available in the PROC MI statement.

</table>
The following options can be used in the PROC MI statement (in alphabetical order):

**ALPHA=\(\alpha\)**

specifies that confidence limits be constructed for the mean estimates with confidence level \(100(1 - \alpha)\%\), where \(0 < \alpha < 1\). The default is `ALPHA=0.05`.

**DATA=SAS-data-set**

names the SAS data set to be analyzed by PROC MI. By default, the procedure uses the most recently created SAS data set.

**MAXIMUM=numbers**

specifies maximum values for imputed variables. When an intended imputed value is greater than the maximum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a `VAR` statement, and the specified numbers must correspond to variables in the `VAR` statement. The default number is a missing value, which indicates no restriction on the maximum for the corresponding variable.

The `MAXIMUM=` option is related to the `MINIMUM=` and `ROUND=` options, which are used to make the imputed values more consistent with the observed variable values. These options are applicable only if you use the MCMC method or the monotone regression method.

When specifying a maximum for the first variable only, you must also specify a missing value after the maximum. Otherwise, the maximum is used for all variables. For example, the `MAXIMUM= 100 .` option sets a maximum of 100 for the first analysis variable only and no maximum for the remaining variables. The `MAXIMUM= . 100` option sets a maximum of 100 for the second analysis variable only and no maximum for the other variables.

**MINIMUM=numbers**

specifies the minimum values for imputed variables. When an intended imputed value is less than the minimum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a `VAR` statement, and the specified numbers must correspond to variables in the `VAR` statement. The default number is a missing value, which indicates no restriction on the minimum for the corresponding variable.

**MINMAXITER=number**

specifies the maximum number of iterations for imputed values to be in the specified range when the option `MINIMUM` or `MAXIMUM` is also specified. The default is `MINMAXITER=100`.

**MU0=numbers**

**THETA0=numbers**

specifies the parameter values \(\mu_0\) under the null hypothesis \(\mu = \mu_0\) for the population means corresponding to the analysis variables. Each hypothesis is tested with a \(t\) test. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a `VAR` statement, and the specified numbers must correspond to variables in the `VAR` statement. The default is `MU0=0`.
If a variable is transformed as specified in a TRANSFORM statement, then the same transformation for that variable is also applied to its corresponding specified MU0= value in the t test. If the parameter values \( \mu_0 \) for a transformed variable is not specified, then a value of zero is used for the resulting \( \mu_0 \) after transformation.

**NIMPUTE=number**  
specifies the number of imputations. The default is NIMPUTE=5. You can specify NIMPUTE=0 to skip the imputation. In this case, only tables of model information, missing data patterns, descriptive statistics (SIMPLE option), and MLE from the EM algorithm (EM statement) are displayed.

**NOPRINT**  
suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

**OUT=SAS-data-set**  
creates an output SAS data set containing imputation results. The data set includes an index variable, _Imputation_, to identify the imputation number. For each imputation, the data set contains all variables in the input data set with missing values being replaced by the imputed values. See the “Output Data Sets” section on page 2559 for a description of this data set.

**ROUND=numbers**  
specifies the units to round variables in the imputation. If only one number is specified, that number is used for all continuous variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. When the CLASS variables are listed in the VAR statement, their corresponding roundoff units are not used. The default number is a missing value, which indicates no rounding for imputed variables.

When specifying a roundoff unit for the first variable only, you must also specify a missing value after the roundoff unit. Otherwise, the roundoff unit is used for all variables. For example, the option “ROUND= 10 .” sets a roundoff unit of 10 for the first analysis variable only and no rounding for the remaining variables. The option “ROUND= . 10” sets a roundoff unit of 10 for the second analysis variable only and no rounding for other variables.

The ROUND= option sets the precision of imputed values. For example, with a roundoff unit of 0.001, each value is rounded to the nearest multiple of 0.001. That is, each value has three significant digits after the decimal point. See Example 44.3 for an illustration of this option.

**SEED=number**  
specifies a positive integer to start the pseudo-random number generator. The default is a value generated from reading the time of day from the computer’s clock. However, in order to duplicate the results under identical situations, you must use the same value of the seed explicitly in subsequent runs of the MI procedure.
The seed information is displayed in the “Model Information” table so that the results can be reproduced by specifying this seed with the SEED= option. You need to specify the same seed number in the future to reproduce the results.

**SIMPLE**

Displays simple descriptive univariate statistics and pairwise correlations from available cases. For a detailed description of these statistics, see the “Descriptive Statistics” section on page 2535.

**SINGULAR=**

Specifies the criterion for determining the singularity of a covariance matrix based on standardized variables, where $0 < p < 1$. The default is SINGULAR=1E-8.

Suppose that $S$ is a covariance matrix and $v$ is the number of variables in $S$. Based on the spectral decomposition $S = \Gamma \Lambda \Gamma'$, where $\Lambda$ is a diagonal matrix of eigenvalues $\lambda_j$, $j = 1, \ldots, v$, where $\lambda_i \geq \lambda_j$ when $i < j$, and $\Gamma$ is a matrix with the corresponding orthonormal eigenvectors of $S$ as columns, $S$ is considered singular when an eigenvalue $\lambda_j$ is less than $p \bar{\lambda}$, where the average $\bar{\lambda} = \sum_{k=1}^{v} \lambda_k / v$.

**BY Statement**

```sas
BY variables;
```

You can specify a BY statement with PROC MI to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MI procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*. 

CLASS Statement (Experimental)

CLASS variables;

The CLASS statement specifies the classification variables in the VAR statement. Classification variables can be either character or numeric. The CLASS statement must be used in conjunction with the MONOTONE statement.

Class levels are determined from the formatted values of the CLASS variables. Refer to the chapter titled “The FORMAT Procedure” in the SAS Procedures Guide.

EM Statement

EM < options >;

The expectation-maximization (EM) algorithm is a technique for maximum likelihood estimation in parametric models for incomplete data. The EM statement uses the EM algorithm to compute the MLE for \((\mu, \Sigma)\), the means and covariance matrix, of a multivariate normal distribution from the input data set with missing values. Either the means and covariances from complete cases or the means and standard deviations from available cases can be used as the initial estimates for the EM algorithm. You can also specify the correlations for the estimates from available cases.

You can also use the EM statement with the NIMPUTE=0 option in the PROC statement to compute the EM estimates without multiple imputation, as shown in Example 44.1 in the “Examples” section on page 2568.

The following seven options are available with the EM statement.

CONVERGE=\(p\)
XCONV=\(p\)
sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than \(p\) for each parameter. That is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-4.

INITIAL=CC | AC | AC(R=\(r\))
sets the initial estimates for the EM algorithm. The INITIAL=CC option uses the means and covariances from complete cases, the INITIAL=AC option uses the means and standard deviations from available cases and the correlations are set to zero, and the INITIAL=AC( R=\(r\)) option uses the means and standard deviations from available cases with correlation \(r\), where \(-1/(p - 1) < r < 1\) and \(p\) is the number of variables to be analyzed. The default is INITIAL=AC.
ITPRINT
prints the iteration history in the EM algorithm.

MAXITER=number
specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.

OUT=SAS-data-set
creates an output SAS data set containing results from the EM algorithm. The data set contains all variables in the input data set with missing values being replaced by the expected values from the EM algorithm. See the “Output Data Sets” section on page 2559 for a description of this data set.

OUTEM=SAS-data-set
creates an output SAS data set of TYPE=COV containing the MLE of the parameter vector \((\mu, \Sigma)\). These estimates are computed with the EM algorithm. See the “Output Data Sets” section on page 2559 for a description of this output data set.

OUTITER < (options) > =SAS-data-set
creates an output SAS data set of TYPE=COV containing parameters for each iteration. The data set includes a variable named _Iteration_ to identify the iteration number. The parameters in the output data set depend on the options specified. You can specify the MEAN and COV options to output the mean and covariance parameters. When no options are specified, the output data set contains the mean parameters for each iteration. See the “Output Data Sets” section on page 2559 for a description of this data set.

FREQ Statement

FREQ variable ;
If one variable in your input data set represents the frequency of occurrence for other values in the observation, specify the variable name in a FREQ statement. PROC MI then treats the data set as if each observation appears \(n\) times, where \(n\) is the value of the FREQ variable for the observation. If the value of the FREQ variable is less than one, the observation is not used in the analysis. Only the integer portion of the value is used. The total number of observations is considered to be equal to the sum of the FREQ variable when PROC MI calculates significance probabilities.

MCMC Statement

MCMC < options > ;
The MCMC statement specifies the details of the MCMC method for imputation.
The following table summarizes the options available for the MCMC statement.

**Table 44.2. Summary of Options in MCMC**

The following options are available for the MCMC statement (in alphabetical order):

**ACFPLOT** < ( options < / display-options > ) >

- displays the autocorrelation function plots of parameters from iterations.

The available options are:

**COV** < ( < variables > < variable1*variable2 > < ... variable1*variable2 > ) >

- displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

**MEAN** < ( variables ) >

- displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

**WLF**

- displays the plot for the worst linear function.

When the **ACFPLOT** is specified without the preceding options, the procedure displays plots of means for all variables that are used.
The display-options provide additional information for the autocorrelation function plots. The available display-options are:

**CCONF=color**

specifies the color of the displayed confidence limits. The default is CCONF=BLACK.

**CFRAME=color**

specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

**CNEEDLES=color**

specifies the color of the vertical line segments (needles) that connect autocorrelations to the reference line. The default is CNEEDLES=BLACK.

**CREF=color**

specifies the color of the displayed reference line. The default is CREF=BLACK.

**CSYMBOL=color**

specifies the color of the displayed data points. The default is CSYMBOL=BLACK.

**HSYMBOL=number**

specifies the height for data points in percentage screen units. The default is HSYMBOL=1.

**LCONF=linetype**

specifies the line type for the displayed confidence limits. The default is LCONF=1, a solid line.

**LOG**

requests that the logarithmic transformations of parameters be used to compute the autocorrelations. It’s generally used for the variances of variables. When a parameter has values less than or equal to zero, the corresponding plot is not created.

**LREF=linetype**

specifies the line type for the displayed reference line. The default is LREF=3, a dashed line.

**NLAG=number**

specifies the maximum lag of the series. The default is NLAG=20. The autocorrelations at each lag are displayed in the graph.

**SYMBOL=value**

specifies the symbol for data points in percentage screen units. The default is SYMBOL=STAR.

**TITLE='string'**

specifies the title to be displayed in the autocorrelation function plots. The default is TITLE=’Autocorrelation Plot’.
Chapter 44. The MI Procedure

**WCONF**=number

specifies the width for the displayed confidence limits in percentage screen units. If you specify the WCONF=0 option, the confidence limits are not displayed. The default is WCONF=1.

**WNEEDLES**=number

specifies the width for the displayed needles that connect autocorrelations to the reference line in percentage screen units. If you specify the WNEEDLES=0 option, the needles are not displayed. The default is WNEEDLES=1.

**WREF**=number

specifies the width for the displayed reference line in percentage screen units. If you specify the WREF=0 option, the reference line is not displayed. The default is WREF=1.

For example, the statement

```plaintext
acfplot( mean( y1) cov(y1) /log);
```

requests autocorrelation function plots for the means and variances of the variable y1, respectively. Logarithmic transformations of both the means and variances are used in the plots. For a detailed description of the autocorrelation function plot, see the “Autocorrelation Function Plot” section on page 2557; refer also to Schafer (1997, pp. 120-126) and the SAS/ETS User’s Guide.

**CHAIN**=SINGLE | MULTIPLE

specifies whether a single chain is used for all imputations or a separate chain is used for each imputation. The default is CHAIN=SINGLE.

**DISPLAYINIT**

displays initial parameter values in the MCMC process for each imputation.

**GOUT**=graphics-catalog

specifies the graphics catalog for saving graphics output from PROC MI. The default is WORK.GSEG. For more information, refer to the chapter “The GREPLAY Procedure” in SAS/GRAPH Software: Reference.

**IMPUTE**=FULL | MONOTONE

specifies whether a full-data imputation is used for all missing values or a monotone-data imputation is used for a subset of missing values to make the imputed data sets have a monotone missing pattern. The default is IMPUTE=FULL. When IMPUTE=MONOTONE is specified, the order in the VAR statement is used to complete the monotone pattern.

**INEST**=SAS-data-set

names a SAS data set of TYPE=EST containing parameter estimates for imputations. These estimates are used to impute values for observations in the DATA= data set. A detailed description of the data set is provided in the “Input Data Sets” section on page 2558.
INITIAL=EM < ( options ) >
INITIAL=INPUT=SAS-data-set

specifies the initial mean and covariance estimates for the MCMC process. The default is INITIAL=EM.

You can specify INITIAL=INPUT=SAS-data-set to read the initial estimates of the mean and covariance matrix for each imputation from a SAS data set. See the “Input Data Sets” section on page 2558 for a description of this data set.

With INITIAL=EM, PROC MI derives parameter estimates for a posterior mode, the highest observed-data posterior density, from the EM algorithm. The MLE from EM is used to start the EM algorithm for the posterior mode, and the resulting EM estimates are used to begin the MCMC process. The prior information specified in the PRIOR= option is also used in the process to compute the posterior mode.

The following four options are available with INITIAL=EM.

BOOTSTRAP < =number >  
requests bootstrap resampling, which uses a simple random sample with replacement from the input data set for the initial estimate. You can explicitly specify the number of observations in the random sample. Alternatively, you can implicitly specify the number of observations in the random sample by specifying the proportion \( p, 0 < p \leq 1 \), to request \( \lceil np \rceil \) observations in the random sample, where \( n \) is the number of observations in the data set and \( \lceil np \rceil \) is the integer part of \( np \). This produces an overdispersed initial estimate that provides different starting values for the MCMC process. If you specify the BOOTSTRAP option without the number, \( p=0.75 \) is used by default.

CONVERGE=\( p \)

sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than \( p \) for each parameter. That is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-4.

ITPRINT

prints the iteration history in the EM algorithm for the posterior mode.

MAXITER=number

specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.
**NBITER=number**
specifies the number of burn-in iterations before the first imputation in each chain. The default is NBITER=200.

**NITER=number**
specifies the number of iterations between imputations in a single chain. The default is NITER=100.

**OUTEST=SAS-data-set**
creates an output SAS data set of TYPE=EST. The data set contains parameter estimates used in each imputation. The data set also includes a variable named _Imputation_ to identify the imputation number. See the “Output Data Sets” section on page 2559 for a description of this data set.

**OUTITER < (options) > =SAS-data-set**
creates an output SAS data set of TYPE=COV containing parameters used in the imputation step for each iteration. The data set includes variables named _Imputation_ and _Iteration_ to identify the imputation number and iteration number.

The parameters in the output data set depend on the options specified. You can specify options MEAN, STD, COV, LR, LR_POST, and WLF to output parameters of means, standard deviations, covariances, -2 log LR statistic, -2 log LR statistic of the posterior mode, and the worst linear function. When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. See the “Output Data Sets” section on page 2559 for a description of this data set.

**PRIOR=name**
specifies the prior information for the means and covariances. Valid values for name are as follows:

- **JEFFREYS** specifies a noninformative prior.
- **RIDGE=number** specifies a ridge prior.
- **INPUT=SAS-data-set** specifies a data set containing prior information.

For a detailed description of the prior information, see the “Bayesian Estimation of the Mean Vector and Covariance Matrix” section on page 2549 and the “Posterior Step” section on page 2550. If you do not specify the PRIOR= option, the default is PRIOR=JEFFREYS.

The PRIOR=INPUT= option specifies a TYPE=COV data set from which the prior information of the mean vector and the covariance matrix is read. See the “Input Data Sets” section on page 2558 for a description of this data set.

**START=VALUE | DIST**
specifies that the initial parameter estimates are used as either the starting value (START=VALUE) or as the starting distribution (START=DIST) in the first imputation step of each chain. If the IMPUTE=MONOTONE option is specified, then START=VALUE is used in the procedure. The default is START=VALUE.
TIMEPLOT < ( options < / display-options > ) >
displays the time-series plots of parameters from iterations.

The available options are:

**COV** < ( < variables > < variable1*variable2 > < ... variable1*variable2 > ) >
displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

**MEAN** < ( variables ) >
displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

**WLF**
displays the plot for the worst linear function.

When the TIMEPLOT is specified without the preceding options, the procedure displays plots of means for all variables are used.

The display-options provide additional information for the time-series plots. The available display-options are:

**CCONNECT=color**
specifies the color for the line segments that connect data points in the time-series plots. The default is CCONNECT=BLACK.

**CFRAME=color**
specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

**CSYMBOL=color**
specifies the color of the data points to be displayed in the time-series plots. The default is CSYMBOL=BLACK.

**HSYMBOL=number**
specifies the height for data points in percentage screen units. The default is HSYMBOL=1.

**LCONNECT=linetype**
specifies the line type for the line segments that connect data points in the time-series plots. The default is LCONNECT=1, a solid line.

**LOG**
requests that the logarithmic transformations of parameters be used. It’s generally used for the variances of variables. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

**SYMBOL=value**
specifies the symbol for data points in percentage screen units. The default is SYMBOL=PLUS.

**TITLE='string'**
specifies the title to be displayed in the time-series plots. The default is TITLE='Time-series Plot for Iterations'.
Chapter 44. The MI Procedure

**WCONNECT=number**
specifies the width for the line segments that connect data points in the time-series plots in percentage screen units. If you specify the `WCONNECT=0` option, the data points are not connected. The default is `WCONNECT=1`.

For a detailed description of the time-series plot, see the “Time-Series Plot” section on page 2556 and Schafer (1997, pp. 120–126).

**WLF**
displays the worst linear function of parameters. This scalar function of parameters $\mu$ and $\Sigma$ is “worst” in the sense that its values from iterations converge most slowly among parameters. For a detailed description of this statistic, see the “Worst Linear Function of Parameters” section on page 2556.

---

**MONOTONE Statement**

```
MONOTONE < method < ( < imputed < = effects > > < / options > ) > >
< ... method < ( < imputed < = effects > > < / options > ) > > > ;
```

The MONOTONE statement specifies imputation methods for data sets with monotone missingness. You must also specify a VAR statement and the data set must have a monotone missing pattern with variables ordered in the VAR list. When both MONOTONE and MCMC statements are specified, the MONOTONE statement is not used.

For each method, you can specify the imputed variables and optionally, a set of the effects to impute these variables. Each effect is a variable or a combination of variables preceding the imputed variable in the VAR statement. The syntax for specification of effects is the same as for the GLM procedure. See Chapter 32, “The GLM Procedure,” for more information.

One general form of an effect involving several variables is

```
X1 * X2 * A * B * C ( D E)
```

where A, B, C, D, and E are class variables and X1 and X2 are continuous variables.

If no covariates are specified, then all preceding variables are used as the covariates. That is, each preceding continuous variable is used as a regressor effect, and each preceding class variable is used as a main effect. For the discriminant function method, only the continuous variables can be used as covariate effects.

When a method for continuous variables is specified without imputed variables, the method is used for all continuous variables in the VAR statement that are not specified in other methods. Similarly, when a method for class variables is specified without imputed variables, the method is used for all class variables in the VAR statement that are not specified in other methods.

When a MONOTONE statement is used without specifying any methods, the regression method is used for all continuous variables and the discriminant function method...
is used for all class variables. The preceding variables of each imputed variable in
the VAR statement are used as the covariates.

With a MONOTONE statement, the variables are imputed sequentially in the order
given by the VAR statement. For a continuous variable, you can use a regression
method, a regression predicted mean matching method, or a propensity score method
to impute missing values.

For a nominal class variable, you can use a discriminant function method to impute
missing values without using the ordering of the class levels. For an ordinal class
variable, you can use a logistic regression method to impute missing values using the
ordering of the class levels. For a binary class variable, either a discriminant function
method or a logistic regression method can be used.

Note that except for the regression method, all other methods impute values from
the observed observation values. You can specify the following methods in a
MONOTONE statement.

**DISCRIM** < ( imputed < = effects > < / options > ) >
specifies the discriminant function method of class variables. Only the continu-
ous variables are allowed as covariate effects. The available options are DETAILS,
PCOV=, and PRIOR=. The DETAILS option displays the group means and pooled
covariance matrix used in each imputation. The PCOV= option specifies the pooled
covariance used in the discriminant method. Valid values for the PCOV= option are:

- **FIXED** uses the observed-data pooled covariance matrix for each
  imputation.
- **POSTERIOR** draws a pooled covariance matrix from its posterior distri-
bution.

The default is PCOV=POSTERIOR. See the “Discriminant Function Method for
Monotone Missing Data” section on page 2544 for a detailed description of the
method.

The PRIOR= option specifies the prior probabilities of group membership. Valid
values for the PRIOR= option are:

- **EQUAL** set the prior probabilities equal for all groups.
- **PROPORTIONAL** set the prior probabilities proportion to the group sample
  sizes.
- **JEFFREYS** < =c > specifies a noninformative prior, \(0 < c < 1\). If the number
  \(c\) is not specified, JEFFREYS=0.5.
- **RIDGE** < =d > specifies a ridge prior, \(d > 0\). If the number \(d\) is not speci-
died, RIDGE=0.25.

The default is PRIOR=JEFFREYS. See the “Discriminant Function Method for
Monotone Missing Data” section on page 2544 for a detailed description of the
method.
LOGISTIC < ( imputed < = effects > < / options > ) >
specifies the logistic regression method of class variables. The available options are 
DETAILS, ORDER=, and DESCENDING. The DETAILS option displays the re-
gression coefficients in the logistic regression model used in each imputation.

When the imputed variable has more than two response levels, the ordinal logistic 
regression method is used. The ORDER= option specifies the sorting order for the 
levels of the response variable. Valid values for the ORDER= option are:

- DATA sorts by the order of appearance in the input data set
- FORMATTED sorts by their external formatted values
- FREQ sorts by the descending frequency counts
- INTERNAL sorts by the unformatted values

By default, ORDER=FORMATTED.

The option DESCENDING reverses the sorting order for the levels of the response 
variables.

See the “Logistic Regression Method for Monotone Missing Data” section on page 
2546 for a detailed description of the method.

REG | REGRESSION < ( imputed < = effects > < / DETAILS > ) >
specifies the regression method of continuous variables. The DETAILS option dis-
plays the regression coefficients in the regression model used in each imputation.

With a regression method, the MAXIMUM=, MINIMUM=, and ROUND= options 
can be used to make the imputed values more consistent with the observed variable 
values.

See the “Regression Method for Monotone Missing Data” section on page 2541 for 
a detailed description of the method.

REGPMM < ( imputed < = effects > < / options > ) >
REGPREDMEANMATCH < ( imputed < = effects > < / options > ) >
specifies the predictive mean matching method for continuous variables. This method 
is similar to the regression method except that it imputes a value randomly from 
a set of observed values whose predicted values are closest to the predicted value 
for the missing value from the simulated regression model (Heitjan and Little 1991; 
Schenker and Taylor 1996).

The available options are DETAILS and K=. The DETAILS option displays the re-
gression coefficients in the regression model used in each imputation. The K= option 
specifies the number of closest observations to be used in the selection. The default 
is K=5.

Note that an optimal K= value is currently not available in the literature on multiple 
imputation. The default K=5 is experimental and may change in future releases.

See the “Predictive Mean Matching Method for Monotone Missing Data” section on 
page 2542 for a detailed description of the method.
**PROPENSITY < ( imputed < = effects > < / options > ) >**
specifies the propensity scores method of variables. Each variable is either a class variable or a continuous variable. The available options are DETAILS and NGROUPS=. The DETAILS option displays the regression coefficients in the logistic regression model for propensity scores. The NGROUPS= option specifies the number of groups created based on propensity scores. The default is NGROUPS=5.

See the “Propensity Score Method for Monotone Missing Data” section on page 2543 for a detailed description of the method.

With a MONOTONE statement, the missing values of a variable are imputed when the variable is either explicitly specified in the method or implicitly specified when a method is specified without imputed variables. These variables are imputed sequentially in the order specified in the VAR statement. For example, the following MI procedure

```
proc mi;
   class c1;
   var y1 y2 c1 y3;
   monotone reg(y3= y1 y2 c1) logistic(c1= y1 y2 y1*y2);
run;
```

uses the logistic regression method to impute variable c1 from effects y1, y2, and y1 * y2 first, then uses the regression method to impute variable y3 from effects y1, y2, and c1. The variables y1 and y2 are not imputed since y1 is the leading variable in the VAR statement and y2 is not specified as an imputed variable in the MONOTONE statement.

**TRANSFORM Statement**

```
TRANSFORM transform ( variables < / options > )
< . . . transform ( variables < / options > ) > ;
```

The TRANSFORM statement lists the transformations and their associated variables to be transformed. The options are transformation options that provide additional information for the transformation.

The MI procedure assumes that the data are from a multivariate normal distribution when either the regression method or the MCMC method is used. When some variables in a data set are clearly non-normal, it is useful to transform these variables to conform to the multivariate normality assumption. With a TRANSFORM statement, variables are transformed before the imputation process and these transformed variable values are displayed in all of the results. When you specify an OUT= option, the variable values are back-transformed to create the imputed data set.

The following transformations can be used in the TRANSFORM statement.

**BOXCOX**
specifies the Box-Cox transformation of variables. The variable Y is transformed to \( (Y+c)^{\frac{1}{\lambda}} \), where c is a constant such that each value of \( Y + c \) must be positive and the constant \( \lambda > 0 \).
EXP
specifies the exponential transformation of variables. The variable Y is transformed to \( e^{(Y+c)} \), where \( c \) is a constant.

LOG
specifies the logarithmic transformation of variables. The variable Y is transformed to \( \log(Y + c) \), where \( c \) is a constant such that each value of \( Y + c \) must be positive.

LOGIT
specifies the logit transformation of variables. The variable Y is transformed to \( \log\left(\frac{Y}{c} \right) \), where the constant \( c > 0 \) and the values of \( Y/c \) must be between 0 and 1.

POWER
specifies the power transformation of variables. The variable Y is transformed to \( (Y + c)^\lambda \), where \( c \) is a constant such that each value of \( Y + c \) must be positive and the constant \( \lambda \neq 0 \).

The following options provide the constant \( c \) and \( \lambda \) values in the transformations.

\textbf{C=number}

specifies the \( c \) value in the transformation. The default is \( c = 1 \) for logit transformation and \( c = 0 \) for other transformations.

\textbf{LAMBDA=number}

specifies the \( \lambda \) value in the power and Box-Cox transformations. You must specify the \( \lambda \) value for these two transformations.

For example, the statement

\texttt{{\small \textbf{transform} log(y1) power(y2/c=1 lambda=.5);}}

requests that variables \texttt{log(y1)}, a logarithmic transformation for the variable \texttt{y1}, and \texttt{sqrt(y2 + 1)}, a power transformation for the variable \texttt{y2}, be used in the imputation.

If the \texttt{MU0=} option is used to specify a parameter value \( \mu_0 \) for a transformed variable, the same transformation for the variable is also applied to its corresponding \texttt{MU0=} value in the t test. Otherwise, \( \mu_0 = 0 \) is used for the transformed variable. See Example 44.10 for a usage of the \texttt{TRANSFORM} statement.

\section*{VAR Statement}

\texttt{VAR variables ;}

The \texttt{VAR} statement lists the variables to be analyzed. The variables can be either character or numeric. If you omit the \texttt{VAR} statement, all continuous variables not mentioned in other statements are used. The \texttt{VAR} statement is required if you specify a \texttt{MONOTONE} statement, an \texttt{IMPUTE=MONOTONE} option in the \texttt{MCMC} statement, or more than one number in the \texttt{MU0=}, \texttt{MAXIMUM=}, \texttt{MINIMUM=}, or \texttt{ROUND=} option.

The character variables are allowed only when they are specified as \texttt{CLASS} variables and the \texttt{MONOTONE} statement is also specified.
Suppose $Y = (y_1, y_2, \ldots, y_n)'$ is the $(n \times p)$ matrix of complete data, which may not be fully observed, $n_0$ is the number of observations fully observed, and $n_j$ is the number of observations with observed values for variable $Y_j$.

With complete cases, the sample mean vector is

$$\bar{y} = \frac{1}{n_0} \sum y_i$$

and the CSSCP matrix is

$$\sum (y_i - \bar{y})(y_i - \bar{y})'$$

where each summation is over the fully observed observations.

The sample covariance matrix is

$$S = \frac{1}{n_0 - 1} \sum (y_i - \bar{y})(y_i - \bar{y})'$$

and is an unbiased estimate of the covariance matrix.

The correlation matrix $R$ containing the Pearson product-moment correlations of the variables is derived by scaling the corresponding covariance matrix:

$$R = D^{-1}SD^{-1}$$

where $D$ is a diagonal matrix whose diagonal elements are the square roots of the diagonal elements of $S$.

With available cases, the corrected sum of squares for variable $Y_j$ is

$$\sum (y_{ji} - \bar{y}_j)^2$$

where $\bar{y}_j = \frac{1}{n_j} \sum y_{ji}$ is the sample mean and each summation is over observations with observed values for variable $Y_j$.

The variance is

$$s_{jj}^2 = \frac{1}{n_j - 1} \sum (y_{ji} - \bar{y}_j)^2$$

The correlations for available cases contain pairwise correlations for each pair of variables. Each correlation is computed from all observations that have nonmissing values for the corresponding pair of variables.
EM Algorithm for Data with Missing Values

The EM algorithm (Dempster, Laird, and Rubin 1977) is a technique that finds maximum likelihood estimates in parametric models for incomplete data. The books by Little and Rubin (1987), Schafer (1997), and McLachlan and Krishnan (1997) provide detailed description and applications of the EM algorithm.

The EM algorithm is an iterative procedure that finds the MLE of the parameter vector by repeating the following steps:

1. The expectation E-step:
Given a set of parameter estimates, such as a mean vector and covariance matrix for a multivariate normal distribution, the E-step calculates the conditional expectation of the complete-data log likelihood given the observed data and the parameter estimates.

2. The maximization M-step:
Given a complete-data log likelihood, the M-step finds the parameter estimates to maximize the complete-data log likelihood from the E-step.

The two steps are iterated until the iterations converge.

In the EM process, the observed-data log likelihood is non-decreasing at each iteration. For multivariate normal data, suppose there are $G$ groups with distinct missing patterns. Then the observed-data log likelihood being maximized can be expressed as

$$\log L(\theta | Y_{obs}) = \sum_{g=1}^{G} \log L_g(\theta | Y_{obs})$$

where $\log L_g(\theta | Y_{obs})$ is the observed-data log likelihood from the $g_{th}$ group, and

$$\log L_g(\theta | Y_{obs}) = -\frac{n_g}{2} \log |\Sigma_g| - \frac{1}{2} \sum_{ig} (y_{ig} - \mu_g)'\Sigma_g^{-1}(y_{ig} - \mu_g)$$

where $n_g$ is the number of observations in the $g_{th}$ group, the summation is over observations in the $g_{th}$ group, $y_{ig}$ is a vector of observed values corresponding to observed variables, $\mu_g$ is the corresponding mean vector, and $\Sigma_g$ is the associated covariance matrix.

A sample covariance matrix is computed at each step of the EM algorithm. If the covariance matrix is singular, the linearly dependent variables for the observed data are excluded from the likelihood function. That is, for each observation with linear dependency among its observed variables, the dependent variables are excluded from the likelihood function. Note that this may result in an unexpected change in the likelihood between iterations prior to the final convergence.

Refer to Schafer (1997, pp. 163–181) for a detailed description of the EM algorithm for multivariate normal data.

PROC MI uses the means and standard deviations from available cases as the initial estimates for the EM algorithm. The correlations are set to zero. It provides a good
starting value with positive definite covariance matrix. For a discussion of suggested
starting values for the algorithm, see Schafer (1997, p. 169).

You can specify the convergence criterion with the CONVERGE= option in the EM
statement. The iterations are considered to have converged when the maximum
change in the parameter estimates between iteration steps is less than the value spec-
ified. You can also specify the maximum number of iterations used in the EM algo-

The IM procedure displays tables of the initial parameter estimates used to begin the
EM process and the MLE parameter estimates derived from EM. You can also dis-
play the EM iteration history with the ITPRINT option. PROC MI lists the iteration
number, the likelihood -2 Log L, and the parameter values \( \mu \) at each iteration. You
can also save the MLE derived from the EM algorithm in a SAS data set specified
with the OUTEM= option.

Statistical Assumptions for Multiple Imputation

The MI procedure assumes that the data are from a continuous multivariate distribu-
tion and contain missing values that can occur for any of the variables. It also assumes
that the data are from a multivariate normal distribution when either the regression
method or the MCMC method is used.

Suppose \( Y \) is the \( n \times p \) matrix of complete data, which is not fully observed, and
denote the observed part of \( Y \) by \( Y_{\text{obs}} \) and the missing part by \( Y_{\text{mis}} \). The SAS MI
and MIANALYZE procedures assume that the missing data are missing at random
(MAR), that is, the probability that an observation is missing can depend on \( Y_{\text{obs}} \),
but not on \( Y_{\text{mis}} \) (Rubin 1976; 1987, p. 53).

To be more precise, suppose that \( R \) is the \( n \times p \) matrix of response indicators whose
elements are zero or one depending on whether the corresponding elements of \( Y \) are
missing or observed. Then the MAR assumption is that the distribution of \( R \) can
depend on \( Y_{\text{obs}} \) but not on \( Y_{\text{mis}} \).

\[
pr(R|Y_{\text{obs}}, Y_{\text{mis}}) = pr(R|Y_{\text{obs}})
\]

For example, consider a trivariate data set with variables \( Y_1 \) and \( Y_2 \) fully observed,
and a variable \( Y_3 \) that has missing values. MAR assumes that the probability that
\( Y_3 \) is missing for an individual can be related to the individual’s values of variables
\( Y_1 \) and \( Y_2 \), but not to its value of \( Y_3 \). On the other hand, if a complete case and an
incomplete case for \( Y_3 \) with exactly the same values for variables \( Y_1 \) and \( Y_2 \) have
systematically different values, then there exists a response bias for \( Y_3 \), and MAR is
violated.

The MAR assumption is not the same as missing completely at random (MCAR),
which is a special case of MAR. Under the MCAR assumption, the missing data
values are a simple random sample of all data values; the missingness does not depend
on the values of any variables in the data set.
Although the MAR assumption cannot be verified with the data and it can be questionable in some situations, the assumption becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook, 1999, p. 687).

Furthermore, the MI and MIANALYZE procedures assume that the parameters $\theta$ of the data model and the parameters $\phi$ of the model for the missing data indicators are distinct. That is, knowing the values of $\theta$ does not provide any additional information about $\phi$, and vice versa. If both the MAR and distinctness assumptions are satisfied, the missing-data mechanism is said to be ignorable (Rubin 1987, pp. 50–54; Schafer 1997, pp. 10–11).

**Missing Data Patterns**

The MI procedure sorts the data into groups based on whether an individual’s value is observed or missing for each variable to be analyzed. Note that the input data set does not need to be sorted in any order.

For example, with variables $Y_1$, $Y_2$, and $Y_3$ (in that order) in a data set, up to eight groups of observations can be formed from the data set. The following figure displays the eight groups of observations and an unique missing pattern for each group:

<table>
<thead>
<tr>
<th>Group</th>
<th>$Y_1$</th>
<th>$Y_2$</th>
<th>$Y_3$</th>
</tr>

</tbody>
</table>

**Figure 44.6.** Missing Data Patterns

Here, an “X” means that the variable is observed in the corresponding group and a “.” means that the variable is missing.

The variable order is used to derive the order of the groups from the data set, and thus, determines the order of missing values in the data to be imputed. If you specify a different order of variables in the VAR statement, then the results are different even if the other specifications remain the same.

A data set with variables $Y_1$, $Y_2$, ..., $Y_p$ (in that order) is said to have a *monotone missing pattern* when the event that a variable $Y_j$ is missing for a particular individual implies that all subsequent variables $Y_k$, $k > j$, are missing for that individual. Alternatively, when a variable $Y_j$ is observed for a particular individual, it is assumed that all previous variables $Y_k$, $k < j$, are also observed for that individual.
For example, the following figure displays a data set of three variables with a monotone missing pattern.

<table>
<thead>
<tr>
<th>Monotone Missing Data Patterns</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group</td>
</tr>
<tr>
<td>-------</td>

</tbody>
</table>

**Figure 44.8.** Non-monotone Missing Patterns

A data set with an arbitrary missing pattern is a data set with either a monotone missing pattern or a non-monotone missing pattern.

**Imputation Methods**

This section describes the methods for multiple imputation that are available in the MI procedure. The method of choice depends on the pattern of missingness in the data and the type of the imputed variable, as summarized in the following table:

<table>
<thead>
<tr>

</table>
To impute missing values for a continuous variable in data sets with monotone missing patterns, you should use either a parametric method that assumes multivariate normality or a nonparametric method that uses propensity scores (Rubin 1987, p. 124, 158; Lavori, Dawson, and Shera 1995). Parametric methods available include the regression method (Rubin 1987, pp. 166–167) and the predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996).

To impute missing values for a CLASS variable in data sets with monotone missing patterns, you should use the logistic regression method or the discriminant function method. Use the logistic regression method when the CLASS variable has a binary or ordinal response, and the discriminant function method when the CLASS variable has a binary or nominal response.

For continuous variables in data sets with arbitrary missing patterns, you can use the Markov Chain Monte Carlo (MCMC) method (Schafer 1997) to impute either all the missing values or just enough missing values to make the imputed data sets have monotone missing patterns.

With a monotone missing data pattern, you have greater flexibility in your choice of imputation models. In addition to the MCMC method, you can implement other methods, such as the regression method, that do not use Markov chains. You can also specify a different set of covariates for each imputed variable.

With an arbitrary missing data pattern, you can often use the MCMC method, which creates multiple imputations by drawing simulations from a Bayesian predictive distribution for normal data. Another way to handle a data set with an arbitrary missing data pattern is to use the MCMC approach to impute just enough values to make the missing data pattern monotone. Then, you can use a more flexible imputation method. This approach is described in the “Producing Monotone Missingness with the MCMC Method” section on page 2552.

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from multivariate normality if the amount of missing information is not large, because the imputation model is effectively applied not to the entire data set but only to its missing part (Schafer 1997, pp. 147–148).

You can also use a TRANSFORM statement to transform variables to conform to the multivariate normality assumption. Variables are transformed before the imputation process and then are reverse-transformed to create the imputed data set.

Li (1988) presented a theoretical argument for convergence of the MCMC method in the continuous case and used it to create imputations for incomplete multivariate continuous data. In practice, however, it is not easy to check the convergence of a Markov chain, especially for a large number of parameters. PROC MI generates statistics and plots which you can use to check for convergence of the MCMC process. The details are described in the “Checking Convergence in MCMC” section on page 2555.
The regression method is the default imputation method for continuous variables in a data set with a monotone missing pattern.

In the regression method, a regression model is fitted for a continuous variable with the covariates constructed from a set of effects. Based on the fitted regression model, a new regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 166–167). That is, for a continuous variable $Y_j$ with missing values, a model

$$Y_j = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_k X_k$$

is fitted using observations with observed values for the variable $Y_j$ and its covariates $X_1, X_2, \ldots, X_k$.

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k)$ and the associated covariance matrix $\hat{\sigma}_j^2 V_j$, where $V_j$ is the usual $X'X$ inverse matrix derived from the intercept and covariates $X_1, X_2, \ldots, X_k$.

The following steps are used to generate imputed values for each imputation:

1. New parameters $\beta_s = (\beta_{s0}, \beta_{s1}, \ldots, \beta_{s(k)})$ and $\sigma^2_{s_j}$ are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k), \sigma^2_j$, and $V_j$. The variance is drawn as

$$\sigma^2_{s_j} = \hat{\sigma}^2_j (n_j - k - 1)/g$$

where $g$ is a $\chi^2_{n_j-k-1}$ random variate and $n_j$ is the number of nonmissing observations for $Y_j$. The regression coefficients are drawn as

$$\beta_s = \hat{\beta} + \sigma_{s_j} V'_{hj} Z$$

where $V'_{hj}$ is the upper triangular matrix in the Cholesky decomposition, $V_j = V'_{hj} V_{hj}$, and $Z$ is a vector of $k + 1$ independent random normal variates.

2. The missing values are then replaced by

$$\beta_{s0} + \beta_{s1} x_1 + \beta_{s2} x_2 + \ldots + \beta_{s(k)} x_k + z_i \sigma_{s_j}$$

where $x_1, x_2, \ldots, x_k$ are the values of the covariates and $z_i$ is a simulated normal deviate.
Predictive Mean Matching Method for Monotone Missing Data

The predictive mean matching method is also an imputation method available for continuous variables. It is similar to the regression method except that for each missing value, it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

Following the description of the model in the “Regression Method for Monotone Missing Data” section on page 2541, the following steps are used to generate imputed values:

1. New parameters $\beta_s = (\beta_{s0}, \beta_{s1}, \ldots, \beta_{s(k)})$ and $\sigma^2_{sj}$ are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k, \hat{\sigma}^2_j, V_j)$, the variance is drawn as $\sigma^2_{sj} = \hat{\sigma}^2_j(n_j - k - 1)/g$ where $g$ is a $\chi^2_{n_j-k-1}$ random variate and $n_j$ is the number of nonmissing observations for $Y_j$. The regression coefficients are drawn as $\beta_s = \hat{\beta} + \sigma_{sj}V'_{hj}Z$

where $V'_{hj}$ is the upper triangular matrix in the Cholesky decomposition, $V_j = V'_{hj}V_{hj}$, and $Z$ is a vector of $k + 1$ independent random normal variates.

2. For each missing value, a predicted value $y_{i*} = \beta_{s0} + \beta_{s1}x_1 + \beta_{s2}x_2 + \ldots + \beta_{s(k)}x_k$ is computed with the covariate values $x_1, x_2, \ldots, x_k$.

3. A set of $k_0$ observations whose corresponding predicted values are closest to $y_{i*}$ is generated. You can specify $k_0$ with the K= option.

4. The missing value is then replaced by a value drawn randomly from these $k_0$ observed values.

The predictive mean matching method requires the number of closest observations to be specified. A smaller $k_0$ tends to increase the correlation among the multiple imputations for the missing observation and results in a higher variability of point estimators in repeated sampling. On the other hand, a larger $k_0$ tends to lessen the effect from the imputation model and results in biased estimators (Schenker and Taylor 1996, p. 430). An optimal $k_0$ is currently not available in the literature on multiple imputation. The default is K=5. This default value is experimental and may change in future releases.

The predictive mean matching method ensures that imputed values are plausible and may be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).
Note that in SAS 9.0, the predictive mean matching method replaces each missing value by the observed value closest to its predicted value. This may result in a higher variability of point estimators in repeated sampling (Schenker and Taylor 1996, p. 430).

Propensity Score Method for Monotone Missing Data

The propensity score method is another imputation method available for continuous variables when the data set has a monotone missing pattern.

A propensity score is generally defined as the conditional probability of assignment to a particular treatment given a vector of observed covariates (Rosenbaum and Rubin 1983). In the propensity score method, for a variable with missing values, a propensity score is generated for each observation to estimate the probability that the observation is missing. The observations are then grouped based on these propensity scores, and an approximate Bayesian bootstrap imputation (Rubin 1987, p. 124) is applied to each group (Lavori, Dawson, and Shera 1995).

The propensity score method uses the following steps to impute values for variable $Y_j$ with missing values:

1. Create an indicator variable $R_j$ with the value 0 for observations with missing $Y_j$ and 1 otherwise.
2. Fit a logistic regression model

   \[
   \text{logit}(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_k X_k
   \]

   where $X_1, X_2, \ldots, X_k$ are covariates for $Y_j$, $p_j = Pr(R_j = 0|X_1, X_2, \ldots, X_k)$, and $\text{logit}(p) = \log(p/(1 - p))$.
3. Create a propensity score for each observation to estimate the probability that it is missing.
4. Divide the observations into a fixed number of groups (typically assumed to be five) based on these propensity scores.
5. Apply an approximate Bayesian bootstrap imputation to each group. In group $k$, suppose that $Y_{obs}$ denotes the $n_1$ observations with nonmissing $Y_j$ values and $Y_{mis}$ denotes the $n_0$ observations with missing $Y_j$. The approximate Bayesian bootstrap imputation first draws $n_1$ observations randomly with replacement from $Y_{obs}$ to create a new data set $Y_{obs}^*$. This is a nonparametric analogue of drawing parameters from the posterior predictive distribution of the parameters. The process then draws the $n_0$ values for $Y_{mis}$ randomly with replacement from $Y_{obs}^*$.

Steps 1 through 5 are repeated sequentially for each variable with missing values.

Note that the propensity score method was originally designed for a randomized experiment with repeated measures on the response variables. The goal was to impute the missing values on the response variables. The method uses only the covariate information that is associated with whether the imputed variable values are missing. It does not use correlations among variables. It is effective for inferences about the
distributions of individual imputed variables, such as an univariate analysis, but it is not appropriate for analyses involving relationship among variables, such as a regression analysis (Schafer 1999, p. 11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

**Discriminant Function Method for Monotone Missing Data**

The discriminant function method is the default imputation method for CLASS variables in a data set with a monotone missing pattern.

For a nominal class variable $Y_j$ with responses 1, ..., $g$, and a set of effects from its preceding variables, if the covariates $X_1, X_2, ..., X_k$ associated with these effects within each group is approximately multivariate normal and the within-group covariance matrices are approximately equal, the discriminant function method (Brand 1999, pp. 95–96) can be used to impute missing values for the variable $Y_j$.

Denote the group-specific means for covariates $X_1, X_2, ..., X_k$ by

$$\bar{X}_t = (\bar{X}_{t1}, \bar{X}_{t2}, \ldots, \bar{X}_{tk}), \ t = 1, 2, ..., g$$

then the pooled covariance matrix is computed as

$$S = \frac{1}{n - g} \sum_{t=1}^{g} (n_t - 1)S_t$$

where $S_t$ is the within-group covariance matrix, $n_t$ is the group-specific sample size, and $n = \sum_{t=1}^{g} n_t$ is the total sample size.

In each imputation, new parameters of the group-specific means ($\mathbf{m}_{*t}$), pooled covariance matrix ($\mathbf{S}_*$), and prior probabilities of group membership ($q_{*t}$) can be drawn from their corresponding posterior distributions (Schafer 1997, p. 356).

**Pooled Covariance Matrix and Group-specific Means**

For each imputation, the MI procedure uses either the fixed observed pooled covariance matrix (PCOV=FIXED) or a drawn pooled covariance matrix (PCOV=POSTERIOR) from its posterior distribution with a noninformative prior. That is,

$$\Sigma|\mathbf{X} \sim W^{-1} (n - g, (n - g)S)$$

where $W^{-1}$ is an inverted Wishart distribution.

The group-specific means are then drawn from their posterior distributions with a noninformative prior

$$\mathbf{\mu}_t|\Sigma, \bar{X}_t) \sim N\left(\bar{X}_t, \frac{1}{n_t} \Sigma\right)$$
See the “Bayesian Estimation of the Mean Vector and Covariance Matrix” section on page 2549 for a complete description of the inverted Wishart distribution and posterior distributions using a noninformative prior.

**Prior Probabilities of Group Membership**

The prior probabilities are computed through the drawing of new group sample sizes. When the total sample size $n$ is considered fixed, the group sample sizes $(n_1, n_2, \ldots, n_g)$ has a multinomial distribution. A new multinomial parameters (group sample sizes) can be drawn from its posterior distribution using a Dirichlet prior with parameters $(\alpha_1, \alpha_2, \ldots, \alpha_g)$.

After the new sample sizes are drawn from the posterior distribution of $(n_1, n_2, \ldots, n_g)$, the prior probabilities $q_{st}$ are computed proportionally to the drawn sample sizes.

**Imputation Steps**

The discriminant function method uses the following steps in each imputation to impute values for a nominal class variable $Y_j$ with $g$ responses:

1. Draw a pooled covariance matrix $S_*$ from its posterior distribution if the PCOV=POSTERIOR option is used.
2. For each group, draw group means $m_{st}$ from the observed group mean $\overline{X}_t$ and either the observed pooled covariance matrix (PCOV=FIXED) or the drawn pooled covariance matrix $S_*$ (PCOV=POSTERIOR).
3. For each group, compute or draw $q_{st}$, prior probabilities of group membership, based on the PRIOR= option:
   - PRIOR=EQUAL, $q_{st} = 1/g$, prior probabilities of group membership are all equal.
   - PRIOR=PROPORTIONAL, $q_{st} = n_t/n$, prior probabilities are proportional to their group sample sizes.
   - PRIOR=JEFFREYS=$c$, a noninformative Dirichlet prior with $\alpha_t = c$ is used.
   - PRIOR=RIDGE=$d$, a ridge prior is used with $\alpha_t = d + n_t/n$ for $d \geq 1$ and $\alpha_t = d + n_t$ for $d < 1$.
4. With the group means $m_{st}$, the pooled covariance matrix $S_*$, and the prior probabilities of group membership $q_{st}$, the discriminant function method derives linear discriminant function and computes the posterior probabilities of an observation belonging to each group

$$p_t(x) = \frac{\exp(-0.5D^2_t(x))}{\sum_{u=1}^{g} \exp(-0.5D^2_u(x))}$$
where $D^2_t(x) = (x - m_{st})'S_t^{-1}(x - m_{st}) - 2 \log(q_{st})$ is the generalized squared distance from $x$ to group $t$.

5. Draw a random uniform variate $u$, between 0 and 1, for each observation with missing group value. With the posterior probabilities, $p_1(x) + p_2(x) + \ldots + p_g(x) = 1$, the discriminant function method imputes $Y_j = 1$ if the value of $u$ is less than $p_1(x)$, $Y_j = 2$ if the value is greater than or equal to $p_1(x)$ but less than $p_1(x) + p_2(x)$, and so on.

### Logistic Regression Method for Monotone Missing Data

The logistic regression method is another imputation method available for CLASS variables in a data set with a monotone missing pattern.

In the logistic regression method, a logistic regression model is fitted for a class variable with a set of covariates constructed from the effects. For a binary class variable, based on the fitted regression model, a new logistic regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 169–170).

For a binary variable $Y_j$ with responses 1 and 2, a logistic regression model is fitted using observations with observed values for the imputed variable $Y_j$ and its covariates $X_1, X_2, \ldots, X_k$.

$$\logit(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_k X_k$$

where $X_1, X_2, \ldots, X_k$ are covariates for $Y_j$, $p_j = \Pr(R_j = 1|X_1, X_2, \ldots, X_k)$, and $\logit(p) = \log(p/(1-p))$.

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_k)$ and the associated covariance matrix $V_j$.

The following steps are used to generate imputed values for a binary variable $Y_j$ with responses 1 and 2:

1. New parameters $\beta_s = (\beta_{s0}, \beta_{s1}, \ldots, \beta_{sk})$ are drawn from the posterior predictive distribution of the parameters.

$$\beta_s = \hat{\beta} + V^\prime_{hj} Z$$

where $V^\prime_{hj}$ is the upper triangular matrix in the Cholesky decomposition, $V_j = V^\prime_{hj} V_{hj}$, and $Z$ is a vector of $k + 1$ independent random normal variates.

2. For an observation with missing $Y_j$ and covariates $x_1, x_2, \ldots, x_k$, compute the expected probability that $Y_j = 1$.

$$p_j = \frac{\exp(\mu_j)}{1 + \exp(\mu_j)}$$

where $\mu_j = \beta_{s0} + \beta_{s1} x_1 + \beta_{s2} x_2 + \ldots + \beta_{sk} x_k$. 
3. Draw a random uniform variate, $u$, between 0 and 1. If the value of $u$ is less than $p_j$, impute $Y_j = 1$, otherwise impute $Y_j = 2$.

The preceding logistic regression method can be extended to include the ordinal class variables with more than two levels of responses. The options ORDER= and DESCENDING can be used to specify the sorting order for the levels of the imputed variables.

### MCMC Method for Arbitrary Missing Data

The Markov Chain Monte Carlo (MCMC) method originated in physics as a tool for exploring equilibrium distributions of interacting molecules. In statistical applications, it is used to generate pseudo-random draws from multidimensional and otherwise intractable probability distributions via Markov chains. A Markov chain is a sequence of random variables in which the distribution of each element depends only on the value of the previous one.

In MCMC simulation, one constructs a Markov chain long enough for the distribution of the elements to stabilize to a stationary distribution, which is the distribution of interest. By repeatedly simulating steps of the chain, the method simulates draws from the distribution of interest. Refer to Schafer (1997) for a detailed discussion of this method.

In Bayesian inference, information about unknown parameters is expressed in the form of a posterior probability distribution. This posterior distribution is computed using Bayes’ theorem

$$p(\theta | y) = \frac{p(y | \theta)p(\theta)}{\int p(y | \theta)p(\theta)d\theta}$$

MCMC has been applied as a method for exploring posterior distributions in Bayesian inference. That is, through MCMC, one can simulate the entire joint posterior distribution of the unknown quantities and obtain simulation-based estimates of posterior parameters that are of interest.

In many incomplete data problems, the observed-data posterior $p(\theta | Y_{obs})$ is intractable and cannot easily be simulated. However, when $Y_{obs}$ is augmented by an estimated/simulated value of the missing data $Y_{mis}$, the complete-data posterior $p(\theta | Y_{obs}, Y_{mis})$ is much easier to simulate. Assuming that the data are from a multivariate normal distribution, data augmentation can be applied to Bayesian inference with missing data by repeating the following steps:

1. **The imputation I-step:**
   Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. That is, if you denote the variables with missing values for observation $i$ by $Y_{i(mis)}$ and the variables with observed values by $Y_{i(obs)}$, then the I-step draws values for $Y_{i(mis)}$ from a conditional distribution for $Y_{i(mis)}$ given $Y_{i(obs)}$. 

2. The posterior P-step:
Given a complete sample, the P-step simulates the posterior population mean vector and covariance matrix. These new estimates are then used in the next I-step. Without prior information about the parameters, a noninformative prior is used. You can also use other informative priors. For example, a prior information about the covariance matrix can be helpful to stabilize the inference about the mean vector for a near singular covariance matrix.

The two steps are iterated long enough for the results to be reliable for a multiply imputed data set (Schafer 1997, p. 72). That is, with a current parameter estimate \( \theta^{(t)} \) at the \( t \)th iteration, the I-step draws \( Y^{(t+1)}_{\text{mis}} \) from \( p(Y_{\text{mis}}|Y_{\text{obs}}, \theta^{(t)}) \) and the P-step draws \( \theta^{(t+1)} \) from \( p(\theta|Y_{\text{obs}}, Y^{(t+1)}_{\text{mis}}) \).

This creates a Markov chain 
\[
(Y^{(1)}_{\text{mis}}, \theta^{(1)}), (Y^{(2)}_{\text{mis}}, \theta^{(2)}), \ldots
\]
which converges in distribution to \( p(Y_{\text{mis}}, \theta|Y_{\text{obs}}) \). Assuming the iterates converge to a stationary distribution, the goal is to simulate an approximately independent draw of the missing values from this distribution.

To validate the imputation results, you should repeat the process with different random number generators and starting values based on different initial parameter estimates.

The next three sections provide details for the imputation step, Bayesian estimation of the mean vector and covariance matrix, and the posterior step.

**Imputation Step**

In each iteration, starting with a given mean vector \( \mu \) and covariance matrix \( \Sigma \), the imputation step draws values for the missing data from the conditional distribution \( Y_{\text{mis}} \) given \( Y_{\text{obs}} \).

Suppose \( \mu = [\mu_1', \mu_2']' \) is the partitioned mean vector of two sets of variables, \( Y_{\text{obs}} \) and \( Y_{\text{mis}} \), where \( \mu_1 \) is the mean vector for variables \( Y_{\text{obs}} \) and \( \mu_2 \) is the mean vector for variables \( Y_{\text{mis}} \).

Also suppose
\[
\Sigma = \begin{bmatrix}
\Sigma_{11} & \Sigma_{12} \\
\Sigma_{12}' & \Sigma_{22}
\end{bmatrix}
\]
is the partitioned covariance matrix for these variables, where \( \Sigma_{11} \) is the covariance matrix for variables \( Y_{\text{obs}} \), \( \Sigma_{22} \) is the covariance matrix for variables \( Y_{\text{mis}} \), and \( \Sigma_{12} \) is the covariance matrix between variables \( Y_{\text{obs}} \) and variables \( Y_{\text{mis}} \).
By using the sweep operator (Goodnight 1979) on the pivots of the \( \Sigma_{11} \) submatrix, the matrix becomes
\[
\begin{bmatrix}
\Sigma_{11}^{-1} & \Sigma_{11}^{-1} \Sigma_{12} \\
-\Sigma_{12}' \Sigma_{11}^{-1} & \Sigma_{22,1}
\end{bmatrix}
\]
where \( \Sigma_{22,1} = \Sigma_{22} - \Sigma_{12}' \Sigma_{11}^{-1} \Sigma_{12} \) can be used to compute the conditional covariance matrix of \( Y_{mis} \) after controlling for \( Y_{obs} \).

For an observation with the preceding missing pattern, the conditional distribution of \( Y_{mis} \) given \( Y_{obs} = y_1 \) is a multivariate normal distribution with the mean vector
\[
\mu_{2,1} = \mu_2 + \Sigma_{12}' \Sigma_{11}^{-1} (y_1 - \mu_1)
\]
and the conditional covariance matrix
\[
\Sigma_{22,1} = \Sigma_{22} - \Sigma_{12}' \Sigma_{11}^{-1} \Sigma_{12}
\]

**Bayesian Estimation of the Mean Vector and Covariance Matrix**

Suppose that \( Y = (y'_1, y'_2, ..., y'_n)' \) is an \( (n \times p) \) matrix made up of \( n \) \( (p \times 1) \) independent vectors \( y_i \), each of which has a multivariate normal distribution with mean zero and covariance matrix \( \Lambda \). Then the SSCP matrix
\[
A = Y'Y = \sum_i y_i y'_i
\]
has a Wishart distribution \( W(n, \Lambda) \).

When each observation \( y_i \) is distributed with a multivariate normal distribution with an unknown mean \( \mu \), then the CSSCP matrix
\[
A = \sum_i (y_i - \overline{y})(y_i - \overline{y})'
\]
has a Wishart distribution \( W(n - 1, \Lambda) \).

If \( A \) has a Wishart distribution \( W(n, \Lambda) \), then \( B = A^{-1} \) has an inverted Wishart distribution \( W^{-1}(n, \Psi) \), where \( n \) is the degrees of freedom and \( \Psi = \Lambda^{-1} \) is the precision matrix (Anderson 1984).

Note that, instead of using the parameter \( \Psi = \Lambda^{-1} \) for the inverted Wishart distribution, Schafer (1997) uses the parameter \( \Lambda \).

Suppose that each observation in the data matrix \( Y \) has a multivariate normal distribution with mean \( \mu \) and covariance matrix \( \Sigma \). Then with a prior inverted Wishart distribution for \( \Sigma \) and a prior normal distribution for \( \mu \)
\[
\Sigma \sim W^{-1}(m, \Psi) \\
\mu | \Sigma \sim N\left(\mu_0, \frac{1}{\tau} \Sigma\right)
\]
where \( \tau > 0 \) is a fixed number.
The posterior distribution (Anderson 1984, p. 270; Schafer 1997, p. 152) is

\[
\Sigma | \mathbf{Y} \sim W^{-1} \left( n + m, (n - 1)\mathbf{S} + \frac{n\tau}{n + \tau} (\mathbf{y} - \mu_0)(\mathbf{y} - \mu_0)' \right)
\]

\[
\mu | (\Sigma, \mathbf{Y}) \sim N \left( \frac{1}{n + \tau} (n\mathbf{y} + \tau\mu_0), \frac{1}{n + \tau} \Sigma \right)
\]

where \((n - 1)\mathbf{S}\) is the CSSCP matrix.

**Posterior Step**

In each iteration, the posterior step simulates the posterior population mean vector \(\mu\) and covariance matrix \(\Sigma\) from prior information for \(\mu\) and \(\Sigma\), and the complete sample estimates.

You can specify the prior parameter information using one of the following methods:

- **PRIOR=JEFFREYS**, which uses a noninformative prior.
- **PRIOR=INPUT=**, which provides a prior information for \(\Sigma\) in the data set. Optionally, it also provides a prior information for \(\mu\) in the data set.
- **PRIOR=RIDGE=**, which uses a ridge prior.

The next four subsections provide details of the posterior step for different prior distributions.

**1. A Noninformative Prior**

Without prior information about the mean and covariance estimates, a noninformative prior can be used by specifying the PRIOR=JEFFREYS option. The posterior distributions (Schafer 1997, p. 154) are

\[
\Sigma^{(t+1)} | \mathbf{Y} \sim W^{-1} \left( n - 1, (n - 1)\mathbf{S} \right)
\]

\[
\mu^{(t+1)} | (\Sigma^{(t+1)}, \mathbf{Y}) \sim N \left( \frac{1}{n} (n\mathbf{y} + \tau\mu_0), \frac{1}{n + \tau} \Sigma \right)
\]

**2. An Informative Prior for \(\mu\) and \(\Sigma\)**

When prior information is available for the parameters \(\mu\) and \(\Sigma\), you can provide it with a SAS data set that you specify with the PRIOR=INPUT= option.

\[
\Sigma \sim W^{-1} (d^*, d^*\mathbf{S}^*)
\]

\[
\mu | \Sigma \sim N \left( \mu_0, \frac{1}{n_0} \Sigma \right)
\]

To obtain the prior distribution for \(\Sigma\), PROC MI reads the matrix \(\mathbf{S}^*\) from observations in the data set with _TYPE_=‘COV’, and it reads \(n^* = d^* + 1\) from observations with _TYPE_=‘N’.
To obtain the prior distribution for $\mu$, PROC MI reads the mean vector $\mu_0$ from observations with _TYPE_='MEAN', and it reads $n_0$ from observations with _TYPE_='N_MEAN'. When there are no observations with _TYPE_='N_MEAN', PROC MI reads $n_0$ from observations with _TYPE_='N'.

The resulting posterior distribution, as described in the “Bayesian Estimation of the Mean Vector and Covariance Matrix” section on page 2549, is given by

$$
\Sigma^{(t+1)}|Y \sim W^{-1}(n + d^*, (n - 1)\Sigma + d^*S^* + S_m)$$

$$
\mu^{(t+1)}|\Sigma^{(t+1)}, Y \sim N\left(\frac{1}{n + n_0}(n\bar{y} + n_0\mu_0), \frac{1}{n + n_0}\Sigma^{(t+1)}\right)
$$

where

$$S_m = \frac{nn_0}{n + n_0}(\bar{y} - \mu_0)(\bar{y} - \mu_0)'$$

3. An Informative Prior for $\Sigma$

When the sample covariance matrix $S$ is singular or near singular, prior information about $\Sigma$ can also be used without prior information about $\mu$ to stabilize the inference about $\mu$. You can provide it with a SAS data set that you specify with the PRIOR=INPUT= option.

To obtain the prior distribution for $\Sigma$, PROC MI reads the matrix $S^*$ from observations in the data set with _TYPE_='COV', and it reads $n^*$ from observations with _TYPE_='N'.

The resulting posterior distribution for $(\mu, \Sigma)$ (Schafer 1997, p. 156) is

$$
\Sigma^{(t+1)}|Y \sim W^{-1}(n + d^*, (n - 1)\Sigma + d^*S^*)$$

$$
\mu^{(t+1)}|\Sigma^{(t+1)}, Y \sim N\left(\bar{y}, \frac{1}{n}\Sigma^{(t+1)}\right)
$$

Note that if the PRIOR=INPUT= data set also contains observations with _TYPE_='MEAN', then a complete informative prior for both $\mu$ and $\Sigma$ will be used.

4. A Ridge Prior

A special case of the preceding adjustment is a ridge prior with $S^* = \text{Diag}(S)$ (Schafer 1997, p. 156). That is, $S^*$ is a diagonal matrix with diagonal elements equal to the corresponding elements in $S$.

You can request a ridge prior by using the PRIOR=RIDGE= option. You can explicitly specify the number $d^* \geq 1$ in the PRIOR=RIDGE=d^* option. Or you can implicitly specify the number by specifying the proportion $p$ in the PRIOR=RIDGE=p option to request $d^* = (n - 1)p$. 
The posterior is then given by

$$
\Sigma^{(t+1)} \mid Y \sim W^{-1}(n + d^*, (n - 1)S + d^* \text{Diag}(S)) \\
\mu^{(t+1)} \mid (\Sigma^{(t+1)}, Y) \sim N\left(\bar{y}, \frac{1}{n} \Sigma^{(t+1)}\right)
$$

### Producing Monotone Missingness with the MCMC Method

The monotone data MCMC method was first proposed by Li (1988), and Liu (1993) described the algorithm. The method is useful especially when a data set is close to having a monotone missing pattern. In this case, the method only needs to impute a few missing values to the data set to have a monotone missing pattern in the imputed data set. Compared to a full data imputation that imputes all missing values, the monotone data MCMC method imputes fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227).

You can request the monotone MCMC method by specifying the option IMPUTE=MONOTONE in the MCMC statement. The “Missing Data Patterns” table now denotes the variables with missing values by ‘.’ or ‘O’. The value ‘.’ means that the variable is missing and will be imputed and the value ‘O’ means that the variable is missing and will not be imputed. The tables of “Multiple Imputation Variance Information” and “Multiple Imputation Parameter Estimates” are not created.

You must specify the variables in the VAR statement. The variable order in the list determines the monotone missing pattern in the imputed data set. With a different order in the VAR list, the results will be different because the monotone missing pattern to be constructed will be different.

Assuming that the data are from a multivariate normal distribution, then similar to the MCMC method, the monotone MCMC method repeats the following steps:

1. **The imputation I-step:**
   Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. Only a subset of missing values are simulated to achieve a monotone pattern of missingness.

2. **The posterior P-step:**
   Given a new sample with a monotone pattern of missingness, the P-step simulates the posterior population mean vector and covariance matrix with a noninformative Jeffreys prior. These new estimates are then used in the next I-step.

### Imputation Step

The I-step is almost identical to the I-step described in the “MCMC Method for Arbitrary Missing Data” section on page 2547 except that only a subset of missing values need to be simulated. To state this precisely, denote the variables with observed values for observation \(i\) by \(Y_{i(\text{obs})}\) and the variables with missing values by \(Y_{i(mis)} = (Y_{i(m1)}, Y_{i(m2)})\), where \(Y_{i(m1)}\) is a subset of the the missing variables that will result a monotone missingness when their values are imputed. Then the I-step draws values for \(Y_{i(m1)}\) from a conditional distribution for \(Y_{i(m1)}\) given \(Y_{i(\text{obs})}\).
**Posterior Step**

The P-step is different from the P-step described in the “MCMC Method for Arbitrary Missing Data” section on page 2547. Instead of simulating the $\mu$ and $\Sigma$ parameters from the full imputed data set, this P-step simulates the $\mu$ and $\Sigma$ parameters through simulated regression coefficients from regression models based on the imputed data set with a monotone pattern of missingness. The step is similar to the process described in the “Regression Method for Monotone Missing Data” section on page 2541.

That is, for the variable $Y_j$, a model

$$Y_j = \beta_0 + \beta_1 Y_1 + \beta_2 Y_2 + \ldots + \beta_{j-1} Y_{j-1}$$

is fitted using $n_j$ nonmissing observations for variable $Y_j$ in the imputed data sets.

The fitted model consists of the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_{j-1})$ and the associated covariance matrix $\hat{\sigma}_j^2 V_j$, where $V_j$ is the usual $X'X$ inverse matrix from the intercept and variables $Y_1, Y_2, \ldots, Y_{j-1}$.

For each imputation, new parameters $\beta_* = (\beta_{0*}, \beta_{1*}, \ldots, \beta_{(j-1)*})$ and $\sigma_*^2$ are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \ldots, \hat{\beta}_{j-1}), \sigma^2_j$, and $V_j$. The variance is drawn as

$$\sigma_*^2 = \hat{\sigma}_j^2 (n_j - j)/g$$

where $g$ is a $\chi^2_{n_j-p+j-1}$ random variate and $n_j$ is the number of nonmissing observations for $Y_j$. The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_*^2 V_{hj}' Z$$

where $V_{hj}'$ is the upper triangular matrix in the Cholesky decomposition

$V_j = V_{hj}' V_{hj}$ and $Z$ is a vector of $j$ independent random normal variates.

These simulated values of $\beta_*$ and $\sigma_*^2$ are then used to re-create the parameters $\mu$ and $\Sigma$. For a detailed description of how to produce monotone-missingness with the MCMC method for a multivariate normal data, refer to Schafer (1997, pp. 226–235).

---

**MCMC Method Specifications**

With MCMC, you can impute either all missing values (IMPUTE=FULL) or just enough missing values to make the imputed data set have a monotone missing pattern (IMPUTE=MONOTONE). In the process, either a single chain for all imputations (CHAIN=SINGLE) or a separate chain for each imputation (CHAIN=MULTIPLE) is used. The single chain may be somewhat more precise for estimating a single quantity such as posterior mean (Schafer 1997, p. 138). Refer to Schafer (1997, pp. 137–138) for a discussion of single versus multiple chains.
You can specify the number of initial burn-in iterations before the first imputation with the \texttt{NBITER=} option. This number is also used for subsequent chains for multiple chains. For a single chain, you can also specify the number of iterations between imputations with the \texttt{NITER=} option.

You can explicitly specify initial parameter values for the MCMC process with the \texttt{INITIAL=INPUT=} data set option. Alternatively, you can use the EM algorithm to derive a set of initial parameter values for MCMC with the option \texttt{INITIAL=EM}. These estimates are used as either the starting value (\texttt{START=VALUE}) or as the starting distribution (\texttt{START=DIST}) for the MCMC process. For multiple chains, these estimates are used again as either the starting value (\texttt{START=VALUE}) or as the starting distribution (\texttt{START=DIST}) for the subsequent chains.

You can specify the prior parameter information in the \texttt{PRIOR=} option. You can use a noninformative prior (\texttt{PRIOR=JEFFREYS}), a ridge prior (\texttt{PRIOR=RIDGE}), or an informative prior specified in a data set (\texttt{PRIOR=INPUT}).

The parameter estimates used to generate imputed values in each imputation can be saved in a data set with the \texttt{OUTEST=} option. Later, this data set can be read with the \texttt{INEST=} option to provide the reference distribution for imputing missing values for a new data set.

By default, the MCMC method uses a single chain to produce five imputations. It completes 200 burn-in iterations before the first imputation and 100 iterations between imputations. The posterior mode computed from the EM algorithm with a noninformative prior is used as the starting values for the MCMC process.

\textbf{\textit{INITIAL=EM} Specifications}

The EM algorithm is used to find the maximum likelihood estimates for incomplete data in the EM statement. You can also use the EM algorithm to find a posterior mode, the parameter estimates that maximize the observed-data posterior density. The resulting posterior mode provides a good starting value for the MCMC process.

With \texttt{INITIAL=EM}, \texttt{PROC MI} uses the MLE of the parameter vector as the initial estimates in the EM algorithm for the posterior mode. You can use the \texttt{ITPRINT} option in \texttt{INITIAL=EM} to display the iteration history for the EM algorithm.

You can use the \texttt{CONVERGE=} option to specify the convergence criterion in deriving the EM posterior mode. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. By default, \texttt{CONVERGE=}1E-4.

You can also use the \texttt{MAXITER=} option to specify the maximum number of iterations in the EM algorithm. By default, \texttt{MAXITER=}200.

With the \texttt{BOOTSTRAP} option, you can use overdispersed starting values for the MCMC process. In this case, \texttt{PROC MI} applies the EM algorithm to a bootstrap sample, a simple random sample with replacement from the input data set, to derive the initial estimates for each chain (Schafer 1997, p. 128).
Checking Convergence in MCMC

The theoretical convergence of the MCMC process has been explored under various conditions, as described in Schafer (1997, p. 70). However, in practice, verification of convergence is not a simple matter.

The parameters used in the imputation step for each iteration can be saved in an output data set with the OUTITER= option. These include the means, standard deviations, covariances, the worst linear function, and observed-data LR statistics. You can then monitor the convergence in a single chain by displaying time-series plots and autocorrelations for those parameter values (Schafer 1997, p. 120). The time-series and autocorrelation function plots for parameters such as variable means, covariances, and the worst linear function can be displayed by specifying the TIMEPLOT and ACFPLOT option.

You can apply EM to a bootstrap sample to obtain overdispersed starting values for multiple chains (Gelman and Rubin 1992). This provides a conservative estimate of the number of iterations needed before each imputation.

The next four subsections describe useful statistics and plots that can be used to check the convergence of the MCMC process.

LR Statistics

You can save the observed-data likelihood ratio (LR) statistic in each iteration with the LR option in the OUTITER= data set. The statistic is based on the observed-data likelihood with parameter values used in the iteration and the observed-data maximum likelihood derived from the EM algorithm.

In each iteration, the LR statistic is given by

\[-2 \log \left( \frac{f(\hat{\theta}_i)}{f(\theta)} \right)\]

where \(f(\hat{\theta})\) is the observed-data maximum likelihood derived from the EM algorithm and \(f(\hat{\theta}_i)\) is the observed-data likelihood for \(\hat{\theta}_i\) used in the iteration.

Similarly, you can also save the observed-data LR posterior mode statistic for each iteration with the LR_POST option. This statistic is based on the observed-data posterior density with parameter values used in each iteration and the observed-data posterior mode derived from the EM algorithm for posterior mode.

For large samples, these LR statistics tend to be approximately \(\chi^2\) distributed with degrees of freedom equal to the dimension of \(\theta\) (Schafer 1997, p. 131). For example, with a large number of iterations, if the values of the LR statistic do not behave like a random sample from the described \(\chi^2\) distribution, then there is evidence that the MCMC process has not converged.
Worst Linear Function of Parameters

The worst linear function (WLF) of parameters (Schafer 1997, pp. 129-131) is a scalar function of parameters $\mu$ and $\Sigma$ that is “worst” in the sense that its function values converge most slowly among parameters in the MCMC process. The convergence of this function is evidence that other parameters are likely to converge as well.

For linear functions of parameters $\theta = (\mu, \Sigma)$, a worst linear function of $\theta$ has the highest asymptotic rate of missing information. The function can be derived from the iterative values of $\theta$ near the posterior mode in the EM algorithm. That is, an estimated worst linear function of $\theta$ is

$$w(\theta) = v^\prime (\theta - \hat{\theta})$$

where $\hat{\theta}$ is the posterior mode and the coefficients $v = \hat{\theta}_{(-1)} - \hat{\theta}$ is the difference between the estimated value of $\theta$ one step prior to convergence and the converged value $\hat{\theta}$.

You can display the coefficients of the worst linear function, $v$, by specifying the WLF option in the MCMC statement. You can save the function value from each iteration in an OUTITER= data set by specifying the WLF option in the OUTITER option. You can also display the worst linear function values from iterations in an autocorrelation plot or a time-series plot by specifying WLF as an ACFPLOT or TIMEPLOT option, respectively.

Note that when the observed-data posterior is nearly normal, the WLF is one of the slowest functions to approach stationarity. When the posterior is not close to normal, other functions may take much longer than the WLF to converge, as described in Schafer (1997, p.130).

Time-Series Plot

A time-series plot for a parameter $\xi$ is a scatter plot of successive parameter estimates $\xi_i$ against the iteration number $i$. The plot provides a simple way to examine the convergence behavior of the estimation algorithm for $\xi$. Long-term trends in the plot indicate that successive iterations are highly correlated and that the series of iterations has not converged.

You can display time-series plots for the worst linear function, the variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for positive parameters in the plots with the LOG option. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

By default, the MI procedure uses solid line segments to connect data points in a time-series plot. You can use the CCONNECT=, LCONNECT=, and WCONNECT= options to change the color, line type, and width of the line segments. When WCONNECT=0 is specified, the data points are not connected, and the procedure
uses the plus sign (+) as the plot symbol to display the points with a height of one (percentage screen unit) in a time-series plot you can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol.

By default, the plot title “Time-Series Plot” is displayed in a time-series plot. You can request another title by using the TITLE= option in the TIMEPLOT option. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. Refer to the chapter “The SAS/GRAPH Statements” in SAS/GRAPH Software: Reference for an illustration of title options. See Example 44.8 for a usage of the time-series plot.

**Autocorrelation Function Plot**

To examine relationships of successive parameter estimates $\xi$, the autocorrelation function (ACF) can be used. For a stationary series, $\xi_i, i \geq 1$, in time series data, the autocorrelation function at lag $k$ is

$$\rho_k = \frac{\text{Cov}(\xi_i, \xi_{i+k})}{\text{Var}(\xi_i)}$$

The sample $k^{th}$ order autocorrelation is computed as

$$r_k = \frac{\sum_{i=1}^{n-k} (\xi_i - \bar{\xi})(\xi_{i+k} - \bar{\xi})}{\sum_{i=1}^{n} (\xi_i - \bar{\xi})^2}$$

You can display autocorrelation function plots for the worst linear function, the variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for parameters in the plots with the LOG option. When a parameter has values less than or equal to zero, the corresponding plot is not created.

You specify the maximum number of lags of the series with the NLAG= option. The autocorrelations at each lag less than or equal to the specified lag are displayed in the graph. In addition, the plot also displays approximate 95% confidence limits for the autocorrelations. At lag $k$, the confidence limits indicate a set of approximate 95% critical values for testing the hypothesis $\rho_j = 0, j \geq k$.

By default, the MI procedure uses the star sign (*) as the plot symbol to display the points with a height of one (percentage screen unit) in the plot, a solid line to display the reference line of zero autocorrelation, vertical line segments to connect autocorrelations to the reference line, and a pair of dashed lines to display approximately 95% confidence limits for the autocorrelations.

You can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol, and the CNEEDLES= and WNEEDLES= options to change the color and width of the needles. You can also use the LREF=,...
CREF=, and WREF= options to change the line type, color, and width of the reference line. Similarly, you can use the LCONF=, CCONF=, and WCONF= options to change the line type, color, and width of the confidence limits.

By default, the plot title “Autocorrelation Plot” is displayed in a autocorrelation function plot. You can request another title by using the TITLE= option in ACFPLOT. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. Refer to the chapter “The SAS/GRAPH Statements” in SAS/GRAPH Software: Reference for a description of title options. See Example 44.8 for an illustration of the autocorrelation function plot.

**Input Data Sets**

You can specify the input data set with missing values with the DATA= option in the PROC MI statement. When an MCMC method is used, you can specify the data set containing the reference distribution information for imputation with the INEST= option, the data set containing initial parameter estimates for the MCMC process with the INITIAL=INPUT= option, and the data set containing information for the prior distribution with the PRIOR=INPUT= option in the MCMC statement.

**DATA=SAS-data-set**

The input DATA= data set is an ordinary SAS data set containing multivariate data with missing values.

**INEST=SAS-data-set**

The input INEST= data set is a TYPE=EST data set and contains a variable _Imputation_ to identify the imputation number. For each imputation, PROC MI reads the point estimate from the observations with _TYPE_='PARM' or _TYPE_='PARMS' and the associated covariances from the observations with _TYPE_='COV' or _TYPE_='COVB'. These estimates are used as the reference distribution to impute values for observations in the DATA= data set. When the input INEST= data set also contains observations with _TYPE_='SEED', PROC MI reads the seed information for the random number generator from these observations. Otherwise, the SEED= option provides the seed information.

**INITIAL=INPUT=SAS-data-set**

The input INITIAL=INPUT= data set is a TYPE=COV or CORR data set and provides initial parameter estimates for the MCMC process. The covariances derived from the TYPE=COV/CORR data set are divided by the number of observations to get the correct covariance matrix for the point estimate (sample mean).

If TYPE=COV, PROC MI reads the number of observations from the observations with _TYPE_='N', the point estimate from the observations with _TYPE_='MEAN', and the covariances from the observations with _TYPE_='COV'.

If TYPE=CORR, PROC MI reads the number of observations from the observations with _TYPE_='N', the point estimate from the observations with
Prior=Input=SAS-data-set
The input Prior=Input= data set is a Type=Cov data set that provides information for the prior distribution. You can use the data set to specify a prior distribution for $\Sigma$ of the form

$$\Sigma \sim W^{-1}(d^*, d^* S^*)$$

where $d^* = n^* - 1$ is the degrees of freedom. PROC MI reads the matrix $S^*$ from observations with _Type_='Cov' and $n^*$ from observations with _Type_='N'.

You can also use this data set to specify a prior distribution for $\mu$ of the form

$$\mu \sim N\left(\mu_0, \frac{1}{n_0} \Sigma\right)$$

PROC MI reads the mean vector $\mu_0$ from observations with _Type_='Mean' and $n_0$ from observations with _Type_='N-Mean'. When there are no observations with _Type_='N-Mean', PROC MI reads $n_0$ from observations with _Type_='N'.

Output Data Sets
You can specify the output data set of imputed values with the OUT= option in the PROC MI statement. When an EM statement is used, you can specify the data set containing the original data set with missing values being replaced by the expected values from the EM algorithm with the OUT= option in the EM statement. You can also specify the data set containing MLE computed with the EM algorithm with the OUTEM= option.

When an MCMC method is used, you can specify the data set containing parameter estimates used in each imputation with the OUTEST= option and the data set containing parameters used in the imputation step for each iteration with the OUTITER option in the MCMC statement.

**OUT=SAS-data-set in the PROC MI statement**
The OUT= data set contains all the variables in the original data set and a new variable named _Imputation_ that identifies the imputation. For each imputation, the data set contains all variables in the input Data= data set with missing values being replaced by imputed values. Note that when the NImpute=1 option is specified, the variable _Imputation_ is not created.

**OUT=SAS-data-set in an EM statement**
The OUT= data set contains the original data set with missing values being replaced by expected values from the EM algorithm.
**OUTEM= SAS-data-set**

The OUTEM= data set is a TYPE=COV data set and contains the MLE computed with the EM algorithm. The observations with `_TYPE_`=`‘MEAN’` contain the estimated mean and the observations with `_TYPE_`=`‘COV’` contain the estimated covariances.

**OUTEST= SAS-data-set**

The OUTEST= data set is a TYPE=EST data set and contains parameter estimates used in each imputation in the MCMC method. It also includes an index variable named `_Imputation_`, which identifies the imputation.

The observations with `_TYPE_`=`‘SEED’` contain the seed information for the random number generator. The observations with `_TYPE_`=`‘PARM’` or `_TYPE_`=`‘PARMS’` contain the point estimate and the observations with `_TYPE_`=`‘COV’` or `_TYPE_`=`‘COVB’` contain the associated covariances. These estimates are used as the parameters of the reference distribution to impute values for observations in the DATA= dataset.

Note that these estimates are the values used in the I-step before each imputation. These are not the parameter values simulated from the P-step in the same iteration. See Example 44.9 for a usage of this option.

**OUTITER < (options) > = SAS-data-set in an EM statement**

The OUTITER= data set in an EM statement is a TYPE=COV data set and contains parameters for each iteration. It also includes a variable `_Iteration_` that provides the iteration number.

The parameters in the output data set depend on the options specified. You can specify the MEAN and COV options for OUTITER. With the MEAN option, the output data set contains the mean parameters in observations with the variable `_TYPE_`=`‘MEAN’`. Similarly, with the MEAN option, the output data set contains the covariance parameters in observations with the variable `_TYPE_`=`‘COV’`. When no options are specified, the output data set contains the mean parameters for each iteration.

**OUTITER < (options) > = SAS-data-set in an MCMC statement**

The OUTITER= data set in an MCMC statement is a TYPE=COV data set and contains parameters used in the imputation step for each iteration. It also includes variables named `_Imputation_` and `_Iteration_`, which provide the imputation number and iteration number.

The parameters in the output data set depend on the options specified. The following table summarizes the options available for OUTITER and the corresponding values for the output variable `_TYPE_`.

<table>

When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. For a detailed description of the worst linear function and LR statistics, see the “Checking Convergence in MCMC” section on page 2555.

Combining Inferences from Multiply Imputed Data Sets

With \( m \) imputations, \( m \) different sets of the point and variance estimates for a parameter \( Q \) can be computed. Suppose \( \hat{Q}_i \) and \( \hat{U}_i \) are the point and variance estimates from the \( i \)th imputed data set, \( i=1, 2, \ldots, m \). Then the combined point estimate for \( Q \) from multiple imputation is the average of the \( m \) complete-data estimates:

\[
\overline{Q} = \frac{1}{m} \sum_{i=1}^{m} \hat{Q}_i
\]

Suppose \( \overline{U} \) is the within-imputation variance, which is the average of the \( m \) complete-data estimates:

\[
\overline{U} = \frac{1}{m} \sum_{i=1}^{m} \hat{U}_i
\]

and \( B \) is the between-imputation variance

\[
B = \frac{1}{m-1} \sum_{i=1}^{m} (\hat{Q}_i - \overline{Q})^2
\]

Then the variance estimate associated with \( \overline{Q} \) is the total variance (Rubin 1987)

\[
T = \overline{U} + (1 + \frac{1}{m})B
\]

The statistic \( (Q - \overline{Q})T^{-(1/2)} \) is approximately distributed as \( t \) with \( v_m \) degrees of freedom (Rubin 1987), where

\[
v_m = (m - 1) \left[ 1 + \frac{W}{(1 + m^{-1})B} \right]^2
\]

The degrees of freedom \( v_m \) depends on \( m \) and the ratio

\[
r = \frac{(1 + m^{-1})B}{\overline{U}}
\]
The ratio $r$ is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about $Q$, the values of $r$ and $B$ are both zero. With a large value of $m$ or a small value of $r$, the degrees of freedom $v_m$ will be large and the distribution of $(Q - \bar{Q})T^{-(1/2)}$ will be approximately normal.

Another useful statistic is the fraction of missing information about $Q$:

$$\hat{\lambda} = \frac{r + 2/(v_m + 3)}{r + 1}$$

Both statistics $r$ and $\lambda$ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about $Q$.

When the complete-data degrees of freedom $v_0$ is small, and there is only a modest proportion of missing data, the computed degrees of freedom, $v_m$, can be much larger than $v_0$, which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of an adjusted degrees of freedom

$$v_m^* = \left[ \frac{1}{v_m} + \frac{1}{\hat{\nu}_{obs}} \right]^{-1}$$

where $\hat{\nu}_{obs} = (1 - \gamma) v_0(v_0 + 1)/(v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

Note that the MI procedure uses the adjusted degrees of freedom, $v_m^*$, for inference.

### Multiple Imputation Efficiency

The relative efficiency (RE) of using the finite $m$ imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of $m$ and $\lambda$ (Rubin 1987, p. 114).

$$RE = \left( 1 + \frac{\lambda}{m} \right)^{-1}$$

The following table shows relative efficiencies with different values of $m$ and $\lambda$.

**Table 44.5. Relative Efficiency**

<table>
<thead>
<tr>
<th>$\lambda$</th>
<th>10%</th>
<th>20%</th>
<th>30%</th>
<th>50%</th>
<th>70%</th>
</tr>
</thead>
<tbody>
<tr>
<td>$m$</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>0.9677</td>
<td>0.9375</td>
<td>0.9091</td>
<td>0.8571</td>
<td>0.8108</td>
</tr>
<tr>
<td>5</td>
<td>0.9804</td>
<td>0.9615</td>
<td>0.9434</td>
<td>0.9091</td>
<td>0.8772</td>
</tr>
<tr>
<td>10</td>
<td>0.9901</td>
<td>0.9804</td>
<td>0.9709</td>
<td>0.9524</td>
<td>0.9346</td>
</tr>
<tr>
<td>20</td>
<td>0.9950</td>
<td>0.9901</td>
<td>0.9852</td>
<td>0.9756</td>
<td>0.9662</td>
</tr>
</tbody>
</table>
The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of $m$ imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

**Imputer’s Model Versus Analyst’s Model**

Multiple imputation inference assumes that the model you used to analyze the multiply imputed data (the analyst’s model) is the same as the model used to impute missing values in multiple imputation (the imputer’s model). But in practice, the two models may not be the same (Schafer 1997, p. 139).

Schafer (1997, pp. 139–143) provides comprehensive coverage of this topic, and the following example is based on his work.

Consider a trivariate data set with variables $Y_1$ and $Y_2$ fully observed, and a variable $Y_3$ with missing values. An imputer creates multiple imputations with the model $Y_3 = Y_1 Y_2$. However, the analyst can later use the simpler model $Y_3 = Y_1$. In this case, the analyst assumes more than the imputer. That is, the analyst assumes there is no relationship between variables $Y_3$ and $Y_2$.

The effect of the discrepancy between the models depends on whether the analyst’s additional assumption is true. If the assumption is true, the imputer’s model still applies. The inferences derived from multiple imputations will still be valid, although they may be somewhat conservative because they reflect the additional uncertainty of estimating the relationship between $Y_3$ and $Y_2$.

On the other hand, suppose that the analyst models $Y_3 = Y_1$, and there is a relationship between variables $Y_3$ and $Y_2$. Then the model $Y_3 = Y_1$ will be biased and is inappropriate. Appropriate results can be generated only from appropriate analyst models.

Another type of discrepancy occurs when the imputer assumes more than the analyst. For example, suppose that an imputer creates multiple imputations with the model $Y_3 = Y_1$, but the analyst later fits a model $Y_3 = Y_1 Y_2$. When the assumption is true, the imputer’s model is a correct model and the inferences still hold.

On the other hand, suppose there is a relationship between $Y_3$ and $Y_2$. Imputations created under the incorrect assumption that there is no relationship between $Y_3$ and $Y_2$ will make the analyst’s estimate of the relationship biased toward zero. Multiple imputations created under an incorrect model can lead to incorrect conclusions.

Thus, generally you should include as many variables as you can when doing multiple imputation. The precision you lose with included unimportant predictors is usually a relatively small price to pay for the general validity of analyses of the resultant multiply imputed data set (Rubin 1996). But at the same time, you need to keep the model building and fitting feasible (Barnard and Meng, 1999, pp. 19–20).

To produce high-quality imputations for a particular variable, the imputation model should also include variables that are potentially related to the imputed variable and variables that are potentially related to the missingness of the imputed variable (Schafer 1997, p. 143).
Similar suggestions were also given by van Buuren, Boshuizen, and Knook (1999, p. 687). They recommended the imputation model includes three sets of covariates: variables in the analyst’s model, variables associated with the missingness of the imputed variable, and variables correlated with the imputed variable. They also recommended the removal of the covariates not in the analyst’s model if they have too many missing values for observations with missing imputed variable.

Note that it is good practice to include a description of the imputer’s model with the multiply imputed data set (Rubin 1996, p. 479). That way, the analysts will have information about the variables involved in the imputation and which relationships among the variables have been implicitly set to zero.

**Parameter Simulation Versus Multiple Imputation**

As an alternative to multiple imputation, parameter simulation can also be used to analyze the data for many incomplete-data problems. Although the MI procedure does not offer parameter simulation, the trade-offs between the two methods (Schafer 1997, pp. 89–90, 135–136) are examined in this section.

The parameter simulation method simulates random values of parameters from the observed-data posterior distribution and makes simple inferences about these parameters (Schafer 1997, p. 89). When a set of well-defined population parameters $\theta$ are of interest, parameter simulation can be used to directly examine and summarize simulated values of $\theta$. This usually requires a large number of iterations, and involves calculating appropriate summaries of the resulting dependent sample of the iterates of the $\theta$. If only a small set of parameters are involved, parameter simulation is suitable (Schafer 1997).

Multiple imputation only requires a small number of imputations. Generating and storing a few imputations can be more efficient than generating and storing a large number of iterations for parameter simulation.

When fractions of missing information are low, methods that average over simulated values of the missing data, as in multiple imputation, can be much more efficient than methods that average over simulated values of $\theta$ as in parameter simulation (Schafer 1997).

**Summary of Issues in Multiple Imputation**

This section summarizes issues which are encountered in applications of the MI procedure.

**The MAR Assumption**

The missing at random (MAR) assumption is needed for the imputation methods in the MI Procedure. Although this assumption cannot be verified with the data, it becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook, 1999, p. 687).
**Number of Imputations**

Based on the theory of multiple imputation, only a small number of imputations are needed for a data set with little missing information (Rubin 1987, p. 114). The number of imputations can be informally verified by replicating sets of \( m \) imputations and checking whether the estimates are stable (Horton and Lipsitz 2001, p. 246).

**Imputation Model**

Generally you should include as many variables as you can in the imputation model (Rubin 1996). At the same time, however, it is important to keep the number of variables in control, as discussed by Barnard and Meng (1999, pp. 19–20). For the imputation of a particular variable, the model should include variables in the complete data model, variables that are correlated with the imputed variable, and variables that are associated with the missingness of the imputed variable (Schafer 1997, p. 143; van Buuren, Boshuizen, and Knook 1999, p. 687).

**Multivariate Normality Assumption**

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from the multivariate normality if the amount of missing information is not large (Schafer 1997, pp. 147–148).

You can use variable transformations to make the normality assumption more tenable. Variables are transformed before the imputation process and then back-transformed to create imputed values.

**Monotone Regression Method**

With the multivariate normality assumption, either the regression method or the predictive mean matching method can be used to impute continuous variables in data sets with monotone missing patterns.

The predictive mean matching method ensures that imputed values are plausible and may be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).

**Monotone Propensity Score Method**

The propensity score method can also be used to impute continuous variables in data sets with monotone missing patterns.

The propensity score method does not use correlations among variables and is not appropriate for analyses involving relationship among variables, such as a regression analysis (Schafer 1999, p.11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

**MCMC Monotone-Data Imputation**

The MCMC Method is used to impute continuous variables in data sets with arbitrary missing patterns, assuming a multivariate normal distribution for the data. It can also be used to impute just enough missing values to make the imputed data sets have a monotone missing pattern. Then, a more flexible monotone imputation method can be used for the remaining missing values.
Checking Convergence in MCMC

In an MCMC process, parameters are drawn after the MCMC is run long enough to converge to its stationary distribution. In practice, however, it is not simple to verify the convergence of the process, especially for a large number of parameters.

You can check for convergence by examining the observed-data likelihood ratio statistic and worst linear function of the parameters in each iteration. You can also check for convergence by examining a plot of autocorrelation function, as well as a time-series plot of parameters (Schafer 1997, p. 120).

EM Estimates

The EM algorithm can be used to compute the MLE of the mean vector and covariance matrix of the data with missing values, assuming a multivariate normal distribution for the data. However, the covariance matrix associated with the estimate of the mean vector cannot be derived from the EM algorithm.

In the MI procedure, you can use the EM algorithm to compute the posterior mode, which provides a good starting value for the MCMC process (Schafer 1997, p. 169).

ODS Table Names

PROC MI assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**ODS Graphics (Experimental)**

This section describes the use of ODS for creating graphics with the MI procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the following options in the MCMC statement. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

**ACFPLOT** < (options < /display-options > ) >
displays plots of the autocorrelation function of parameters from iterations.

For a detailed description of the ACFPLOT option, see the “Autocorrelation Function Plot” section on page 2557. Note that for the display-options, only the LOG, NLAG=, and TITLE= options are applicable.

**TIMEPLOT** < (options < /display-options > ) >
displays time-series plots of parameters from iterations.

For a detailed description of the TIMEPLOT option, see the “Time-Series Plot” section on page 2556. Note that for the display-options, only the LOG, WCONNECT=, and TITLE= options are applicable. If you specify the WCONNECT=0 option, a scatter plot is created. Otherwise, a line plot is created.

**ODS Graph Names**

PROC MI assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 44.7.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 44.7. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

Examples

The Fish data described in the STEPDISC procedure are measurements of 159 fish of seven species caught in Finland’s lake Laengelmavesi. For each fish, the length, height, and width are measured. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail (Length1), from the nose to the notch of its tail (Length2), and from the nose to the end of its tail (Length3). See Chapter 67, “The STEPDISC Procedure,” for more information.

The Fish1 data set is constructed from the Fish data set and contains only one species of the fish and the three length measurements. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables Length1, Length2, and Length3. The Fish1 data set is used in Example 44.2 with the propensity score method and in Example 44.3 with the regression method.

The Fish2 data set is also constructed from the Fish data set and contains two species of fish. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables Length3, Height, Width, and Species. The Fish2 data set is used in Example 44.4 with the logistic regression method and in Example 44.5 with the discriminant function method. Note that some values of the variable Species have also been altered in the data set.

The FitMiss data set created in the “Getting Started” section is used in other examples. The following statements create the Fish1 data set.

```sas
/*---------- Fishes of Species Bream ----------*/
data Fish1;
  title 'Fish Measurement Data';
  input Length1 Length2 Length3 @@;

;```

The Fish2 data set contains two of the seven species in the Fish data set. For each of the two species (Bream and Parkki), the length from the nose of the fish to the end of its tail, the height, and the width of each fish are measured. The height and width are recorded as percentages of the length variable.
The following statements create the Fish2 data set.

/*-------- Fishes of Species Bream and Parkki Pike --------*/

Example 44.1. EM Algorithm for MLE

This example uses the EM algorithm to compute the maximum likelihood estimates for parameters of a multivariate normal distribution using data with missing values. The following statements invoke the MI procedure and request the EM algorithm to compute the MLE for $\mu$, $\Sigma$ of a multivariate normal distribution from the input data set FitMiss.

```
proc mi data=FitMiss seed=1518971 simple nimpute=0;
   em itprint outem=outem;
   var Oxygen RunTime RunPulse;
run;
```

Note that when you specify the NIMPUTE=0 option, the missing values will not be imputed. The procedure generates the following output:
Output 44.1.1. Model Information

The “Model Information” table shown in Output 44.1.1 describes the method and options used in the procedure if a positive number is specified in the NIMPUTE= option.

The “Missing Data Patterns” table shown in Output 44.1.2 lists distinct missing data patterns with corresponding frequencies and percents. Here, a value of “X” means that the variable is observed in the corresponding group and a value of “." means that the variable is missing. The table also displays group-specific variable means.

</tbody>
</table>

You can also output the EM (MLE) parameter estimates into an output data set with the OUTEM= option. The following statements list the observations in the output data set outem.

```plaintext
proc print data=outem;
   title 'EM Estimates';
run;
```

**Output 44.1.8.  EM Estimates**

<table>
<thead>
<tr>
<th>Obs</th>
<th><em>TYPE</em></th>
<th><em>NAME</em></th>
<th>Oxygen</th>
<th>RunTime</th>
<th>RunPulse</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>MEAN</td>
<td></td>
<td>47.1041</td>
<td>10.5549</td>
<td>171.382</td>
</tr>
<tr>
<td>2</td>

</tr>
<tr>
<td>4</td>
<td>COV</td>
<td>RunPulse</td>
<td>-18.031</td>
<td>3.5163</td>
<td>97.767</td>
</tr>
</tbody>
</table>

The output data set outem shown in Output 44.1.8 is a TYPE=COV data set. The observation with _TYPE_='MEAN' contains the MLE for the parameter $\mu$ and the observations with _TYPE_='COV' contain the MLE for the parameter $\Sigma$ of a multivariate normal distribution from the data set FitMiss.

**Example 44.2. Propensity Score Method**

This example uses the propensity score method to impute missing values for variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the propensity score method. The resulting data set is named outex2.
proc mi data=Fish1 seed=899603 out=outex2;
   monotone propensity;
   var Length1 Length2 Length3;
run;

Note that the VAR statement is required and the data set must have a monotone missing pattern with variables as ordered in the VAR statement. The procedure generates the following output:

**Output 44.2.1.** Model Information

```
The MI Procedure

Model Information

Data Set       WORK.FISH1
Method         Monotone
Number of Imputations  5
Seed for random number generator  899603
```

The “Model Information” table shown in Output 44.2.1 describes the method and options used in the multiple imputation process. By default, five imputations are created for the missing data.

When monotone methods are used in the imputation, MONOTONE is displayed as the method. The “Monotone Model Specification” table shown in Output 44.2.2 displays the detailed model specification. By default, the observations are sorted into five groups based on their propensity scores.

**Output 44.2.2.** Monotone Model Specification

```
The MI Procedure

Monotone Model Specification

Imputed Variables

Propensity( Groups= 5) Length2 Length3
```

Without covariates specified for imputed variables Length2 and Length3, the variable Length1 is used as the covariate for Length2, and variables Length1 and Length2 are used as covariates for Length3.
Output 44.2.3. Missing Data Patterns

The MI Procedure

<table>
<thead>
<tr>
<th>Group</th>
<th>Length1</th>
<th>Length2</th>
<th>Length3</th>
<th>Freq</th>
<th>Percent</th>

</tr>
</tbody>
</table>

The “Missing Data Patterns” table shown in Output 44.2.3 lists distinct missing data patterns with corresponding frequencies and percents. Here, values of “X” and “.” indicate that the variable is observed or missing in the corresponding group. The table confirms a monotone missing pattern for these three variables.

For the imputation process, first, missing values of Length2 in Group 3 are imputed using observed values of Length1. Then the missing values of Length3 in Group 2 are imputed using observed values of Length1 and Length2. And finally, the missing values of Length3 in Group 3 are imputed using observed values of Length1 and imputed values of Length2.

After the completion of $m$ imputations, the “Multiple Imputation Variance Information” table shown in Output 44.2.4 displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. A detailed description of these statistics is provided in the “Combining Inferences from Multiply Imputed Data Sets” section on page 2561.
Output 44.2.4. Variance Information

The MI Procedure

Multiple Imputation Variance Information

<table>

Example 44.3. Regression Method

This example uses the regression method to impute missing values for all variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the regression method for variable Length2 and the predictive mean matching method for variable Length3. The resulting data set is named outex3.

```plaintext
proc mi data=Fish1 round=.1 mu0=0 35 45
   seed=13951639 out=outex3;
   monotone reg(Length2/ details)
      regpmm(Length3= Length1 Length2 Length1*Length2/ details);
   var Length1 Length2 Length3;
run;
```

The ROUND= option is used to round the imputed values to the same precision as observed values. The values specified with the ROUND= option are matched with the variables Length1, Length2, and Length3 in the order listed in the VAR statement. The MU0= option requests t tests for the hypotheses that the population means corresponding to the variables in the VAR statement are Length2=35 and Length3=45.

Note that an optimal K= value is currently not available for the REGPMM option in the literature on multiple imputation. The default K=5 is experimental and may change in future releases.
The “Missing Data Patterns” table lists distinct missing data patterns with corresponding frequencies and percents. It is identical to the table displayed in Output 44.2.3 in the previous example.

The “Monotone Model Specification” table shown in Output 44.3.1 displays the model specification.

Example 44.4. Logistic Regression Method for CLASS Variables

This example uses logistic regression method to impute values for a binary variable in a data set with a monotone missing pattern.

The logistic regression method is used for the binary and ordinal CLASS variables. Since the variable Species is not an ordinal variable, only the first two species are used.

```
proc mi data=Fish2 seed=1305417 out=outex4;
   class Species;
   monotone logistic( Species= Height Width Height*Width/ details);
   var Height Width Species;
run;
```

The “Model Information” table shown in Output 44.4.1 describes the method and options used in the multiple imputation process.

Output 44.4.1. Model Information

</table>

Note that a missing value of the variable Species is not imputed if the corresponding covariates are missing and not imputed, as shown by observation 4 in the table.

Example 44.5. Discriminant Function Method for CLASS Variables

This example uses discriminant monotone methods to impute values of a CLASS variable from the observed observation values in a data set with a monotone missing pattern.

The following statements impute the continuous variables Height and Width with the regression method and the CLASS variable Species with the discriminant function method.

```
proc mi data=Fish2 seed=7545417 nimpute=3 out=outex5;
   class Species;
   monotone reg( Height Width)
       discrim( Species= Length3 Height Width/ details);
   var Length3 Height Width Species;
run;
```

</tr>
<tr>
<td>Number of Burn-in Iterations</td>
<td>200</td>
</tr>
<tr>
<td>Seed for random number generator</td>
<td>21355417</td>
</tr>
</tbody>
</table>

The “Model Information” table shown in Output 44.6.1 describes the method used in the multiple imputation process. With CHAIN=MULTIPLE, the procedure uses multiple chains and completes the default 200 burn-in iterations before each imputation. The 200 burn-in iterations are used to make the iterations converge to the stationary distribution before the imputation.

By default, the procedure uses a noninformative Jeffreys prior to derive the posterior mode from the EM algorithm as the starting values for the MCMC process.

The “Missing Data Patterns” table shown in Output 44.6.2 lists distinct missing data patterns with corresponding statistics.

With the DISPLAYINIT option in the MCMC statement, the “Initial Parameter Estimates for MCMC” table shown in Output 44.6.4 displays the starting mean and covariance estimates used in MCMC. The same starting estimates are used for the MCMC process for multiple chains because the EM algorithm is applied to the same data set in each chain. You can explicitly specify different initial estimates for different imputations, or you can use the bootstrap to generate different parameter estimates from the EM algorithm for the MCMC process.

Example 44.7. Producing Monotone Missingness with MCMC

This example uses the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern based on the order of variables in the VAR statement.

The following statements invoke the MI procedure and specify the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern. You must specify a VAR statement to provide the order of variables for the imputed data to achieve a monotone missing pattern.

```
proc mi data=FitMiss seed=17655417 out=outex7;
   mcmc impute=monotone;
   var Oxygen RunTime RunPulse;
run;
```

Output 44.7.1. Model Information

The “Model Information” table shown in Output 44.7.1 describes the method used in the multiple imputation process.

The “Missing Data Patterns” table shown in Output 44.7.2 lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.
Output 44.7.2. Missing Data Pattern

The MI Procedure

</tr>
</tbody>
</table>

As shown in the table, the MI procedure only needs to impute three missing values from Group 4 and Group 5 to achieve a monotone missing pattern for the imputed data set.

When using the MCMC method to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.

The following statements are used just to show the monotone missingness of the output data set outex7.

```plaintext
proc mi data=outex7 nimpute=0;
  var Oxygen RunTime RunPulse;
run;
```
Example 44.8. Checking Convergence in MCMC

Output 44.7.3. Monotone Missing Data Pattern

The MI Procedure

<table>

</tbody>
</table>

Missing Data Patterns

<table>
<thead>
<tr>
<th>Group Means</th>
</tr>
</thead>
<tbody>
<tr>
<td>Group Oxygen RunTime RunPulse</td>
</tr>
<tr>
<td>1 46.152428 10.861364 171.863636</td>
</tr>
<tr>
<td>2 47.796038 10.053333 .</td>
</tr>
<tr>
<td>3 52.461667 . .</td>
</tr>
</tbody>
</table>

The “Missing Data Patterns” table shown in Output 44.7.3 displays a monotone missing data pattern.

The following statements impute one value for each missing value in the monotone missingness data set outex7.

```sas
proc mi data=outex7 nimpute=1 seed=51343672 out=outds;
  monotone method=reg;
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the MIANALYZE procedure. Note that the VAR statement is required with a MONOTONE statement to provide the variable order for the monotone missing pattern.

Example 44.8. Checking Convergence in MCMC

This example uses the MCMC method with a single chain. It also displays time-series and autocorrelation plots to check convergence for the single chain.

The following statements use the MCMC method to create an iteration plot for the successive estimates of the mean of Oxygen. Note that iterations during the burn-in period are indicated with negative iteration numbers. These statements also create an autocorrelation function plot for the variable Oxygen.

```sas
proc mi data=FitMiss seed=42037921 noprint nimpute=2;
  mcmc timeplot(mean(Oxygen)) acfplot(mean(Oxygen));
  var Oxygen RunTime RunPulse;
run;
```
Output 44.8.1. Time-Series Plot for Oxygen

With the TIMEPLOT(MEAN(Oxygen)) option, the procedure displays a time-series plot for the mean of Oxygen in Output 44.8.1.

By default, the MI procedure displays solid line segments that connect data points in the time-series plot. The plot shows no apparent trends for the variable Oxygen.

Output 44.8.2. Autocorrelation Function Plot for Oxygen
With the ACFPLOT(MEAN(oxygen)) option, the procedure displays an autocorrelation plot for the mean of Oxygen in Output 44.8.2.

By default, the MI procedure uses the star sign (*) as the plot symbol to display the points in the plot, a solid line to display the reference line of zero autocorrelation, and a pair of dashed lines to display approximately 95% confidence limits for the autocorrelations. The autocorrelation function plot shows no significant positive or negative autocorrelation.

The following statements use display options to modify the autocorrelation function plot for Oxygen in Output 44.8.3.

```
proc mi data=FitMiss seed=423921 noprint nimpute=2;
    mcmc acfplot(mean(Oxygen) / symbol=dot lref=2);
    var Oxygen RunTime RunPulse;
run;
```

**Output 44.8.3.** Autocorrelation Function Plot for Oxygen

You can also create plots for the worst linear function, the means of other variables, the variances of variables, and covariances between variables. Alternatively, you can use the OUTITER option to save statistics such as the means, standard deviations, covariances, $-2\log \text{LR}$ statistic, $-2\log \text{LR}$ statistic of the posterior mode, and worst linear function from each iteration in an output data set. Then you can do a more in-depth time-series analysis of the iterations with other procedures, such as PROC AUTOREG and PROC ARIMA in the *SAS/ETS User’s Guide*. 
With the experimental ODS GRAPHICS statement specified in the following statements

```plaintext
ods html;
ods graphics on;

proc mi data=FitMiss seed=42037921 noprint nimpute=2;
    mcmc timeplot(mean(Oxygen)) acfplot(mean(Oxygen));
    var Oxygen RunTime RunPulse;
run;

ods graphics off;
ods html close;
```

the MI procedure produces the experimental graphs, as shown in Output 44.8.4 and Output 44.8.5.

**Output 44.8.4.** Time-Series Plot for Oxygen (Experimental)
**Output 44.8.5.** Autocorrelation Function Plot for Oxygen (Experimental)

For general information about ODS graphics see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MI procedure, see the “ODS Graphics” section on page 2567.

**Example 44.9. Saving and Using Parameters for MCMC**

This example uses the MCMC method with multiple chains as specified in Example 44.6. It saves the parameter values used for each imputation in an output data set of type EST called *miest*. This output data set can then be used to impute missing values in other similar input data sets. The following statements invoke the MI procedure and specify the MCMC method with multiple chains to create three imputations.

```plaintext
proc mi data=FitMiss seed=21355417 nimpute=6 mu0=50 10 180 ;
  mcmc chain=multiple initial=em outest=miest;
  var Oxygen RunTime RunPulse;
run;
```

The following statements list the parameters used for the imputations in **Output 44.9.1.** Note that the data set includes observations with `_TYPE_`='SEED' containing the seed to start the next random number generator.
The following statements invoke the MI procedure and use the INEST= option in the MCMC statement.

```sas
proc mi data=FitMiss;
   mcmc inest=miest;
   var Oxygen RunTime RunPulse;
run;
```

**Output 44.9.2.** Model Information

The "Model Information" table shown in **Output 44.9.2** describes the method used in the multiple imputation process. The remaining tables for the example are identical to the tables in **Output 44.6.2**, **Output 44.6.4**, **Output 44.6.5**, and **Output 44.6.6** in Example 44.6.
Example 44.10. Transforming to Normality

This example applies the MCMC method to the FitMiss data set in which the variable Oxygen is transformed. Assume that Oxygen is skewed and can be transformed to normality with a logarithmic transformation. The following statements invoke the MI procedure and specify the transformation. The TRANSFORM statement specifies the log transformation for Oxygen. Note that the values displayed for Oxygen in all of the results correspond to transformed values.

```sas
proc mi data=FitMiss seed=32937921 mu0=50 10 180 out=outex10;
    transform log(Oxygen);
    mcmc chain=multiple displayinit;
    var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table shown in Output 44.10.1 lists distinct missing data patterns with corresponding statistics for the FitMiss data. Note that the values of Oxygen shown in the tables are transformed values.

</tbody>
</table>

Note that the preceding results can also be produced from the following statements without using a TRANSFORM statement. A transformed value of log(50)=3.91202 is used in the MU0= option.

```sas
data temp;
  set FitMiss;
  LogOxygen= log(Oxygen);
run;
proc mi data=temp seed=14337921 mu0=3.91202 10 180 out=outtemp;
  mcmc chain=multiple displayinit;
  var LogOxygen RunTime RunPulse;
run;
data outex10;
  set outtemp;
  Oxygen= exp(LogOxygen);
run;
```

**Example 44.11. Multistage Imputation**

This example uses two separate imputation procedures to complete the imputation process. The first MI procedure uses the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern. The second MI procedure uses a MONOTONE statement to impute missing values for data sets with monotone missing patterns.
The following statements are identical to Example 44.7. The statements invoke the MI procedure and specify the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern.

```plaintext
proc mi data=FitMiss seed=17655417 out=outex11;
    mcmc impute=monotone;
    var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table shown in Output 44.11.1 lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.

**Output 44.11.1. Missing Data Pattern**

<table>
<thead>
<tr>
<th>Group</th>
<th>Oxygen</th>
<th>Run</th>
<th>Run</th>
<th>Freq</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>X</td>
<td>X</td>
<td>X</td>
<td>21</td>
<td>67.74</td>
</tr>
<tr>
<td>2</td>
<td>X</td>
<td>X</td>
<td>O</td>
<td>4</td>
<td>12.90</td>
</tr>
<tr>
<td>3</td>
<td>X</td>
<td>O</td>
<td>O</td>
<td>3</td>
<td>9.68</td>

<td>3.23</td>
</tr>
<tr>
<td>5</td>
<td>.</td>
<td>X</td>
<td>O</td>
<td>2</td>
<td>6.45</td>
</tr>
</tbody>
</table>

```

As shown in the table, the MI procedure only needs to impute three missing values from Group 4 and Group 5 to achieve a monotone missing pattern for the imputed data set. When the MCMC method is used to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.
The following statements impute one value for each missing value in the monotone missingness data set `outex11`.

```sas
proc mi data=outex11
   nimpute=1 seed=51343672
   out=outex11a;
   monotone reg;
   var Oxygen RunTime RunPulse;
   by _Imputation_
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the procedure MIANALYZE. Note that the VAR statement is required with a MONOTONE statement to provide the variable order for the monotone missing pattern.

The “Model Information” table displayed in Output 44.11.2 shows that a monotone method is used to generate imputed values in the first BY group.

**Output 44.11.2. Model Information**

```
------------------------------- Imputation Number=1 ------------------------------
   The MI Procedure
   Model Information
   Data Set WORK.OUTEX11
   Method Monotone
   Number of Imputations 1
   Seed for random number generator 51343672
```

The “Monotone Model Specification” table shown in Output 44.11.3 describes methods and imputed variables in the imputation model. The procedure uses the regression method to impute variables `RunTime` and `RunPulse` in the model.

**Output 44.11.3. Monotone Model Specification**

```
------------------------------- Imputation Number=1 ------------------------------
   The MI Procedure
   Monotone Model Specification
   Imputed Method Variables
   Regression RunTime RunPulse
```
The “Missing Data Patterns” table shown in Output 44.11.4 lists distinct missing data patterns with corresponding statistics. It shows a monotone missing pattern for the imputed data set.

### Output 44.11.4. Missing Data Pattern

```
<table>
<thead>
<tr>
<th>Group</th>
<th>Oxygen</th>
<th>Run Time</th>
<th>Run Pulse</th>
<th>Freq</th>
<th>Percent</th>

</tbody>
</table>
```
This example presents an alternative to the full-data MCMC imputation. When imputation of only a few missing values are needed to achieve a monotone missing pattern for the imputed data set. The example uses a monotone MCMC method that impute fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227). The example also demonstrates how to combine the monotone MCMC method with a method for monotone missing data, which does not rely on iterations of steps.

Chapter 45
The MIANALYZE Procedure

Overview

The MIANALYZE procedure combines the results of the analyses of imputations and generates valid statistical inferences. Multiple imputation provides a useful strategy for analyzing data sets with missing values. Instead of filling in a single value for each missing value, Rubin's (1976; 1987) multiple imputation strategy replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute. You can implement the strategy with two SAS procedures: PROC MI, which generates imputed data sets, and PROC MIANALYZE, which combines the results of analyses carried out on the data sets.

The analyses of imputations are obtained by using standard SAS procedures (such as PROC REG) for complete data. No matter which complete-data analysis is used, the process of combining results from different imputed data sets is essentially the same and results in valid statistical inferences that properly reflect the uncertainty due to missing values.

The MIANALYZE procedure reads parameter estimates and associated standard errors or covariance matrix that are computed by the standard statistical procedure for each imputed data set. The MIANALYZE procedure then derives valid univariate inference for these parameters. With an additional assumption about the population between and within imputation covariance matrices, multivariate inference based on Wald tests can also be derived.

For some parameters of interest, you can use TEST statements to test linear hypotheses about the parameters. For others, it is not straightforward to compute estimates and associated covariance matrices with standard statistical SAS procedures. Examples include correlation coefficients between two variables and ratios of variable means. These special cases are described in the “Examples of the Complete-Data Inferences” section on page 2628.

In SAS 9, the VAR statement has been replaced by the MODELEFFECTS statement to accommodate various effects to be analyzed. A STDERR statement has been added to specify the standard errors when both parameter estimates and associated standard errors are stored as variables in the same data set.

Also, an experimental CLASS statement has been added to specify classification variables in the MODELEFFECTS statement. The CLASS statement must be used in conjunction with the MODELEFFECTS statement.
Getting Started

The Fitness data set has been altered to contain an arbitrary missing pattern:

```
*----------------- Data on Physical Fitness -----------------*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University. |
| Only selected variables of |
| Oxygen (oxygen intake, ml per kg body weight per minute), |
| Runtime (time to run 1.5 miles in minutes), and |
| RunPulse (heart rate while running) are used. |
| Certain values were changed to missing for the analysis. |
*------------------------------------------------------------*;

data FitMiss;
  input Oxygen RunTime RunPulse @@;
datalines;
44.609 11.37 178 45.313 10.07 185
54.297 8.65 156 59.571 . .
49.874 9.22 170 44.811 11.63 176
. 11.95 176 . 10.85 .
39.442 13.08 174 60.055 8.63 170
50.541 . . 37.388 14.03 186
44.754 11.12 176 47.273 . .
51.855 10.33 166 49.156 8.95 180
40.836 10.95 168 46.672 10.00 .
46.774 10.25 . 50.388 10.08 168
39.407 12.63 174 46.080 11.17 156
45.441 9.63 164 . 8.92 .
45.118 11.08 . 39.203 12.88 168
45.790 10.47 186 50.545 9.93 148
48.673 9.40 186 47.920 11.50 170
47.467 10.50 170
```

Suppose that the data are multivariate normally distributed and that the missing data are missing at random (see the “Statistical Assumptions for Multiple Imputation” section in “The MI Procedure” chapter for a description of these assumptions). The following statements use the MI procedure to impute missing values for the FitMiss data set.

```
proc mi data=FitMiss noprint out=outmi seed=3237851;
  var Oxygen RunTime RunPulse;
run;
```

The MI procedure creates imputed data sets, which are stored in the outmi data set. A variable named _Imputation_ indicates the imputation numbers. Based on \( m \) imputations, \( m \) different sets of the point and variance estimates for a parameter can be computed. In this example, \( m = 5 \) is the default.
The following statements generate regression coefficients for each of the five imputed data sets:

```
proc reg data=outmi outest=outreg covout noprint;
    model Oxygen= RunTime RunPulse;
    by _Imputation_;
run;
```

The following statements display parameter estimates and covariance matrices from the first two imputed data sets in Figure 45.1.

```
proc print data=outreg(obs=8);
    var _Imputation_ _Type_ _Name_
        Intercept RunTime RunPulse;
    title 'Parameter Estimates from Imputed Data Sets';
run;
```

Multiple Imputation Parameter Estimates

| Parameter   | t for H0: Parameter=Theta0 | Pr > |t| |
|-------------|---------------------------|-------|
| Intercept   | 7.93                      | <.0001 |
| RunTime     | -8.43                     | <.0001 |
| RunPulse    | -1.12                     | 0.2695 |
The “Multiple Imputation Parameter Estimates” table shown in Figure 45.4 displays a combined estimate and standard error for each regression coefficient (parameter). Inferences are based on $t$ distributions. The table displays a 95% confidence interval and a $t$-test with the associated $p$-value for the hypothesis that the parameter is equal to the value specified with the THETA0= option (in this case, zero by default). The minimum and maximum parameter estimates from the imputed data sets are also displayed.

Syntax

The following statements are available in PROC MIANALYZE.

```
PROC MIANALYZE < options > ;
   BY variables ;
   CLASS variables ;
   MODELEFFECTS effects ;
          < label: > TEST equation1 < , . . . , < equationk >> < /options > ;
   STDERR variables ;
```

The BY statement specifies groups in which separate analyses are performed.

The CLASS statement lists the classification variables in the EFFECT statement. Classification variables can be either character or numeric.

The required MODELEFFECTS statement lists the effects to be analyzed. The variables in the statement that are not specified in a CLASS statement are assumed to be continuous.

The STDERR statement lists the standard errors associated with the effects in the MODELEFFECTS statement when both parameter estimates and standard errors are saved as variable in the same DATA= data set. The STDERR statement can be used only when each effect in the MODELEFFECTS statement is a continuous variable by itself.

The TEST statement tests linear hypotheses about the parameters. An $F$ statistic is used to test jointly the null hypothesis ($H_0: L\beta = c$) specified in a single TEST statement. Several TEST statements can be used.

The PROC MIANALYZE and MODELEFFECTS statements are required for the MI procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MIANALYZE statement. The remaining statements are in alphabetical order.
The following are explanations of the options that can be used in the PROC MIANALYZE statement (in alphabetical order):

**ALPHA=p**
specifies that confidence limits are to be constructed for the parameter estimates with confidence level $100(1 - p)\%$, where $0 < p < 1$. The default is $p=0.05$.

**BCOV**
displays the between-imputation covariance matrix.

**COVB**(EFFECTVAR=STACKING | ROWCOL)=SAS-data-set
names an input SAS data set that contains covariance matrices of the parameter estimates from imputed data sets. If you provide a COVB= data set, you must also provide a PARMS= data set.

The EFFECTVAR= option identifies the variables for parameters displayed in the covariance matrix and is used only when the PARMINFO= option is not specified. The default is EFFECTVAR= STACKING.

See the “Input Data Sets” section on page 2620 for a detailed description of the COVB= option.
DATA=SAS-data-set
names an input SAS data set.

If the input DATA= data set is not a specially structured SAS data set, the data set contains both the parameter estimates and associated standard errors. The parameter estimates are specified in the MODELEFFECTS statement and the standard errors are specified in the STDERR statement.

If the data set is a specially structured input SAS data set, it must have a TYPE of EST, COV, or CORR that contains estimates from imputed data sets:

- **TYPE=EST**, the data set contains the parameter estimates and associated covariance matrices.
- **TYPE=COV**, the data set contains the sample means, sample sizes, and covariance matrices. Each covariance matrix for variables is divided by the sample size \( n \) to create the covariance matrix for parameter estimates.
- **TYPE=CORR**, the data set contains the sample means, sample sizes, standard errors, and correlation matrices. The covariance matrices are computed from the correlation matrices and associated standard errors. Each covariance matrix for variables is divided by the sample size \( n \) to create the covariance matrix for parameter estimates.

If you do not specify an input data set with the DATA= or PARMS= option, then the most recently created SAS data set is used as an input DATA= data set. See the “Input Data Sets” section on page 2620 for a detailed description of the input data sets.

EDF=number
specifies the complete-data degrees of freedom for the parameter estimates. This is used to compute an adjusted degrees of freedom for each parameter estimate. By default, EDF=\( \infty \) and the degrees of freedom for each parameter estimate is not adjusted.

MULT
MULTIVARIATE
requests multivariate inference for the parameters. It is based on Wald tests and is a generalization of the univariate inference. See the “Multivariate Inferences” section on page 2626 for a detailed description of the multivariate inference.

PARMINFO=SAS-data-set
names an input SAS data set that contains parameter information associated with variables PRM1, PRM2,..., and so on. These variables are used as variables for parameters in a COVB= data set. See the “Input Data Sets” section on page 2620 for a detailed description of the PARMINFO= option.

PARMS <(CLASSVAR= ctype)> =SAS-data-set
names an input SAS data set that contains parameter estimates computed from imputed data sets. When a COVB= data set is not specified, the input PARMS= data set also contains standard errors associated with these parameter estimates. If multivariate inference is requested, you must also provide a COVB= or XPXI= data set.
When the effects contain CLASS variables, the option CLASSVAR= ctype can be used to identify the associated CLASS variables when reading the classification levels from observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL. See the “Input Data Sets” section on page 2620 for a detailed description of the PARMS= option.

TCOV
displays the total covariance matrix derived by assuming that the population between-imputation and within-imputation covariance matrices are proportional to each other.

THETA0=numbers
MU0=numbers
specifies the parameter values \( \theta_0 \) under the null hypothesis \( \theta = \theta_0 \) in the \( t \) tests for location for the effects. If only one number \( \theta_0 \) is specified, that number is used for all effects. If more than one number is specified, the specified numbers correspond to effects in the MODELEFFECTS statement in the order in which they appear in the statement. When an effect contains CLASS variables, the corresponding value is not used and the test is not performed.

WCOV
displays the within-imputation covariance matrices.

XPXI=SAS-data-set
names an input SAS data set that contains the \((X'X)^{-1}\) matrices associated with the parameter estimates computed from imputed data sets. If you provide an XPXI= data set, you must also provide a PARMS= data set. In this case, PROC MIANALYZE reads the standard errors of the estimates from the PARMS= data. The standard errors and \((X'X)^{-1}\) matrices are used to derive the covariance matrices.

**BY Statement**

```
BY  variables ;
```

You can specify a BY statement with PROC MIANALYZE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MI procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.
For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**CLASS Statement** (Experimental)

```
CLASS variables;
```

The CLASS statement specifies the classification variables in the MODELEFFECTS statement. Classification variables can be either character or numeric.

Classification levels are determined from the formatted values of the CLASS variables. Refer to the chapter titled “The FORMAT Procedure” in the *SAS Procedures Guide*.

**MODELEFFECTS Statement**

```
MODELEFFECTS effects;
```

The MODELEFFECTS statement lists the effects in the data set to be analyzed. Each effect is a variable or a combination of variables, and is specified with a special notation using variable names and operators.

Each variable is either a classification (or CLASS) variable or a continuous variable. If a variable is not declared in the CLASS statement, it is assumed to be continuous. Crossing and nesting operators can be used in an effect to create crossed and nested effects.

One general form of an effect involving several variables is

```
X1 * X2 * A * B * C (D E)
```

where A, B, C, D, and E are CLASS variables and X1 and X2 are continuous variables.

When the input DATA= data set is not a specially structured SAS data set, you must also specify standard errors of the parameter estimates in a STDERR statement.

**STDERR Statement**

```
STDERR variables;
```

The STDERR statement lists standard errors associated with effects in the MODELEFFECTS statement, when the input DATA= data set contains both parameter estimates and standard errors as variables in the data set.

With the STDERR statement, only continuous effects are allowed in the MODELEFFECTS statement. The specified standard errors are corresponding to parameter estimates in the order in which they appear in the MODELEFFECTS statement.
For example, you can use the following MODELEFFECTS and STDERR statements to identify both the parameter estimates and associated standard errors in a SAS data set.

```sas
proc mianalyze;
  var y1-y3;
  stderr s1-sy3;
run;
```

**TEST Statement**

```
< label: > TEST equation1 < , . . . , < equationk >> < /options > ;
```

The TEST statement tests linear hypotheses about the parameters $\beta$. An $F$ test is used to test jointly the null hypotheses ($H_0: L\beta = c$) specified in a single TEST statement.

Each *equation* specifies a linear hypothesis (a row of the $L$ matrix and the corresponding element of the $c$ vector); multiple *equations* are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output. You can submit multiple TEST statements. When a label is not included in a TEST statement, a label of “Test $j$” is used for the $j$th TEST statement.

The form of an *equation* is as follows:

```
term < $\pm$ term . . . > $<=$ $\pm$ term < $\pm$ term . . . > >
```

where *term* is a parameter of the model, or a constant, or a constant times a parameter. When no equal sign appears, the expression is set to 0. Only parameters for regressor effects (continuous variables by themselves) are allowed.

For each TEST statement, PROC MIANALYZE displays a “Test Specification” table of the $L$ matrix and the $c$ vector. The procedure also displays a “Multiple Imputation Variance Information” table of the between-imputation, within-imputation, and total variances for combining complete-data inferences, and a “Multiple Imputation Parameter Estimates” table of a combined estimate and standard error for each linear component. The linear components are labeled TestPrm1, TestPrm2, ... in the tables.

The following code illustrates possible uses of the TEST statement:

```sas
proc mianalyze;
  var intercept a1 a2 a3;
  test1: test intercept + a2 = 0;
  test2: test intercept + a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```
The first and second TEST statements are equivalent and correspond to the following specification

```
   The MIANALYZE Procedure
   Test: test1
   Test Specification
   -----------------------L Matrix-----------------------
   Parameter   intercept   a1      a2      a3      C
   TestPrm1    1.000000    0       1.000000  0       0
```

Figure 45.5. Test Specification for test1 and test2

The third and fourth TEST statements are also equivalent and correspond to the specification

```
   The MIANALYZE Procedure
   Test: test3
   Test Specification
   -----------------------L Matrix-----------------------
   Parameter   intercept   a1      a2      a3      C
   TestPrm1    0            1.000000 -1.000000 0       0
   TestPrm2    0            0         1.000000 -1.000000 0
```

Figure 45.6. Test Specification for test3 and test4

The ALPHA= and EDF options specified in the PROC MIANALYZE statement are also applied to the TEST statement. You can specify the following options in the TEST statement after a slash(/).

- **BCOV** displays the between-imputation covariance matrix.
- **MULT** displays the multivariate inference for parameters.
- **TCOV** displays the total covariance matrix.
- **WCOV** displays the within-imputation covariance matrix.

For more information, see the “Testing Linear Hypotheses about the Parameters” section on page 2628.
Details

Input Data Sets

You specify input data sets based on the type of inference you requested. For univariate inference, you can use one of the following options:

- a DATA= data set, which provides both parameter estimates and the associated standard errors.
- a DATA= type EST, COV, or CORR data set, which provides both parameter estimates and the associated standard errors either explicitly (type CORR) or through the covariance matrix (type EST, COV).
- PARMS= data set, which provides both parameter estimates and the associated standard errors.

For multivariate inference, which includes the testing of linear hypotheses about parameters, you can use one of the following option combinations:

- a DATA= type EST, COV, or CORR data set, which provides parameter estimates and the associated covariance matrix either explicitly (type EST, COV) or through the correlation matrix and standard errors (type CORR) in a single data set.
- PARMS= and COVB= data sets, which provide parameter estimates in a PARMS= data set and the associated covariance matrix in a COVB= data set.
- PARMS=, COVB=, and PARMINFO= data sets, which provide parameter estimates in a PARMS= data set, the associated covariance matrix in a COVB= data set with variables named PRM1, PRM2, ..., and the effects associated with these variables in a PARMINFO= data set.
- PARMS= and XPXI= data sets, which provide parameter estimates and the associated standard errors in a PARMS= data set and the associated \((X'X)^{-1}\) matrix in an XPXI= data set.

The appropriate combination depends on the type of inference and the SAS procedure you used to create the data sets. For instance, if you used PROC REG to create an OUTEST= data set containing the parameter estimates and covariance matrix, you would use the DATA= option to read the OUTEST= data set.

When the input DATA= data set is not a specially structured SAS data set, each observation corresponds to an imputation and contains both parameter estimates and associated standard errors. For others, each input data set must contains the variable _Imputation_ to identify the imputation by number.

If you do not specify an input data set with the DATA= or PARMS= option, then the most recently created SAS data set is used as an input DATA= data set. Note that with a DATA= data set, each effect represents a continuous variable, only regressor effects (continuous variables by themselves) are allowed in the MODELEFFECTS statement.
**DATA= SAS data set**

The **DATA=** data set provides both parameter estimates and the associated standard errors computed from imputed data sets. Such data sets are typically created with an **OUTPUT** statement using procedures such as PROC MEANS and PROC UNIVARIATE.

The **MIANALYZE** procedure reads parameter estimates from observations with variables in the **MODELEFFECTS** statement, and standard errors for parameter estimates from observations with variables in the **STDERR** statement. The order of the variables for standard errors must match the order of the variables for parameter estimates.

**DATA= type EST, COV, or CORR SAS data set**

The specially structured **DATA=** data set provides both parameter estimates and the associated covariance matrix computed from imputed data sets. Such data sets are created by procedures such as PROC CORR (type **COV**, **CORR**) and PROC REG (type **EST**).

With **TYPE=EST**, the **MIANALYZE** procedure reads parameter estimates from observations with:
- **_TYPE_=**‘PARM’,
- **_TYPE_=**‘PARMS’,
- **_TYPE_=**‘OLS’, or
- **_TYPE_=**‘FINAL’, and covariance matrices for parameter estimates from observations with **_TYPE_=**‘COV’ or **_TYPE_=**‘COVB’.

With **TYPE=COV**, the procedure reads sample means from observations with **_TYPE_=**‘MEAN’, sample size **n** from observations with **_TYPE_=**‘N’, and covariance matrices for variables from observations with **_TYPE_=**‘COV’.

With **TYPE=CORR**, the procedure reads sample means from observations with **_TYPE_=**‘MEAN’, sample size **n** from observations with **_TYPE_=**‘N’, correlation matrices for variables from observations with **_TYPE_=**‘CORR’, and standard errors for variables from observations with **_TYPE_=**‘STD’. The standard errors and correlation matrix are used to generate a covariance matrix for the variables.

Note that with **TYPE=COV** or **CORR**, each covariance matrix for the variables is divided by **n** to create the covariance matrix for the sample means.

**PARMS <(CLASSVAR= ctype)> = data set**

The **PARMS=** data set contains parameter estimates and associated standard errors computed from imputed data sets. Such data sets are typically created with an **ODS OUTPUT** statement using procedures such as PROC GENMOD, PROC GLM, PROC LOGISTIC, and PROC MIXED.

The **MIANALYZE** procedure reads effect names from observations with the variable **Parameter**, **Effect**, **Variable**, or **Parm**. It then reads parameter estimates from observations with the variable **Estimate** and standard errors for parameter estimates from observations with the variable **StdErr**.

When the effects contain CLASS variables, the option **CLASSVAR= ctype** can be used to identify associated CLASS variables when reading the CLASS levels from...
observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL.

With CLASSVAR=FULL, the data set contains the CLASS variables explicitly. PROC MIANALYZE reads the CLASS levels from observations with their corresponding CLASS variables. PROC MIXED generates this type of tables.

With CLASSVAR=LEVEL, PROC MIANALYZE reads the classification levels for the effect from observations with variables Level1, Level2, and so on, where the variable Level1 contains the classification level for the first CLASS variable in the effect, the variable Level2 contains the classification level for the second CLASS variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the CLASS statement is used for variables inside each list. PROC GENMOD generates this type of tables.

For example, with the following statements,

```plaintext
proc mianalyze parms(classvar=Level)= dataparm;
class c1 c2 c3;
model effects c2 c3(c2 c1);
run;
```

the variable Level1 has the classification level of the variable c2 for the effect c2. For the effect c3(c2 c1), the variable Level1 has the classification level of the variable c3, Level2 has the level of c1, and Level3 has the level of c2.

Similarly, with CLASSVAR=CLASSVAL, PROC MIANALYZE reads the classification levels for the effect from observations with variables ClassVal0, ClassVal1, and so on, where the variable ClassVal0 contains the classification level for the first CLASS variable in the effect, the variable ClassVal1 contains the classification level for the second CLASS variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the CLASS statement is used for variables inside each list. PROC LOGISTIC generates this type of tables.

**PARMS <(CLASSVAR= ctype)> = and COVB= data sets**

The PARMS= data set contains parameter estimates and the COVB= data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using procedures such as PROC LOGISTIC, PROC MIXED, and PROC REG.

With a PARMS= data set, the MIANALYZE procedure reads effect names from observations with the variable Parameter, Effect, Variable, or Parm. It then reads parameter estimates from observations with the variable Estimate.

When the effects contain CLASS variables, the option CLASSVAR= ctype can be used to identify the associated CLASS variables when reading the CLASS levels from observations. The available types are FULL, LEVEL, and CLASSVAL, and are described in the “PARMS <(CLASSVAR= ctype)> = data set” section on page 2621. The default is CLASSVAR= FULL.
The option EFFECTVAR=etype identifies the variables for parameters displayed in the covariance matrix. The available types are STACKING and ROWCOL. The default is EFFECTVAR=STACKING.

With EFFECTVAR=STACKING, each parameter is displayed by stacking variables in the effect. Begin with the variables in the crossed list, followed by the continuous list, then followed by the nested list. Each CLASS variable is displayed with its CLASS level attached. PROC LOGISTIC generates this type of tables.

When each effect is a continuous variable by itself, each stacked parameter name reduces to the effect name. PROC REG generates this type of tables.

With EFFECTVAR=STACKING, the MIANALYZE procedure reads parameter names from observations with the variable Parameter, Effect, Variable, Parm, or RowName. It then reads covariance matrices from observations with the stacked variables in a COVB= data set.

With EFFECTVAR=ROWCOL, parameters are displayed by the variables Col1, Col2, ... The parameter associated with the variable Col1 is identified by the observation with value 1 for the variable Row. The parameter associated with the variable Col2 is identified by the observation with value 2 for the variable Row. PROC MIXED generates this type of table.

With EFFECTVAR=ROWCOL, the MIANALYZE procedure reads the parameter indices from observations with the variable Row, the effect names from observations with the variable Parameter, Effect, Variable, Parm, or RowName, and covariance matrices from observations with the variables Col1, Col2, ... in a COVB= data set.

When the effects contain CLASS variables, the data set contains the CLASS variables explicitly and the MIANALYZE procedure also reads the CLASS levels from their corresponding CLASS variables.

**PARMS <(CLASSVAR= ctype)> =, PARMINFO=, and COVB= data sets**

The input PARMS= data set contains parameter estimates and the input COVB= data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using procedure such as PROC GENMOD.

With a PARMS= data set, the MIANALYZE procedure reads effect names from observations with the variable Parameter, Effect, Variable, or Parm. It then reads parameter estimates from observations with the variable Estimate.

When the effects contain CLASS variables, the option CLASSVAR=ctype can be used to identify the associated CLASS variables when reading the CLASS levels from observations. The available types are FULL, LEVEL, and CLASSVAL, and are described in the “PARMS <(CLASSVAR=ctype)> = data set” section on page 2621. The default is CLASSVAR=FULL.

With a COVB= data set, the MIANALYZE procedure reads parameter names from observations with the variable Parameter, Effect, Variable, Parm, or RowName and covariance matrices from observations with variables Prm1, Prm2, and so on.
The parameters associated with the variables Prm1, Prm2, ... are identified in the PARMINFO= data set. PROC MIANALYZE reads the parameter names from observations with the variable Parameter and the corresponding effect from observations with the variable Effect. When the effects contain CLASS variables, the data set contains the CLASS variables explicitly and the MIANALYZE procedure also reads the CLASS levels from observations with their corresponding CLASS variables.

**PARMS= and XPIXI= data sets**

The input PARMS= data set contains parameter estimates and the input XPIXI= data set contains associated \((X'X)^{-1}\) matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using a procedure such as PROC GLM.

With a PARMS= data set, the MIANALYZE procedure reads parameter names from observations with the variable Parameter, Effect, Variable, or Parm. It then reads parameter estimates from observations with the variable Estimate and standard errors for parameter estimates from observations with the variable StdErr.

With a XPIXI= data set, the MIANALYZE procedure reads parameter names from observations with the variable Parameter and \((X'X)^{-1}\) matrices from observations with the parameter variables in the data set.

Note that this combination can only be used when each effect is a continuous variable by itself.

**Combining Inferences from Imputed Data Sets**

With \(m\) imputations, \(m\) different sets of the point and variance estimates for a parameter \(Q\) can be computed. Suppose that \(\hat{Q}_i\) and \(\hat{U}_i\) are the point and variance estimates from the \(i\)th imputed data set, \(i=1, 2, ..., m\). Then the combined point estimate for \(Q\) from multiple imputation is the average of the \(m\) complete-data estimates:

\[
\bar{Q} = \frac{1}{m} \sum_{i=1}^{m} \hat{Q}_i
\]

Suppose that \(\bar{W}\) is the within-imputation variance, which is the average of the \(m\) complete-data estimates:

\[
\bar{W} = \frac{1}{m} \sum_{i=1}^{m} \hat{W}_i
\]

and \(B\) be the between-imputation variance

\[
B = \frac{1}{m-1} \sum_{i=1}^{m} (\hat{Q}_i - \bar{Q})^2
\]
Then the variance estimate associated with $\bar{Q}$ is the total variance (Rubin 1987)

$$T = W + (1 + \frac{1}{m})B$$

The statistic $(Q - \bar{Q})T^{-1/2}$ is approximately distributed as $t$ with $v_m$ degrees of freedom (Rubin 1987), where

$$v_m = (m - 1) \left[ 1 + \frac{W}{(1 + m^{-1})B} \right]^2$$

The degrees of freedom $v_m$ depends on $m$ and the ratio

$$r = \frac{(1 + m^{-1})B}{W}$$

The ratio $r$ is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about $Q$, the values of $r$ and $B$ are both zero. With a large value of $m$ or a small value of $r$, the degrees of freedom $v_m$ will be large and the distribution of $(Q - \bar{Q})T^{-1/2}$ will be approximately normal.

Another useful statistic is the fraction of missing information about $Q$:

$$\hat{\lambda} = \frac{r + 2}{(v_m + 3)}$$

Both statistics $r$ and $\lambda$ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about $Q$.

When the complete-data degrees of freedom $v_0$ is small, and there is only a modest proportion of missing data, the computed degrees of freedom, $v_m$, can be much larger than $v_0$, which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of an adjusted degrees of freedom

$$v_m^* = \left[ \frac{1}{v_m} + \frac{1}{\hat{v}_{obs}} \right]^{-1}$$

where $\hat{v}_{obs} = (1 - \gamma) v_0(v_0 + 1)/(v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

If you specify the complete-data degrees of freedom $v_0$ with the EDF= option, the MIANALYZE procedure uses the adjusted degrees of freedom, $v_m^*$, for inference. Otherwise, the degrees of freedom $v_m$ is used.
**Multiple Imputation Efficiency**

The relative efficiency (RE) of using the finite \( m \) imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of \( m \) and \( \lambda \) (Rubin 1987, p. 114).

\[
RE = (1 + \frac{\lambda}{m})^{-1}
\]

The following table shows relative efficiencies with different values of \( m \) and \( \lambda \).

**Table 45.2. Relative Efficiency**

<table>
<thead>
<tr>
<th>( \lambda )</th>
<th>10%</th>
<th>20%</th>
<th>30%</th>
<th>50%</th>
<th>70%</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>0.9677</td>
<td>0.9375</td>
<td>0.9091</td>
<td>0.8571</td>
<td>0.8108</td>
</tr>
<tr>
<td>5</td>
<td>0.9804</td>
<td>0.9615</td>
<td>0.9434</td>
<td>0.9091</td>
<td>0.8772</td>
</tr>
<tr>
<td>10</td>
<td>0.9901</td>
<td>0.9804</td>
<td>0.9709</td>
<td>0.9524</td>
<td>0.9346</td>
</tr>
<tr>
<td>20</td>
<td>0.9950</td>
<td>0.9901</td>
<td>0.9852</td>
<td>0.9756</td>
<td>0.9662</td>
</tr>
</tbody>
</table>

The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of \( m \) imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

**Multivariate Inferences**

Multivariate inference based on Wald tests can be done with \( m \) imputed data sets. The approach is a generalization of the approach taken in the univariate case (Rubin 1987, p. 137; Schafer 1997, p. 113). Suppose that \( \hat{Q}_i \) and \( \hat{U}_i \) are the point and covariance matrix estimates for a \( p \)-dimensional parameter \( Q \) (such as a multivariate mean) from the \( i \)th imputed data set, \( i = 1, 2, ..., m \). Then the combined point estimate for \( Q \) from the multiple imputation is the average of the \( m \) complete-data estimates:

\[
\overline{Q} = \frac{1}{m} \sum_{i=1}^{m} \hat{Q}_i
\]

Suppose that \( \overline{U} \) is the within-imputation covariance matrix, which is the average of the \( m \) complete-data estimates

\[
\overline{W} = \frac{1}{m} \sum_{i=1}^{m} \hat{W}_i
\]

and suppose that \( B \) is the between-imputation covariance matrix

\[
B = \frac{1}{m-1} \sum_{i=1}^{m} (\hat{Q}_i - \overline{Q})(\hat{Q}_i - \overline{Q})'
\]
Then the covariance matrix associated with $\mathbf{Q}$ is the total covariance matrix

$$
\mathbf{T}_0 = \mathbf{W} + (1 + \frac{1}{m})\mathbf{B}
$$

The natural multivariate extension of the $t$ statistic used in the univariate case is the $F$ statistic

$$
F_0 = (\mathbf{Q} - \overline{\mathbf{Q}})'\mathbf{T}_0^{-1}(\mathbf{Q} - \overline{\mathbf{Q}})
$$

with degrees of freedom $p$ and

$$
v = (m - 1)(1 + 1/r)^2
$$

where

$$
r = (1 + \frac{1}{m})\text{trace}(\mathbf{B}\mathbf{W}^{-1})/p
$$

is an average relative increase in variance due to nonresponse (Rubin 1987, p. 137; Schafer 1997, p. 114).

However, the reference distribution of the statistic $F_0$ is not easily derived. Especially for small $m$, the between-imputation covariance matrix $\mathbf{B}$ is unstable and does not have full rank for $m \leq p$ (Schafer 1997, p. 113).

One solution is to make an additional assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other (Schafer 1997, p. 113). This assumption implies that the fractions of missing information for all components of $\mathbf{Q}$ are equal. Under this assumption, a more stable estimate of the total covariance matrix is

$$
\mathbf{T} = (1 + r)\mathbf{W}
$$

With the total covariance matrix $\mathbf{T}$, the $F$ statistic (Rubin 1987, p. 137)

$$
F = (\mathbf{Q} - \overline{\mathbf{Q}})'\mathbf{T}^{-1}(\mathbf{Q} - \overline{\mathbf{Q}})/p
$$

has an $F$ distribution with degrees of freedom $p$ and $v_1$, where

$$
v_1 = \frac{1}{2}(p + 1)(m - 1)(1 + \frac{1}{r})^2
$$

For $t = p(m - 1) \leq 4$, PROC MIANALYZE uses the degrees of freedom $v_1$ in the analysis. For $t = p(m - 1) > 4$, PROC MIANALYZE uses $v_2$, a better approximation of the degrees of freedom given by Li, Raghunathan, and Rubin (1991).

$$
v_2 = 4 + (t - 4) \left[ 1 + \frac{1}{r} \left( \frac{2}{t} \right) \right]^2
$$
Testing Linear Hypotheses about the Parameters

Linear hypotheses for parameters $\beta$ are expressed in matrix form as

$$H_0: L\beta = c$$

where $L$ is a matrix of coefficients for the linear hypotheses, and $c$ is a vector of constants.

Suppose that $\hat{Q}_i$ and $\hat{U}_i$ are the point and covariance matrix estimates for a $p$-dimensional parameter $Q$ from the $i$th imputed data set, $i=1, 2, ..., m$. Then for a given matrix $L$, the point and covariance matrix estimates for the linear functions $LQ$ in the $i$th imputed data set are

$$L\hat{Q}_i$$

$$L\hat{U}_i L'$$

The inferences described in the “Combining Inferences from Imputed Data Sets” section on page 2624 and the “Multivariate Inferences” section on page 2626 are applied to these linear estimates for testing the null hypothesis $H_0: L\beta = c$.

For each TEST statement, the “Test Specification” table displays the $L$ matrix and the $c$ vector, the “Multiple Imputation Variance Information” table displays the between-imputation, within-imputation, and total variances for combining complete-data inferences, the “Multiple Imputation Parameter Estimates” table displays a combined estimate and standard error for each linear component.

With the WCOV and BCOV options in the TEST statement, the procedure displays the within-imputation and between-imputation covariance matrices, respectively.

With the TCOV option, the procedure displays the total covariance matrix derived under the assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other.

With the MULT option in the TEST statement, the “Multiple Imputation Multivariate Inference” table displays an $F$ test for the null hypothesis $L\beta = c$ of the linear components.

Examples of the Complete-Data Inferences

For a given parameter of interest, it is not always possible to compute the estimate and associated covariance matrix directly from a SAS procedure. This section describes examples of parameters with their estimates and associated covariance matrices, which provide the input to the MIANALYZE procedure. Some are straightforward, and others require special techniques.
**Means**

For a population mean vector $\mu$, the usual estimate is the sample mean vector

$$\bar{y} = \frac{1}{n} \sum y_i$$

A variance estimate for $\bar{y}$ is $\frac{1}{n} S$, where $S$ is the sample covariance matrix

$$S = \frac{1}{n-1} \sum (y_i - \bar{y})(y_i - \bar{y})'$$

These statistics can be computed from a procedure such as CORR. This approach is illustrated in Example 45.2.

**Regression Coefficients**

Many SAS procedures are available for regression analysis. Among them, PROC REG provides the most general analysis capabilities, and others like PROC LOGISTIC and PROC MIXED provide more specialized analyses.

Some regression procedures, such as REG and LOGISTIC, create an EST type data set that contains both the parameter estimates for the regression coefficients and their associated covariance matrix. You can read an EST type data set in the MIANALYZE procedure with the DATA= option. This approach is illustrated in Example 45.3.

Other procedures, such as GLM, MIXED, and GENMOD, do not generate EST type data sets for regression coefficients. For PROC MIXED and PROC GENMOD, you can use ODS OUTPUT statement to save parameter estimates in a data set and the associated covariance matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and COVB= options, respectively. This approach is illustrated in Example 45.4 for PROC MIXED and in Example 45.5 for PROC GENMOD.

PROC GLM does not display tables for covariance matrices. However, you can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set and the associated $(X'X)^{-1}$ matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and XPXI= options, respectively. This approach is illustrated in Example 45.6.

For univariate inference, only parameter estimates and associated standard errors are needed. You can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set. These data set is then read in the MIANALYZE procedure with the PARMS= option. This approach is illustrated in Example 45.4.
**Correlation Coefficients**

For the population correlation coefficient $\rho$, a point estimate is the sample correlation coefficient $r$. However, for nonzero $\rho$, the distribution of $r$ is skewed.

The distribution of $r$ can be normalized through Fisher’s $z$ transformation

$$z(r) = \frac{1}{2} \log \left( \frac{1 + r}{1 - r} \right)$$

$z(r)$ is approximately normally distributed with mean $z(\rho)$ and variance $1/(n - 3)$.

With a point estimate $\hat{z}$ and an approximate 95% confidence interval $(z_1, z_2)$ for $z(\rho)$, a point estimate $\hat{r}$ and a 95% confidence interval $(r_1, r_2)$ for $\rho$ can be obtained by applying the inverse transformation

$$r = \tanh(z) = \frac{e^{2z} - 1}{e^{2z} + 1}$$

to $z = \hat{z}, z_1, \text{and} \; z_2$.

This approach is illustrated in Example 45.10.

**Ratios of Variable Means**

For the ratio $\mu_1/\mu_2$ of means for variables $Y_1$ and $Y_2$, the point estimate is $\overline{y}_1/\overline{y}_2$, the ratio of the sample means. The Taylor expansion and delta method can be applied to the function $y_1/y_2$ to obtain the variance estimate (Schafer 1997, p. 196)

$$\frac{1}{n} \left[ \left( \frac{\overline{y}_1}{\overline{y}_2} \right)^2 s_{22} - 2 \left( \frac{\overline{y}_1}{\overline{y}_2} \right) \left( \frac{1}{\overline{y}_2} \right) s_{12} + \left( \frac{1}{\overline{y}_2} \right)^2 s_{11} \right]$$

where $s_{11}$ and $s_{22}$ are the sample variances of $Y_1$ and $Y_2$, respectively, and $s_{12}$ is the sample covariance between $Y_1$ and $Y_2$.

A ratio of sample means will be approximately unbiased and normally distributed if the coefficient of variation of the denominator (the standard error for the mean divided by the estimated mean) is 10% or less (Cochran 1977, p. 166; Schafer 1997, p. 196).
**ODS Table Names**

PROC MIANALYZE assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**Examples**

The following statements generate five imputed data sets to be used in this section. The data set FitMiss was created in the section “Getting Started” on page 2610. See “The MI Procedure” chapter for details concerning the MI procedure.

```latex
proc mi data=FitMiss seed=3237851 noprint out=outmi;
  var Oxygen RunTime RunPulse;
run;
```

The Fish data described in the STEPDIC procedure are measurements of 159 fish of seven species caught in Finland’s lake Laengelmavesi. For each fish, the length, height, and width are measured. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail (Length1), from the nose to the notch of its tail (Length2), and from the nose to the end of its tail (Length3). See Chapter 67, “The STEPDIC Procedure,” for more information.

The Fish2 data set is constructed from the Fish data set and contains two species of fish. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables Length3, Height, Width, and Species. Note that some values of the variable Species have also been altered in the data set.
The following statements create the Fish2 data set. It contains the first two species of fish in the Fish data set.

```plaintext
/*-------- Fishes of Species Bream and Parkki Pike --------*/
data Fish2 (drop=HtPct WidthPct);
title 'Fish Measurement Data';
input Species $ Length3 HtPct WidthPct @@;
Height= HtPct*Length3/100;
Width= WidthPct*Length3/100;
datalines;

;```

The following statements generate five imputed data sets to be used in this section. The regression method is used to impute missing values in the variable Width and the discriminant function method is used to impute the variable Species.

```plaintext
proc mi data=Fish2 seed=1305417 out=outfish;
class Species;
    monotone reg (Width)
    discrim( Species= Length3 Height Width);
    var Length3 Height Width Species;
run;
```

Examples 1-6 use different input option combinations to combine parameter estimates computed from different procedures, Examples 7-8 combine parameter estimates with CLASS variables, Example 9 shows the use of a TEST statement, and Example 10 combines statistics that are not directly derived from procedures.
Example 45.1. Reading Means and Standard Errors from Variables in a DATA= Data Set

This example creates an ordinary SAS data set that contains sample means and standard errors computed from imputed data sets. These estimates are then combined to generate valid univariate inferences about the population means.

The following statements use the UNIVARIATE procedure to generate sample means and standard errors for the variables in each imputed data set.

```
proc univariate data=outmi noprint;
  var Oxygen RunTime RunPulse;
  output out=outuni mean=Oxygen RunTime RunPulse stderr=S0xygen SRunTime SRunPulse;
  by _Imputation_;
run;
```

The following statements display the output data set from PROC UNIVARIATE in Output 45.1.1:

```
proc print data=outuni;
  title 'UNIVARIATE Means and Standard Errors';
run;
```

Output 45.1.1. UNIVARIATE Output Data Set

The “Model Information” table shown in Output 45.1.2 lists the input data set(s) and the number of imputations.

The “Multiple Imputation Variance Information” table shown in Output 45.1.2 displays the between-imputation variance, within-imputation variance, and total variance for each univariate inference. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency for each imputed variable are also displayed. A detailed description of these statistics is provided in the “Combining Inferences from Imputed Data Sets” section on page 2624 and the “Multiple Imputation Efficiency” section on page 2626.
### Example 45.1.3. Multiple Imputation Parameter Estimates

</tbody>
</table>

Multiple Imputation Parameter Estimates

| Parameter   | t for H0: Parameter=Theta0 | Pr > |t| |
|-------------|---------------------------|-------|
| Oxygen      | 47.64                     | <.0001|
| RunTime     | 37.96                     | <.0001|
| RunPulse    | 93.80                     | <.0001|

The “Multiple Imputation Parameter Estimates” table shown in **Output 45.1.3** displays the estimated mean and corresponding standard error for each variable. The table also displays a 95% confidence interval for the mean and a $t$ statistic with the associated $p$-value for testing the hypothesis that the mean is equal to the value specified. You can use the THETA0= option to specify the value for the null hypothesis, which is zero by default. The table also displays the minimum and maximum parameter estimates from the imputed data sets.

Note that the results in this example could also have been obtained with the MI procedure.

### Example 45.2. Reading Means and Covariance Matrices from a DATA= COV Data Set

This example creates a COV type data set that contains sample means and covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the population means.

The following statements use the CORR procedure to generate sample means and a covariance matrix for the variables in each imputed data set.

```plaintext
proc corr data=outmi cov nocorr noprint out=outcov(type=cov);
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display sample means and covariance matrices from the first two imputed data sets in **Output 45.2.1**.
```plaintext
proc print data=outcov(obs=12);
title 'CORR Means and Covariance Matrices'
     '(First Two Imputations)';
run;
```

**Output 45.2.1. COV Data Set**

</tbody>
</table>

Note that the covariance matrices in the data set OUTCOV are estimated covariance matrices of variables, $V(y)$. The estimated covariance matrix of the sample means is $V(\bar{y}) = V(y)/n$, where $n$ is the sample size, and is not the same as an estimated covariance matrix for variables.

The following statements combine the results for the imputed data sets, and derive both univariate and multivariate inferences about the means. The EDF= option is specified to request that the adjusted degrees of freedom be used in the analysis. For sample means based on 31 observations, the complete-data error degrees of freedom is 30.

```plaintext
proc mianalyze data=outcov edf=30 wcov bcov tcov mult;
modeleffects Oxygen RunTime RunPulse;
run;
```

The “Multiple Imputation Variance Information” and “Multiple Imputation Parameter Estimates” tables display the same results as in Output 45.1.2 and Output 45.1.3 in Example 45.1.

With the WCOV, BCOV, and TCOV options, the procedure displays the between-imputation covariance matrix, within-imputation covariance matrix, and total covariance matrix assuming that the between-imputation covariance matrix is proportional to the within-imputation covariance matrix in Output 45.2.2.
Output 45.2.2. Covariance Matrices

The MIANALYZE Procedure

The “Multiple Imputation Multivariate Inference” table displayed in Output 45.2.3 shows a significant $p$-value for the null hypothesis that the population means are all equal to zero.
Example 45.3. Reading Regression Results from a DATA= EST Data Set

This example creates an EST type data set that contains regression coefficients and their corresponding covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the regression model.

The following statements use the REG procedure to generate regression coefficients:

```plaintext
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display regression coefficients and their covariance matrices from the first two imputed data sets in Output 45.3.1.

```plaintext
proc print data=outreg(obs=8);
  var _Imputation_ _Type_ _Name_
     Intercept RunTime RunPulse;
  title 'REG Model Coefficients and Covariance matrices'
    ' (First Two Imputations)';
run;
```

Output 45.3.1. EST Type Data Set

Multiple Imputation Parameter Estimates

| Parameter | t for H0: Theta0=Parameter | Pr > |t| |
|-----------|-----------------------------|------|---|
| Intercept | 7.93                         | <.0001 |
| RunTime   | -8.43                       | <.0001 |
| RunPulse  | -1.12                       | 0.2842 |
The “Multiple Imputation Parameter Estimates” table shown in Output 45.3.3 displays the estimated mean and standard error of the regression coefficients. The inferences are based on the \( t \) distribution. The table also displays a 95\% mean confidence interval and a \( t \) test with the associated \( p \)-value for the hypothesis that the regression coefficient is equal to zero. Since the \( p \)-value for RunPulse is 0.1597, this variable can be removed from the regression model.

**Example 45.4. Reading Mixed Model Results from PARMS= and COVB= Data Sets**

This example creates data sets containing parameter estimates and covariance matrices computed by a mixed model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the parameters.

The following PROC MIXED statements generate the fixed-effect parameter estimates and covariance matrix for each imputed data set:

```plaintext
proc mixed data=outmi;
   model Oxygen= RunTime RunPulse RunTime*RunPulse/solution covb;
   by _Imputation_;
   ods output SolutionF=mixparms CovB=mixcovb;
run;
```

The following statements display parameter estimates from the first two imputed data sets in Output 45.4.1.

```plaintext
proc print data=mixparms (obs=8);
   var _Imputation_ Effect Estimate StdErr;
   title 'MIXED Model Coefficients (First Two Imputations)';
run;
```

**Output 45.4.1. PROC MIXED Model Coefficients**

```

The “Multiple Imputation Parameter Estimates” table shown in Output 45.4.4 displays the estimated mean and standard error of the regression coefficients.

Since each covariance matrix contains variables Row, Col1, Col2, Col3, and Col4 for parameters, the EFFECTVAR=ROWCOL option is needed when specifying the COVB= option. The following statements illustrate the use of the MIANALYZE procedure with input PARMS= and COVB(EFFECTVAR=ROWCOL)= data sets:

```r
proc mianalyze parms=mixparms edf=28
covb(effectvar=rowcol)=mixcovb;
modeleffects Intercept RunTime RunPulse RunTime*RunPulse;
run;
```
Example 45.5. Reading Generalized Linear Model Results from PARMS=, PARMINFO=, and COVB= Data Sets

This example creates data sets containing parameter estimates and corresponding covariance matrices computed by a generalized linear model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC GENMOD to generate the parameter estimates and covariance matrix for each imputed data set:

```plaintext
proc genmod data=outmi;
  model Oxygen= RunTime RunPulse/covb;
  by _Imputation_;
  ods output ParameterEstimates=gmparms
      ParmInfo=gmpinfo
      CovB=gmcovb;
run;
```

The following statements print parameter estimates and covariance matrix from the first two imputed data sets in Output 45.5.1.

```plaintext
proc print data=gmparms (obs=8);
  var _Imputation_ Parameter Estimate StdErr;
  title 'GENMOD Model Coefficients (First Two Imputations)';
run;
```

Output 45.5.1.  PROC GENMOD Model Coefficients

```

The following statements use the MIANALYZE procedure with input PARMS=, PARMINFO=, and COVB= data sets:
Since the GENMOD procedure computes maximum likelihood estimates for the covariance matrix, the EDF= option is not used. The resulting model coefficients are identical to the estimates in Example 45.3 in Output 45.3.3 but the standard errors are slightly different because in this example, maximum likelihood estimates for the standard errors are combined without the EDF= option, whereas in Example 45.3, unbiased estimates for the standard errors are combined with the EDF= option.

### Example 45.6. Reading GLM Results from PARMS= and XPXI= Data Sets

This example creates data sets containing parameter estimates and corresponding \((X'X)^{-1}\) matrices computed by a general linear model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC GLM to generate the parameter estimates and \((X'X)^{-1}\) matrix for each imputed data set:

```sas
proc glm data=outmi;
  model Oxygen= RunTime RunPulse/inverse;
  by _Imputation_;
  ods output ParameterEstimates=glmparms
    InvXPX=glmxpxi;
quit;
```

The following statements display parameter estimates and standard errors from imputed data sets in Output 45.6.1.

```sas
proc print data=glmparms (obs=6);
  var _Imputation_ Parameter Estimate StdErr;
  title 'GLM Model Coefficients (First Two Imputations)';
run;
```

**Output 45.6.1. PROC GLM Model Coefficients**

Example 45.8. Reading Mixed Model Results with CLASS Variables

The “Multiple Imputation Parameter Estimates” table shown in Output 45.7.4 displays the combined parameter estimates with associated standard errors.

Example 45.8. Reading Mixed Model Results with CLASS Variables

This example creates data sets containing parameter estimates and corresponding covariance matrices with CLASS variables computed by a mixed regression model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC MIXED to generate the parameter estimates and covariance matrix for each imputed data set:

```plaintext
proc mixed data=outfish;
   class Species;
   model Length3= Species Height Width/ solution covb;
   by _Imputation_;
   ods output SolutionF=mxparms CovB=mxcovb;
run;
```
The following statements display the mixed model coefficients from the first two imputations in Output 45.8.1.

```plaintext
proc print data=mxparms (obs=10);
  var _Imputation_ Effect Species Estimate StdErr;
  title 'MIXED Model Coefficients (First Two Imputations)';
run;
```

The “Multiple Imputation Parameter Estimates” table shown in Output 45.8.3 displays the combined parameter estimates with associated standard errors.

Example 45.9. Using a TEST statement

This example creates an EST type data set that contains regression coefficients and their corresponding covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the regression model. A TEST statement is used to test linear hypotheses about the parameters.

The following statements use the REG procedure to generate regression coefficients:

```plaintext
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements combine the results for the imputed data sets. A TEST statement is used to test linear hypotheses of Intercept=0 and RunTime=RunPulse.

proc mianalyze data=outreg edf=28;
  modeleffects Intercept RunTime RunPulse;
  test Intercept, RunTime=RunPulse / mult;
run;

**Output 45.9.1.** Test Specification

<table>

Example 45.10. Combining Correlation Coefficients

This example combines sample correlation coefficients computed from a set of imputed data sets using Fisher’s $z$ transformation.

Fisher’s $z$ transformation of the sample correlation $r$ is

$$z = \frac{1}{2} \log \left( \frac{1 + r}{1 - r} \right)$$
The statistic $z$ is approximately normally distributed with mean

$$\log \left( \frac{1 + \rho}{1 - \rho} \right)$$

and variance $1/(n - 3)$, where $\rho$ is the population correlation coefficient and $n$ is the number of observations.

The following statements use the CORR procedure to compute the correlation $r$ and its associated Fisher’s $z$ statistic between variables Oxygen and RunTime for each imputed data set. The ODS statement is used to save Fisher’s $z$ statistic in an output data set.

```sas
proc corr data=outmi fisher(biasadj=no);
  var Oxygen RunTime;
  by _Imputation_;
  ods output FisherPearsonCorr= outz;
run;
```

The following statements display the number of observations and Fisher’s $z$ statistic for each imputed data set in Output 45.10.1.

```sas
proc print data=outz;
  title 'Fisher’s Correlation Statistics';
  var _Imputation_ NObs ZVal;
run;
```

**Output 45.10.1.** Output $z$ Statistics

<table>
<thead>
<tr>
<th>Fisher’s Correlation Statistics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Obs</td>
</tr>
<tr>
<td>-----</td>
</tr>
<tr>
<td>1</td>
</tr>
<tr>
<td>2</td>
</tr>
<tr>
<td>3</td>
</tr>
<tr>
<td>4</td>
</tr>
<tr>
<td>5</td>
</tr>
</tbody>
</table>

The following statements generate the standard error associated with the $z$ statistic, $1/\sqrt{n - 3}$:

```sas
data outz;
  set outz;
  StdZ= 1. / sqrt(NObs-3);
run;
```
The following statements use the MIANALYZE procedure to generate a combined parameter estimate \( \hat{z} \) and its variance, as shown in Output 45.10.2. The ODS statement is used to save the parameter estimates in an output data set.

```plaintext
proc mianalyze data=outz;
   ods output ParameterEstimates=parms;
   modeleffects ZVal;
   stderr StdZ;
run;
```

**Output 45.10.2.** Combining Fisher's z statistics

The MIANALYZE Procedure

Multiple Imputation Parameter Estimates

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Estimate</th>
<th>Std Error</th>
<th>95% Confidence Limits</th>
<th>DF</th>
</tr>
</thead>
<tbody>
<tr>
<td>ZVal</td>
<td>-1.331787</td>
<td>0.200327</td>
<td>-1.72587</td>
<td>-0.93771</td>
</tr>
</tbody>
</table>

Multiple Imputation Parameter Estimates

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Minimum</th>
<th>Maximum</th>
</tr>
</thead>
<tbody>
<tr>
<td>ZVal</td>
<td>-1.401459</td>
<td>-1.278686</td>
</tr>
</tbody>
</table>

Multiple Imputation Parameter Estimates

| t for H0: | Parameter | Theta0 | Parameter=Theta0 | Pr > |t|   |
|-----------|-----------|--------|------------------|------|-----|
| ZVal      | 0         | -6.65  | <.0001           |

In addition to the estimate for \( z \), PROC MIANALYZE also generates 95% confidence limits for \( z, \hat{z}_{0.025} \) and \( \hat{z}_{0.975} \). The following statements print the estimate and 95% confidence limits for \( z \) in Output 45.10.3.

```plaintext
proc print data=parms;
   title 'Parameter Estimates with 95% Confidence Limits';
   var Estimate LCLMean UCLMean;
run;
```

**Output 45.10.3.** Parameter Estimates with 95% Confidence Limits

<table>
<thead>
<tr>
<th>Parameter Estimates with 95% Confidence Limits</th>
</tr>
</thead>
<tbody>
<tr>
<td>Obs</td>
</tr>
<tr>
<td>-----</td>
</tr>
<tr>
<td>1</td>
</tr>
</tbody>
</table>
An estimate of the correlation coefficient and 95% confidence limits are then generated from the following inverse transformation as described in the “Correlation Coefficients” section on page 2630

\[ r = \tanh(z) = \frac{e^{2z} - 1}{e^{2z} + 1} \]

for \( z = \hat{z}, \hat{z}_{0.025}, \) and \( \hat{z}_{0.975} \).

The following statements generate and display an estimate of the correlation coefficient and its 95% confidence limits.

```sas
data corr_ci;
  set parms;
  r = tanh( Estimate);
  r_lower= tanh( LCLMean);
  r_upper= tanh( UCLMean);
run;

proc print data=corr_ci;
  title 'Estimated Correlation Coefficient'
    'with 95% Confidence Limits';
  var r r_lower r_upper;
run;
```

**Output 45.10.4.** Estimated Correlation Coefficient

<table>
<thead>
<tr>
<th>Obs</th>
<th>r</th>
<th>r_lower</th>
<th>r_upper</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>-0.86969</td>
<td>-0.93857</td>

Chapter 46
The MIXED Procedure

Overview

The MIXED procedure fits a variety of mixed linear models to data and enables you to use these fitted models to make statistical inferences about the data. A mixed linear model is a generalization of the standard linear model used in the GLM procedure, the generalization being that the data are permitted to exhibit correlation and nonconstant variability. The mixed linear model, therefore, provides you with the flexibility of modeling not only the means of your data (as in the standard linear model) but their variances and covariances as well.

The primary assumptions underlying the analyses performed by PROC MIXED are as follows:

- The data are normally distributed (Gaussian).
- The means (expected values) of the data are linear in terms of a certain set of parameters.
- The variances and covariances of the data are in terms of a different set of parameters, and they exhibit a structure matching one of those available in PROC MIXED.

Since Gaussian data can be modeled entirely in terms of their means and variances/covariances, the two sets of parameters in a mixed linear model actually specify the complete probability distribution of the data. The parameters of the mean model are referred to as fixed-effects parameters, and the parameters of the variance-covariance model are referred to as covariance parameters.

The fixed-effects parameters are associated with known explanatory variables, as in the standard linear model. These variables can be either qualitative (as in the traditional analysis of variance) or quantitative (as in standard linear regression). However, the covariance parameters are what distinguishes the mixed linear model from the standard linear model.

The need for covariance parameters arises quite frequently in applications, the following being the two most typical scenarios:

- The experimental units on which the data are measured can be grouped into clusters, and the data from a common cluster are correlated.
- Repeated measurements are taken on the same experimental unit, and these repeated measurements are correlated or exhibit variability that changes.

The first scenario can be generalized to include one set of clusters nested within another. For example, if students are the experimental unit, they can be clustered into
classes, which in turn can be clustered into schools. Each level of this hierarchy can introduce an additional source of variability and correlation. The second scenario occurs in longitudinal studies, where repeated measurements are taken over time. Alternatively, the repeated measures could be spatial or multivariate in nature.

PROC MIXED provides a variety of covariance structures to handle the previous two scenarios. The most common of these structures arises from the use of random-effects parameters, which are additional unknown random variables assumed to impact the variability of the data. The variances of the random-effects parameters, commonly known as variance components, become the covariance parameters for this particular structure. Traditional mixed linear models contain both fixed- and random-effects parameters, and, in fact, it is the combination of these two types of effects that led to the name mixed model. PROC MIXED fits not only these traditional variance component models but numerous other covariance structures as well.

PROC MIXED fits the structure you select to the data using the method of restricted maximum likelihood (REML), also known as residual maximum likelihood. It is here that the Gaussian assumption for the data is exploited. Other estimation methods are also available, including maximum likelihood and MIVQUE0. The details behind these estimation methods are discussed in subsequent sections.

Once a model has been fit to your data, you can use it to draw statistical inferences via both the fixed-effects and covariance parameters. PROC MIXED computes several different statistics suitable for generating hypothesis tests and confidence intervals. The validity of these statistics depends upon the mean and variance-covariance model you select, so it is important to choose the model carefully. Some of the output from PROC MIXED helps you assess your model and compare it with others.

### Basic Features

PROC MIXED provides easy accessibility to numerous mixed linear models that are useful in many common statistical analyses. In the style of the GLM procedure, PROC MIXED fits the specified mixed linear model and produces appropriate statistics.

Some basic features of PROC MIXED are

- covariance structures, including variance components, compound symmetry, unstructured, AR(1), Toeplitz, spatial, general linear, and factor analytic
- GLM-type grammar, using MODEL, RANDOM, and REPEATED statements for model specification and CONTRAST, ESTIMATE, and LSMEANS statements for inferences
- appropriate standard errors for all specified estimable linear combinations of fixed and random effects, and corresponding t- and F-tests
- subject and group effects that enable blocking and heterogeneity, respectively
- REML and ML estimation methods implemented with a Newton-Raphson algorithm
• capacity to handle unbalanced data
• ability to create a SAS data set corresponding to any table

PROC MIXED uses the Output Delivery System (ODS), a SAS subsystem that provides capabilities for displaying and controlling the output from SAS procedures. ODS enables you to convert any of the output from PROC MIXED into a SAS data set. See the “ODS Table Names” section on page 2752.

Experimental graphics are now available with the MIXED procedure. For more information, see the “ODS Graphics” section on page 2757.

**Notation for the Mixed Model**

This section introduces the mathematical notation used throughout this chapter to describe the mixed linear model. You should be familiar with basic matrix algebra (refer to Searle 1982). A more detailed description of the mixed model is contained in the “Mixed Models Theory” section on page 2731.

A statistical model is a mathematical description of how data are generated. The standard linear model, as used by the GLM procedure, is one of the most common statistical models:

\[ y = X\beta + \epsilon \]

In this expression, \( y \) represents a vector of observed data, \( \beta \) is an unknown vector of fixed-effects parameters with known design matrix \( X \), and \( \epsilon \) is an unknown random error vector modeling the statistical noise around \( X\beta \). The focus of the standard linear model is to model the mean of \( y \) by using the fixed-effects parameters \( \beta \). The residual errors \( \epsilon \) are assumed to be independent and identically distributed Gaussian random variables with mean 0 and variance \( \sigma^2 \).

The mixed model generalizes the standard linear model as follows:

\[ y = X\beta + Z\gamma + \epsilon \]

Here, \( \gamma \) is an unknown vector of random-effects parameters with known design matrix \( Z \), and \( \epsilon \) is an unknown random error vector whose elements are no longer required to be independent and homogeneous.

To further develop this notion of variance modeling, assume that \( \gamma \) and \( \epsilon \) are Gaussian random variables that are uncorrelated and have expectations \( 0 \) and variances \( G \) and \( R \), respectively. The variance of \( y \) is thus

\[ V = ZGZ' + R \]

Note that, when \( R = \sigma^2 I \) and \( Z = 0 \), the mixed model reduces to the standard linear model.
You can model the variance of the data, $y$, by specifying the structure (or form) of $Z$, $G$, and $R$. The model matrix $Z$ is set up in the same fashion as $X$, the model matrix for the fixed-effects parameters. For $G$ and $R$, you must select some covariance structure. Possible covariance structures include:

- variance components
- compound symmetry (common covariance plus diagonal)
- unstructured (general covariance)
- autoregressive
- spatial
- general linear
- factor analytic

By appropriately defining the model matrices $X$ and $Z$, as well as the covariance structure matrices $G$ and $R$, you can perform numerous mixed model analyses.

**PROC MIXED Contrasted with Other SAS Procedures**

PROC MIXED is a generalization of the GLM procedure in the sense that PROC GLM fits standard linear models, and PROC MIXED fits the wider class of mixed linear models. Both procedures have similar CLASS, MODEL, CONTRAST, ESTIMATE, and LSMEANS statements, but their RANDOM and REPEATED statements differ (see the following paragraphs). Both procedures use the non-full-rank model parameterization, although the sorting of classification levels can differ between the two. PROC MIXED computes only Type I–Type III tests of fixed effects, while PROC GLM offers Types I–IV.

The RANDOM statement in PROC MIXED incorporates random effects constituting the $\gamma$ vector in the mixed model. However, in PROC GLM, effects specified in the RANDOM statement are still treated as fixed as far as the model fit is concerned, and they serve only to produce corresponding expected mean squares. These expected mean squares lead to the traditional ANOVA estimates of variance components. PROC MIXED computes REML and ML estimates of variance parameters, which are generally preferred to the ANOVA estimates (Searle 1988; Harville 1988; Searle, Casella, and McCulloch 1992). Optionally, PROC MIXED also computes MIVQUE0 estimates, which are similar to ANOVA estimates.

The REPEATED statement in PROC MIXED is used to specify covariance structures for repeated measurements on subjects, while the REPEATED statement in PROC GLM is used to specify various transformations with which to conduct the traditional univariate or multivariate tests. In repeated measures situations, the mixed model approach used in PROC MIXED is more flexible and more widely applicable than either the univariate or multivariate approaches. In particular, the mixed model approach provides a larger class of covariance structures and a better mechanism for handling missing values (Wolfinger and Chang 1995).
PROC MIXED subsumes the VARCOMP procedure. PROC MIXED provides a wide variety of covariance structures, while PROC VARCOMP estimates only simple random effects. PROC MIXED carries out several analyses that are absent in PROC VARCOMP, including the estimation and testing of linear combinations of fixed and random effects.

The ARIMA and AUTOREG procedures provide more time series structures than PROC MIXED, although they do not fit variance component models. The CALIS procedure fits general covariance matrices, but it does not allow fixed effects as does PROC MIXED. The LATTICE and NESTED procedures fit special types of mixed linear models that can also be handled in PROC MIXED, although PROC MIXED may run slower because of its more general algorithm. The TSCSREG procedure analyzes time-series cross-sectional data, and it fits some structures not available in PROC MIXED.

**Getting Started**

**Clustered Data Example**

Consider the following SAS data set as an introductory example:

```sas
data heights;
  input Family Gender$ Height @@;
datalines;
  1 F  67 1 F  66 1 F  64 1 M  71 1 M  72 2 F  63
  2 F  63 2 F  67 2 M  69 2 M  68 2 M  70 3 F  63
  3 M  64 4 F  67 4 F  66 4 M  67 4 M  69
run;
```

The response variable Height measures the heights (in inches) of 18 individuals. The individuals are classified according to Family and Gender. You can perform a traditional two-way analysis of variance of these data with the following PROC MIXED code:

```sas
proc mixed;
  class Family Gender;
  model Height = Gender Family Family*Gender;
run;
```

The PROC MIXED statement invokes the procedure. The CLASS statement instructs PROC MIXED to consider both Family and Gender as classification variables. Dummy (indicator) variables are, as a result, created corresponding to all of the distinct levels of Family and Gender. For these data, Family has four levels and Gender has two levels.

The MODEL statement first specifies the response (dependent) variable Height. The explanatory (independent) variables are then listed after the equal (=) sign. Here, the two explanatory variables are Gender and Family, and they comprise the main
effects of the design. The third explanatory term, Family*Gender, models an interaction between the two main effects.

PROC MIXED uses the dummy variables associated with Gender, Family, and Family*Gender to construct the $X$ matrix for the linear model. A column of 1s is also included as the first column of $X$ to model a global intercept. There are no $Z$ or $G$ matrices for this model, and $R$ is assumed to equal $\sigma^2 I$, where $I$ is an $18 \times 18$ identity matrix.

The RUN statement completes the specification. The coding is precisely the same as with the GLM procedure. However, much of the output from PROC MIXED is different from that produced by PROC GLM.

The following is the output from PROC MIXED.

```
The Mixed Procedure
Model Information
Data Set WORK.HEIGHTS
Dependent Variable Height
Covariance Structure Diagonal
Estimation Method REML
Residual Variance Method Profile
Fixed Effects SE Method Model-Based

Figure 46.7. Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table displays significance tests for the three effects listed in the MODEL statement. The Type III $F$-statistics and $p$-values are the same as those produced by the GLM procedure. However, because PROC MIXED uses a likelihood-based estimation scheme, it does not directly compute or display sums of squares for this analysis.

The Type 3 test for Family*Gender effect is not significant at the 5% level, but the tests for both main effects are significant.

The important assumptions behind this analysis are that the data are normally distributed and that they are independent with constant variance. For these data, the normality assumption is probably realistic since the data are observed heights. However, since the data occur in clusters (families), it is very likely that observations from the same family are statistically correlated, that is, not independent.

The methods implemented in PROC MIXED are still based on the assumption of normally distributed data, but you can drop the assumption of independence by modeling statistical correlation in a variety of ways. You can also model variances that are heterogeneous, that is, nonconstant.

For the height data, one of the simplest ways of modeling correlation is through the use of random effects. Here the family effect is assumed to be normally distributed with zero mean and some unknown variance. This is in contrast to the previous model in which the family effects are just constants, or fixed effects. Declaring Family as a random effect sets up a common correlation among all observations having the same level of Family.

Declaring Family*Gender as a random effect models an additional correlation between all observations that have the same level of both Family and Gender. One interpretation of this effect is that a female in a certain family exhibits more correlation with the other females in that family than with the other males, and likewise for a male. With the height data, this model seems reasonable.

The code to fit this correlation model in PROC MIXED is as follows:
proc mixed;
  class Family Gender;
  model Height = Gender;
  random Family Family*Gender;
run;

Note that Family and Family*Gender are now listed in the RANDOM statement.
The dummy variables associated with them are used to construct the $Z$ matrix in the mixed model. The $X$ matrix now consists of a column of 1s and the dummy variables for Gender.

The $G$ matrix for this model is diagonal, and it contains the variance components for both Family and Family*Gender. The $R$ matrix is still assumed to equal $\sigma^2 I$, where $I$ is an identity matrix.

The output from this analysis is as follows.

</table>

**Figure 46.14.** Type 3 Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table contains a significance test for the lone fixed effect, Gender. Note that the associated $p$-value is not nearly as significant as in the previous analysis. This illustrates the importance of correctly modeling correlation in your data.

An additional benefit of the random effects analysis is that it enables you to make inferences about gender that apply to an entire population of families, whereas the inferences about gender from the analysis where Family and Family*Gender are fixed effects apply only to the particular families in the data set.

PROC MIXED thus offers you the ability to model correlation directly and to make inferences about fixed effects that apply to entire populations of random effects.
Syntax

The following statements are available in PROC MIXED.

\begin{verbatim}
PROC MIXED < options > ;
   BY variables ;
   CLASS variables ;
   ID variables ;
   MODEL dependent = < fixed-effects > < / options > ;
   RANDOM random-effects < / options > ;
   REPEATED < repeated-effect >= < / options > ;
   P ARMS (value-list) . . . < / options > ;
   PRIOR < distribution >= < / options > ;
   CONTRAST 'label' < fixed-effect values ... >
       < | random-effect values ... > , . . . < / options > ;
   ESTIMATE 'label' < fixed-effect values ... >
       < | random-effect values ... > < / options > ;
   LSMEANS fixed-effects < / options > ;
   WEIGHT variable ;
\end{verbatim}

Items within angle brackets ( < > ) are optional. The CONTRAST, ESTIMATE, LSMEANS, and RANDOM statements can appear multiple times; all other statements can appear only once.

The PROC MIXED and MODEL statements are required, and the MODEL statement must appear after the CLASS statement if a CLASS statement is included. The CONTRAST, ESTIMATE, LSMEANS, RANDOM, and REPEATED statements must follow the MODEL statement. The CONTRAST and ESTIMATE statements must also follow any RANDOM statements.

Table 46.1 summarizes the basic functions and important options of each PROC MIXED statement. The syntax of each statement in Table 46.1 is described in the following sections in alphabetical order after the description of the PROC MIXED statement.
Table 46.1. Summary of PROC MIXED Statements

PROC MIXED Statement

PROC MIXED < options >;

The PROC MIXED statement invokes the procedure. You can specify the following options.

ABSOLUTE
makes the convergence criterion absolute. By default, it is relative (divided by the current objective function value). See the CONVF, CONVG, and CONVH options in this section for a description of various convergence criteria.

ALPHA=number
requests that confidence limits be constructed for the covariance parameter estimates with confidence level $1 - number$. The value of number must be between 0 and 1; the default is 0.05.

ASYCORR
produces the asymptotic correlation matrix of the covariance parameter estimates. It is computed from the corresponding asymptotic covariance matrix (see the description of the ASYCOV option, which follows). For ODS purposes, the label of the “Asymptotic Correlation” table is “AsyCorr.”

ASYCOV
requests that the asymptotic covariance matrix of the covariance parameters be displayed. By default, this matrix is the observed inverse Fisher information matrix, which equals $2H^{-1}$, where $H$ is the Hessian (second derivative) matrix of the objective function. See the “Covariance Parameter Estimates” section on page 2750 for more information about this matrix. When you use the SCORING= option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute the covariance matrix instead of the observed Hessian. For ODS purposes, the label of the “Asymptotic Covariance” table is “AsyCov.”

CL<,WALD>
requests confidence limits for the covariance parameter estimates. A Satterthwaite approximation is used to construct limits for all parameters that have a lower boundary constraint of zero. These limits take the form

$$\frac{\nu\hat{\sigma}^2}{\chi^2_{\nu,1-\alpha/2}} \leq \sigma^2 \leq \frac{\nu\hat{\sigma}^2}{\chi^2_{\nu,\alpha/2}}$$

where $\nu = 2Z^2$, $Z$ is the Wald statistic $\hat{\sigma}^2 / \text{se}(\hat{\sigma}^2)$, and the denominators are quantiles of the $\chi^2$-distribution with $\nu$ degrees of freedom. Refer to Milliken and Johnson (1992) and Burdick and Graybill (1992) for similar techniques.

For all other parameters, Wald $Z$-scores and normal quantiles are used to construct the limits. Wald limits are also provided for variance components if you specify the NOBOUND option. The optional =WALD specification requests Wald limits for all parameters.
The confidence limits are displayed as extra columns in the “Covariance Parameter Estimates” table. The confidence level is \(1 - \alpha = 0.95\) by default; this can be changed with the `ALPHA=` option.

**CONVF</number>**
requests the relative function convergence criterion with tolerance `number`. The relative function convergence criterion is

\[
\frac{|f_k - f_{k-1}|}{|f_k|} \leq number
\]

where \(f_k\) is the value of the objective function at iteration \(k\). To prevent the division by \(|f_k|\), use the `ABSOLUTE` option. The default convergence criterion is `CONVH`, and the default tolerance is `1E−8`.

**CONVG </number>**
requests the relative gradient convergence criterion with tolerance `number`. The relative gradient convergence criterion is

\[
\frac{\max_j |g_{jk}|}{|f_k|} \leq number
\]

where \(f_k\) is the value of the objective function, and \(g_{jk}\) is the \(j\)th element of the gradient (first derivative) of the objective function, both at iteration \(k\). To prevent division by \(|f_k|\), use the `ABSOLUTE` option. The default convergence criterion is `CONVH`, and the default tolerance is `1E−8`.

**CONVH</number>**
requests the relative Hessian convergence criterion with tolerance `number`. The relative Hessian convergence criterion is

\[
\frac{g_k'H_k^{-1}g_k}{|f_k|} \leq number
\]

where \(f_k\) is the value of the objective function, \(g_k\) is the gradient (first derivative) of the objective function, and \(H_k\) is the Hessian (second derivative) of the objective function, all at iteration \(k\).

If \(H_k\) is singular, then PROC MIXED uses the following relative criterion:

\[
\frac{g_k'g_k}{|f_k|} \leq number
\]

To prevent the division by \(|f_k|\), use the `ABSOLUTE` option. The default convergence criterion is `CONVH`, and the default tolerance is `1E−8`. 
COVTEST
produces asymptotic standard errors and Wald Z-tests for the covariance parameter estimates.

DATA=SAS-data-set
names the SAS data set to be used by PROC MIXED. The default is the most recently created data set.

DFBW
has the same effect as the DDFM=BW option in the MODEL statement.

EMPIRICAL
computes the estimated variance-covariance matrix of the fixed-effects parameters by using the asymptotically consistent estimator described in Huber (1967), White (1980), Liang and Zeger (1986), and Diggle, Liang, and Zeger (1994). This estimator is commonly referred to as the “sandwich” estimator, and it is computed as follows:

\[(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\left(\sum_{i=1}^{S}\mathbf{X}_i'\hat{\mathbf{V}}_i^{-1}\hat{\mathbf{\varepsilon}}_i\hat{\mathbf{\varepsilon}}_i'\hat{\mathbf{V}}_i^{-1}\mathbf{X}_i\right)\left(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X}\right)^{-1}\]

Here, \(\hat{\mathbf{\varepsilon}}_i = y_i - \mathbf{X}_i\hat{\mathbf{\beta}}\), \(S\) is the number of subjects, and matrices with an \(i\) subscript are those for the \(i\)th subject. You must include the SUBJECT= option in either a RANDOM or REPEATED statement for this option to take effect.

When you specify the EMPIRICAL option, PROC MIXED adjusts all standard errors and test statistics involving the fixed-effects parameters. This changes output in the following tables (listed in Table 46.8 on page 2752): Contrast, CorrB, CovB, Diffs, Estimates, InvCovB, LSMeans, MMEM, MMESol, Slices, SolutionF, Tests1–Tests3. The OUTP= and OUTPM= data sets are also affected. Finally, the Satterthwaite and Kenward-Roger degrees of freedom methods are not available if you specify EMPIRICAL.

IC
displays a table of various information criteria. The criteria are all in smaller-is-better form, and are described in Table 46.2.

<tr>
<td>CAIC</td>
<td>(-2\ell + d(\log n + 1))</td>
<td>Bozdogan (1987)</td>
</tr>
</tbody>
</table>

Here \(\ell\) denotes the maximum value of the (possibly restricted) log likelihood, \(d\) the dimension of the model, and \(n\) the number of observations. In Version 6 of SAS/STAT software, \(n\) equals the number of valid observations for maximum likelihood estimation and \(n - p\) for restricted maximum likelihood estimation, where \(p\) equals the rank of \(\mathbf{X}\). In later versions, \(n\) equals the number of effective subjects as displayed in the
“Dimensions” table, unless this value equals 1, in which case \( n \) equals the number of levels of the first RANDOM effect you specify. If the number of effective subjects equals 1 and you have no RANDOM statements, then \( n \) reverts to the Version 6 values. For AICC (a finite-sample corrected version of AIC), \( n^* \) equals the Version 6 values of \( n \), unless this number is less than \( d + 2 \), in which case it equals \( d + 2 \).

For restricted likelihood estimation, \( d \) equals \( q \) the effective number of estimated covariance parameters. In Version 6, when a parameter estimate lies on a boundary constraint, then it is still included in the calculation of \( d \), but in later versions it is not. The most common example of this behavior is when a variance component is estimated to equal zero. For maximum likelihood estimation, \( d \) equals \( q + p \).

For ODS purposes, the name of the “Information Criteria” table is “InfoCrit.”

INFO

is a default option. The creation of the “Model Information”, “Dimensions”, and “Number of Observations” tables can be suppressed using the NOINFO option.

Note that, in Version 6, this option displays the “Model Information” and “Dimensions” tables.

ITDETAILS
displays the parameter values at each iteration and enables the writing of notes to the SAS log pertaining to “infinite likelihood” and “singularities” during Newton-Raphson iterations.

LOGNOTE

writes periodic notes to the log describing the current status of computations. It is designed for use with analyses requiring extensive CPU resources.

MAXFUNC=number

specifies the maximum number of likelihood evaluations in the optimization process. The default is 150.

MAXITER=number

specifies the maximum number of iterations. The default is 50.

METHOD=REML
METHOD=ML
METHOD=MIVQUE0
METHOD=TYPE1
METHOD=TYPE2
METHOD=TYPE3

specifies the estimation method for the covariance parameters. The REML specification performs residual (restricted) maximum likelihood, and it is the default method. The ML specification performs maximum likelihood, and the MIVQUE0 specification performs minimum variance quadratic unbiased estimation of the covariance parameters.

The METHOD=TYPE\( n \) specifications apply only to variance component models with no SUBJECT= effects and no REPEATED statement. An analysis of variance table is included in the output, and the expected mean squares are used to estimate
the variance components (see Chapter 32, “The GLM Procedure,” for further explanation). The resulting method-of-moment variance component estimates are used in subsequent calculations, including standard errors computed from ESTIMATE and LSMEANS statements. For ODS purposes, the new table names are “Type1,” “Type2,” and “Type3,” respectively.

**MMEQ**

requests that coefficients of the mixed model equations be displayed. These are

\[
\begin{bmatrix}
X'\hat{\mathbf{R}}^{-1}X & X'\hat{\mathbf{R}}^{-1}Z \\
Z'\hat{\mathbf{R}}^{-1}X & Z'\hat{\mathbf{R}}^{-1}Z + \hat{\mathbf{G}}^{-1}
\end{bmatrix},
\begin{bmatrix}
X'\hat{\mathbf{R}}^{-1}y \\
Z'\hat{\mathbf{R}}^{-1}y
\end{bmatrix}
\]

assuming that \(\hat{\mathbf{G}}\) is nonsingular. If \(\hat{\mathbf{G}}\) is singular, PROC MIXED produces the following coefficients

\[
\begin{bmatrix}
X'\hat{\mathbf{R}}^{-1}X & X'\hat{\mathbf{R}}^{-1}Z\hat{\mathbf{G}} \\
\hat{\mathbf{G}}Z'\hat{\mathbf{R}}^{-1}X & \hat{\mathbf{G}}Z'\hat{\mathbf{R}}^{-1}Z\hat{\mathbf{G}} + \hat{\mathbf{G}}
\end{bmatrix},
\begin{bmatrix}
X'\hat{\mathbf{R}}^{-1}y \\
\hat{\mathbf{G}}Z'\hat{\mathbf{R}}^{-1}y
\end{bmatrix}
\]

See the “Estimating \(\beta\) and \(\gamma\) in the Mixed Model” section on page 2739 for further information on these equations.

**MMEQSOL**

requests that a solution to the mixed model equations be produced, as well as the inverted coefficients matrix. Formulas for these equations are provided in the preceding description of the MMEQ option.

When \(\hat{\mathbf{G}}\) is singular, \(\hat{\tau}\) and a generalized inverse of the left-hand-side coefficient matrix are transformed using \(\hat{\mathbf{G}}\) to produce \(\hat{\gamma}\) and \(\hat{\mathbf{C}}\), respectively, where \(\hat{\mathbf{C}}\) is a generalized inverse of the left-hand-side coefficient matrix of the original equations.

**NAMELEN<=number>**

specifies the length to which long effect names are shortened. The default and minimum value is 20.

**NOBOUND**

has the same effect as the NOBOUND option in the PARMS statement (see page 2707).

**NOCLPRINT<=number>**

suppresses the display of the “Class Level Information” table if you do not specify number. If you do specify number, only levels with totals that are less than number are listed in the table.

**NOINFO**

suppresses the display of the “Model Information”, “Dimensions”, and “Number of Observations” tables.
NOITPRINT
suppresses the display of the “Iteration History” table.

NOPROFILE
includes the residual variance as part of the Newton-Raphson iterations. This option applies only to models that have a residual variance parameter. By default, this parameter is profiled out of the likelihood calculations, except when you have specified the HOLD= or NOITER option in the PARMS statement.

ORD
displays ordinates of the relevant distribution in addition to $p$-values. The ordinate can be viewed as an approximate odds ratio of hypothesis probabilities.

ORDER=DATA
ORDER=FORMATTED
ORDER=FREQ
ORDER=INTERNAL
specifies the sorting order for the levels of all CLASS variables. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use CONTRAST or ESTIMATE statements.

The default is ORDER=FORMATTED, and its behavior has been modified for Version 8. When the default ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values. In order to revert to the previous method you can specify this format explicitly for the CLASS variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and required you to use an explicit format or ORDER=INTERNAL to get the more natural ordering.

The following table shows how PROC MIXED interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

For FORMATTED and INTERNAL, the sort order is machine dependent. For more information on sorting order, see the chapter on the SORT procedure in the SAS

**RATIO**
produces the ratio of the covariance parameter estimates to the estimate of the residual variance when the latter exists in the model.

**RIDGE=number**
specifies the starting value for the minimum ridge value used in the Newton-Raphson algorithm. The default is 0.3125.

**SCORING<=number>**
requests that Fisher scoring be used in association with the estimation method up to iteration number, which is 0 by default. When you use the SCORING= option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute approximate standard errors for the covariance parameters instead of the observed Hessian. The output from the ASYCOV and ASYCORR options is similarly adjusted.

**SIGITER**
is an alias for the NOPROFILE option.

**UPDATE**
is an alias for the LOGNOTE option.

---

**BY Statement**

**BY variables ;**
You can specify a BY statement with PROC MIXED to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement options NOTSORTED or DESCENDING in the BY statement for the MIXED procedure. The NOTSORTED option does not mean that the data are unsorted but rather means that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

Since sorting the data changes the order in which PROC MIXED reads observations, the sorting order for the levels of the CLASS variable may be affected if you have specified ORDER=DATA in the PROC MIXED statement. This, in turn, affects specifications in the CONTRAST statements.
For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**CLASS Statement**

```
CLASS variables ;
```

The CLASS statement names the classification variables to be used in the analysis. If the CLASS statement is used, it must appear before the MODEL statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option in the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide* and to the discussions of the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*. You can adjust the order of CLASS variable levels with the ORDER= option in the PROC MIXED statement.

You can specify the following option in the CLASS statement after a slash(/):

```
TRUNCATE MIXED
```

TRUNCATE MIXED specifies that class levels should be determined using only no more than the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

**CONTRAST Statement**

```
CONTRAST 'label' < fixed-effect values . . >
( | random-effect values . . > , . . < / options > ) ;
```

The CONTRAST statement provides a mechanism for obtaining custom hypothesis tests. It is patterned after the CONTRAST statement in PROC GLM, although it has been extended to include random effects. This enables you to select an appropriate inference space (McLean, Sanders, and Stroup 1991).

You can test the hypothesis $L'\phi = 0$, where $L' = (K' M')$ and $\phi' = (\beta' \gamma')$, in several inference spaces. The inference space corresponds to the choice of $M$. When $M = 0$, your inferences apply to the entire population from which the random effects are sampled; this is known as the broad inference space. When all elements of $M$ are nonzero, your inferences apply only to the observed levels of the random effects. This is known as the narrow inference space, and you can also choose it by specifying all of the random effects as fixed. The GLM procedure uses the narrow inference space. Finally, by zeroing portions of $M$ corresponding to selected main effects and interactions, you can choose intermediate inference spaces. The broad
inference space is usually the most appropriate, and it is used when you do not specify any random effects in the CONTRAST statement.

In the CONTRAST statement,

\textit{label} identifies the contrast in the table. A label is required for every contrast specified. Labels can be up to 20 characters and must be enclosed in single quotes.

\textit{fixed-effect} identifies an effect that appears in the MODEL statement. The keyword INTERCEPT can be used as an effect when an intercept is fitted in the model. You do not need to include all effects that are in the MODEL statement.

\textit{random-effect} identifies an effect that appears in the RANDOM statement. The first random effect must follow a vertical bar (\(|\)). However, random effects do not have to be specified.

\textit{values} are constants that are elements of the \(L\) matrix associated with the fixed and random effects.

The rows of \(L'\) are specified in order and are separated by commas. The rows of the \(K'\) component of \(L'\) are specified on the left side of the vertical bars (\(|\)). These rows test the fixed effects and are, therefore, checked for estimability. The rows of the \(M'\) component of \(L'\) are specified on the right side of the vertical bars. They test the random effects, and no estimability checking is necessary.

If PROC MIXED finds the fixed-effects portion of the specified contrast to be nonestimable (see the SINGULAR= option on page 2684), then it displays “Non-est” for the contrast entries.

The following CONTRAST statement reproduces the \(F\)-test for the effect \(A\) in the split-plot example (see Example 46.1 on page 2777):

```plaintext
contrast 'A broad'
   A 1 -1 0   A*B .5 .5 -.5 -.5 0 0
   A 1 0 -1   A*B .5 .5 0 0 -.5 -.5 / df=6;
```

Note that no random effects are specified in the preceding contrast; thus, the inference space is broad. The resulting \(F\)-test has two numerator degrees of freedom because \(L'\) has two rows. The denominator degrees of freedom is, by default, the residual degrees of freedom (9), but the DF= option changes the denominator degrees of freedom to 6.

The following CONTRAST statement reproduces the \(F\)-test for \(A\) when Block and A\(^*\)Block are considered fixed effects (the narrow inference space):
The preceding contrast does not contain coefficients for B and Block because they cancel out in estimated differences between levels of A. Coefficients for B and Block are necessary when estimating the mean of one of the levels of A in the narrow inference space (see Example 46.1 on page 2777).

If the elements of L are not specified for an effect that contains a specified effect, then the elements of the specified effect are automatically “filled in” over the levels of the higher-order effect. This feature is designed to preserve estimability for cases when there are complex higher-order effects. The coefficients for the higher-order effect are determined by equitably distributing the coefficients of the lower-level effect as in the construction of least squares means. In addition, if the intercept is specified, it is distributed over all classification effects that are not contained by any other specified effect. If an effect is not specified and does not contain any specified effects, then all of its coefficients in L are set to 0. You can override this behavior by specifying coefficients for the higher-order effect.

If too many values are specified for an effect, the extra ones are ignored; if too few are specified, the remaining ones are set to 0. If no random effects are specified, the vertical bar can be omitted; otherwise, it must be present. If a SUBJECT effect is used in the RANDOM statement, then the coefficients specified for the effects in the RANDOM statement are equitably distributed across the levels of the SUBJECT effect. You can use the E option to see exactly what L matrix is used.

The SUBJECT and GROUP options in the CONTRAST statement are useful for the case when a SUBJECT= or GROUP= variable appears in the RANDOM statement, and you want to contrast different subjects or groups. By default, CONTRAST statement coefficients on random effects are distributed equally across subjects and groups.

PROC MIXED handles missing level combinations of classification variables similarly to the way PROC GLM does. Both procedures delete fixed-effects parameters corresponding to missing levels in order to preserve estimability. However, PROC MIXED does not delete missing level combinations for random-effects parameters because linear combinations of the random-effects parameters are always estimable. These conventions can affect the way you specify your CONTRAST coefficients.
Chapter 46. The MIXED Procedure

The CONTRAST statement computes the statistic

\[ F = \left( \begin{array}{c} \hat{\beta} \\ \hat{\gamma} \end{array} \right) ' L (L' \hat{C} L)^{-1} L' \left( \begin{array}{c} \hat{\beta} \\ \hat{\gamma} \end{array} \right) \]

and approximates its distribution with an F-distribution. In this expression, \( \hat{C} \) is an estimate of the generalized inverse of the coefficient matrix in the mixed model equations. See the “Inference and Test Statistics” section on page 2741 for more information on this F-statistic.

The numerator degrees of freedom in the F-approximation is \( \text{rank}(L) \), and the denominator degrees of freedom is taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the CONTRAST statement. You can change the denominator degrees of freedom by using the DF= option.

You can specify the following options in the CONTRAST statement after a slash (/).

- **CHISQ**
  requests that \( \chi^2 \)-tests be performed in addition to any F-tests. A \( \chi^2 \)-statistic equals its corresponding F-statistic times the associate numerator degrees of freedom, and this same degrees of freedom is used to compute the \( p \)-value for the \( \chi^2 \)-test. This \( p \)-value will always be less than that for the F-test, as it effectively corresponds to an F-test with infinite denominator degrees of freedom.

- **DF=number**
  specifies the denominator degrees of freedom for the F-test. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the CONTRAST statement.

- **E**
  requests that the \( L \) matrix coefficients for the contrast be displayed. For ODS purposes, the label of this “L Matrix Coefficients” table is “Coeff.”

- **GROUP coeffs**
  GRP coeffs
  sets up random-effect contrasts between different groups when a GROUP= variable appears in the RANDOM statement. By default, CONTRAST statement coefficients on random effects are distributed equally across groups.

- **SINGULAR=number**
  tunes the estimability checking. If \( v \) is a vector, define \( \text{ABS}(v) \) to be the absolute value of the element of \( v \) with the largest absolute value. If \( \text{ABS}(K'-K'T) \) is greater than \( C*number \) for any row of \( K' \) in the contrast, then \( K \) is declared nonestimable. Here \( T \) is the Hermite form matrix \( (X'X)^{-1}X'X \), and \( C \) is \( \text{ABS}(K') \) except when it equals 0, and then \( C \) is 1. The value for number must be between 0 and 1; the default is 1E−4.
SUBJECT coeffs
SUB coeffs
sets up random-effect contrasts between different subjects when a SUBJECT= variable appears on the RANDOM statement. By default, CONTRAST statement coefficients on random effects are distributed equally across subjects.

**ESTIMATE Statement**

```
ESTIMATE 'label' < fixed-effect values ... >
< | random-effect values ... > , ... < / options > ;
```

The ESTIMATE statement is exactly like a CONTRAST statement, except only one-row L matrices are permitted. The actual estimate, $L\hat{\beta}$, is displayed along with its approximate standard error. An approximate $t$-test that $L\hat{\beta} = 0$ is also produced.

PROC MIXED selects the degrees of freedom to match those displayed in the “Tests of Fixed Effects” table for the final effect you list in the ESTIMATE statement. You can modify the degrees of freedom using the DF= option.

If PROC MIXED finds the fixed-effects portion of the specified estimate to be non-estimable, then it displays “Non-est” for the estimate entries.

The following examples of ESTIMATE statements compute the mean of the first level of A in the split-plot example (see Example 46.1 on page 2777) for various inference spaces.

```
estimate 'A1 mean narrow' intercept 1
 A 1 B .5 .5 A*B .5 .5 |
 block .25 .25 .25 .25
 A*Block .25 .25 .25 .25
 0 0 0 0
 0 0 0 0 ;

estimate 'A1 mean intermed' intercept 1
 A 1 B .5 .5 A*B .5 .5 |
 Block .25 .25 .25 .25 ;

estimate 'A1 mean broad' intercept 1
 A 1 B .5 .5 A*B .5 .5 ;
```

The construction of the L vector for an ESTIMATE statement follows the same rules as listed under the CONTRAST statement.

You can specify the following options in the ESTIMATE statement after a slash (/).

** ALPHA=number**
requests that a $t$-type confidence interval be constructed with confidence level $1 - number$. The value of number must be between 0 and 1; the default is 0.05.

** CL**
requests that $t$-type confidence limits be constructed. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.
DF=number
specifies the degrees of freedom for the $t$-test and confidence limits. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the ESTIMATE statement.

DIVISOR=number
specifies a value by which to divide all coefficients so that fractional coefficients can be entered as integer numerators.

E requests that the $L$ matrix coefficients be displayed. For ODS purposes, the label of this “$L$ Matrix Coefficients” table is “Coef.”

GROUP coeffs
GRP coeffs
sets up random-effect contrasts between different groups when a GROUP= variable appears in the RANDOM statement. By default, ESTIMATE statement coefficients on random effects are distributed equally across groups.

LOWER LOWERTAILED
requests that the $p$-value for the $t$-test be based only on values less than the $t$-statistic. A two-tailed test is the default. A lower-tailed confidence limit is also produced if you specify the CL option.

SINGULAR=number
tunes the estimability checking as documented for the CONTRAST statement.

SUBJECT coeffs
SUB coeffs
sets up random-effect contrasts between different subjects when a SUBJECT= variable appears in the RANDOM statement. By default, ESTIMATE statement coefficients on random effects are distributed equally across subjects.

For example, the ESTIMATE statement in the following code from Example 46.5 constructs the difference between the random slopes of the first two batches.

```plaintext
proc mixed data=rc;
   class batch;
   model y = month / s;
   random int month / type=un sub=batch s;
   estimate 'slope b1 - slope b2' | month 1 / subject 1 -1;
run;
```

UPPER UPPERTAILED
requests that the $p$-value for the $t$-test be based only on values greater than the $t$-statistic. A two-tailed test is the default. An upper-tailed confidence limit is also produced if you specify the CL option.
**ID Statement**

`ID variables ;`

The ID statement specifies which variables from the input data set are to be included in the OUTP= and OUTPM= data sets from the MODEL statement. If you do not specify an ID statement, then all variables are included in these data sets. Otherwise, only the variables you list in the ID statement are included. Specifying an ID statement with no variables prevents any variables from being included in these data sets.

**LSMEANS Statement**

`LSMEANS fixed-effects < / options > ;`

The LSMEANS statement computes least-squares means (LS-means) of fixed effects. As in the GLM procedure, LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs. The $L$ matrix constructed to compute them is the same as the $L$ matrix formed in PROC GLM; however, the standard errors are adjusted for the covariance parameters in the model.

Each LS-mean is computed as $L\hat{\beta}$ where $L$ is the coefficient matrix associated with the least-squares mean and $\hat{\beta}$ is the estimate of the fixed-effects parameter vector (see the “Estimating $\beta$ and $\gamma$ in the Mixed Model” section on page 2739). The approximate standard errors for the LS-mean is computed as the square root of $L(X'\hat{V}^{-1}X)^{-1}L'$.

LS-means can be computed for any effect in the MODEL statement that involves CLASS variables. You can specify multiple effects in one LSMEANS statement or in multiple LSMEANS statements, and all LSMEANS statements must appear after the MODEL statement. As in the ESTIMATE statement, the $L$ matrix is tested for estimability, and if this test fails, PROC MIXED displays “Non-est” for the LS-means entries.

Assuming the LS-mean is estimable, PROC MIXED constructs an approximate $t$-test to test the null hypothesis that the associated population quantity equals zero. By default, the denominator degrees of freedom for this test are the same as those displayed for the effect in the “Tests of Fixed Effects” table (see the “Default Output” section on page 2748).

You can specify the following options in the LSMEANS statement after a slash (/).

- `ADJUST=BON`
- `ADJUST=DUNNETT`
- `ADJUST=SCHEFFE`
- `ADJUST=SIDAK`
- `ADJUST=SIMULATE<(simoptions)>`
- `ADJUST=SMM | GT2`
- `ADJUST=TUKEY`

requests a multiple comparison adjustment for the $p$-values and confidence
limits for the differences of LS-means. By default, PROC MIXED adjusts all pairwise differences unless you specify ADJUST=DUNNETT, in which case PROC MIXED analyzes all differences with a control level. The ADJUST= option implies the DIFF option (see page 2690).

The BON (Bonferroni) and SIDAK adjustments involve correction factors described in Chapter 32, “The GLM Procedure,” and Chapter 48, “The MULTTEST Procedure,”; also refer to Westfall and Young (1993) and Westfall et al. (1999). When you specify ADJUST=TUKEY and your data are unbalanced, PROC MIXED uses the approximation described in Kramer (1956). Similarly, when you specify ADJUST=DUNNETT and the LS-means are correlated, PROC MIXED uses the factor-analytic covariance approximation described in Hsu (1992). The preceding references also describe the SCHEFFE and SMM adjustments.

The SIMULATE adjustment computes adjusted \( p \)-values and confidence limits from the simulated distribution of the maximum or maximum absolute value of a multivariate \( t \) random vector. All covariance parameters except the residual variance are fixed at their estimated values throughout the simulation, potentially resulting in some underdispersion. The simulation estimates \( q \), the true \( (1 - \alpha) \)th quantile, where \( 1 - \alpha \) is the confidence coefficient. The default \( \alpha \) is 0.05, and you can change this value with the ALPHA= option in the LSMEANS statement.

The number of samples is set so that the tail area for the simulated \( q \) is within \( \gamma \) of \( 1 - \alpha \) with 100(1 - \( \epsilon \))% confidence. In equation form,

\[
P(|F(\hat{q}) - (1 - \alpha)| \leq \gamma) = 1 - \epsilon
\]

where \( \hat{q} \) is the simulated \( q \) and \( F \) is the true distribution function of the maximum; refer to Edwards and Berry (1987) for details. By default, \( \gamma = 0.005 \) and \( \epsilon = 0.01 \), placing the tail area of \( \hat{q} \) within 0.005 of 0.95 with 99% confidence. The ACC= and EPS= simoptions reset \( \gamma \) and \( \epsilon \), respectively; the NSAMP= simoption sets the sample size directly; and the SEED= simoption specifies an integer used to start the pseudorandom number generator for the simulation. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. For additional descriptions of these and other simulation options, see the “LSMEANS Statement” section on page 1753 in Chapter 32, “The GLM Procedure.”

**ALPHA=number**
requests that a \( t \)-type confidence interval be constructed for each of the LS-means with confidence level \( 1 - number \). The value of \( number \) must be between 0 and 1; the default is 0.05.

**AT variable = value**
**AT (variable-list) = (value-list)**
**AT MEANS**
enables you to modify the values of the covariates used in computing LS-means. By default, all covariate effects are set equal to their mean values for computation of standard LS-means. The AT option enables you to assign arbitrary values to the covariates. Additional columns in the output table indicate the values of the covariates.
If there is an effect containing two or more covariates, the AT option sets the effect equal to the product of the individual means rather than the mean of the product (as with standard LS-means calculations). The AT MEANS option sets covariates equal to their mean values (as with standard LS-means) and incorporates this adjustment to cross products of covariates.

As an example, consider the following invocation of PROC MIXED:

```plaintext
proc mixed;
   class A;
   model Y = A X1 X2 X1*X2;
   lsmeans A;
   lsmeans A / at means;
   lsmeans A / at X1=1.2;
   lsmeans A / at (X1 X2)=(1.2 0.3);
run;
```

For the first two LSMEANS statements, the LS-means coefficient for X1 is \(\bar{x}_1\) (the mean of X1) and for X2 is \(\bar{x}_2\) (the mean of X2). However, for the first LSMEANS statement, the coefficient for X1*X2 is \(\bar{x}_1 \cdot \bar{x}_2\), but for the second LSMEANS statement, the coefficient is \(\bar{x}_1 \cdot \bar{x}_2\). The third LSMEANS statement sets the coefficient for X1 equal to 1.2 and leaves it at \(\bar{x}_2\) for X2, and the final LSMEANS statement sets these values to 1.2 and 0.3, respectively.

If a WEIGHT variable is present, it is used in processing AT variables. Also, observations with missing dependent variables are included in computing the covariate means, unless these observations form a missing cell and the FULLX option in the MODEL statement is not in effect. You can use the E option in conjunction with the AT option to check that the modified LS-means coefficients are the ones you desire.

The AT option is disabled if you specify the BYLEVEL option.

**BYLEVEL** requests PROC MIXED to process the OM data set by each level of the LS-mean effect (LSMEANS effect) in question. For more details, see the OM option later in this section.

**CL** requests that \(t\)-type confidence limits be constructed for each of the LS-means. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.

**CORR** displays the estimated correlation matrix of the least-squares means as part of the “Least Squares Means” table.

**COV** displays the estimated covariance matrix of the least-squares means as part of the “Least Squares Means” table.
DF=\textit{number}

specifies the degrees of freedom for the t-test and confidence limits. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table corresponding to the LS-means effect unless the DDFM=SATTERTH or DDFM=KENWARDROGER option is in effect on the MODEL statement. For these DDFM= methods degrees of freedom are determined separately for each test; see the DDFM= option on page 2693 for more information.

\texttt{DIFF=<\textit{difftype}>}

\texttt{PDIFF=<\textit{difftype}>}

requests that differences of the LS-means be displayed. The optional \textit{difftype} specifies which differences to produce, with possible values being ALL, CONTROL, CONTROLL, and CONTROLU. The \textit{difftype} ALL requests all pairwise differences, and it is the default. The \textit{difftype} CONTROL requests the differences with a control, which, by default, is the first level of each of the specified LSMEANS effects.

To specify which levels of the effects are the controls, list the quoted formatted values in parentheses after the keyword CONTROL. For example, if the effects A, B, and C are class variables, each having two levels, 1 and 2, the following LSMEANS statement specifies the (1,2) level of A*B and the (2,1) level of B*C as controls:

\texttt{lsmeans A*B B*C / diff=control('1' '2' '2' '1');}

For multiple effects, the results depend upon the order of the list, and so you should check the output to make sure that the controls are correct.

Two-tailed tests and confidence limits are associated with the CONTROL \textit{difftype}. For one-tailed results, use either the CONTROLL or CONTROLU \textit{difftype}. The CONTROLL \textit{difftype} tests whether the noncontrol levels are significantly smaller than the control; the upper confidence limits for the control minus the noncontrol levels are considered to be infinity and are displayed as missing. Conversely, the CONTROLU \textit{difftype} tests whether the noncontrol levels are significantly larger than the control; the upper confidence limits for the noncontrol levels minus the control are considered to be infinity and are displayed as missing.

If you want to perform multiple comparison adjustments on the differences of LS-Means, you must specify the ADJUST= option.

The differences of the LS-means are displayed in a table titled “Differences of Least Squares Means.” For ODS purposes, the table name is “Diff.”

\texttt{E}

requests that the \texttt{L} matrix coefficients for all LSMEANS effects be displayed. For ODS purposes, the label of this “\texttt{L} Matrix Coefficients” table is “Coef.”

\texttt{OM=<OM-data-set>}

\texttt{OBSMARGINS=<OM-data-set>}

specifies a potentially different weighting scheme for the computation of LS-means coefficients. The standard LS-means have equal coefficients across classification effects; however, the OM option changes these coefficients to be proportional to those found in \texttt{OM-data-set}. This adjustment is reasonable when you want your inferences
to apply to a population that is not necessarily balanced but has the margins observed in **OM-data-set**.

By default, **OM-data-set** is the same as the analysis data set. You can optionally specify another data set that describes the population for which you want to make inferences. This data set must contain all model variables except for the dependent variable (which is ignored if it is present). In addition, the levels of all CLASS variables must be the same as those occurring in the analysis data set. Specifying an **OM-data-set** enables you to construct arbitrarily weighted LS-means.

In computing the observed margins, PROC MIXED uses all observations for which there are no missing or invalid independent variables, including those for which there are missing dependent variables. Also, if **OM-data-set** has a WEIGHT variable, PROC MIXED uses weighted margins to construct the LS-means coefficients. If **OM-data-set** is balanced, the LS-means are unchanged by the OM option.

The **BYLEVEL** option modifies the observed-margins LS-means. Instead of computing the margins across all of the **OM-data-set**, PROC MIXED computes separate margins for each level of the LSMEANS effect in question. In this case the resulting LS-means are actually equal to raw means for fixed effects models and certain balanced random effects models, but their estimated standard errors account for the covariance structure that you have specified. If the AT option is specified, the BYLEVEL option disables it.

You can use the **E** option in conjunction with either the OM or BYLEVEL option to check that the modified LS-means coefficients are the ones you desire. It is possible that the modified LS-means are not estimable when the standard ones are, or vice versa. Nonestimable LS-means are noted as “Non-est” in the output.

**PDIFF**

is the same as the **DIFF** option. See the description of the **DIFF** option on page 2690.

**SINGULAR=number**

 tunes the estimability checking as documented on the “**CONTRAST Statement**” section on page 2681.

**SLICE= fixed-effect**

**SLICE= (fixed-effects)**

specifies effects by which to partition interaction LSMEANS effects. This can produce what are known as tests of simple effects (Winer 1971). For example, suppose that **A*B** is significant, and you want to test the effect of **A** for each level of **B**. The appropriate LSMEANS statement is

```
lsmeans A*B / slice=B;
```

This code tests for the simple main effects of **A** for **B**, which are calculated by extracting the appropriate rows from the coefficient matrix for the **A*B** LS-means and using them to form an $F$-test. See the “**Inference and Test Statistics**” section on page 2741 for more information on this $F$-test.

The SLICE option produces a table titled “Tests of Effect Slices.” For ODS purposes, the table name is “Slices.”
MODEL Statement

MODEL  dependent = < fixed-effects > / options ;

The MODEL statement names a single dependent variable and the fixed effects, which determine the \( X \) matrix of the mixed model (see the “Parameterization of Mixed Models” section on page 2743 for details). The specification of effects is the same as in the GLM procedure; however, unlike PROC GLM, you do not specify random effects in the MODEL statement. The MODEL statement is required.

An intercept is included in the fixed-effects model by default. If no fixed effects are specified, only this intercept term is fit. The intercept can be removed by using the NOINT option.

You can specify the following options in the MODEL statement after a slash (/).

ALPHA=number
requests that a \( t \)-type confidence interval be constructed for each of the fixed-effects parameters with confidence level \( 1 - \text{number} \). The value of \text{number} must be between 0 and 1; the default is 0.05.

ALPHAP=number
requests that a \( t \)-type confidence interval be constructed for the predicted values with confidence level \( 1 - \text{number} \). The value of \text{number} must be between 0 and 1; the default is 0.05.

CHISQ
requests that \( \chi^2 \)-tests be performed for all specified effects in addition to the \( F \)-tests. Type III tests are the default; you can produce the Type I and Type II tests using the HTYPE= option.

CL
requests that \( t \)-type confidence limits be constructed for each of the fixed-effects parameter estimates. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.

CONTAIN
has the same effect as the DDFM=CONTAIN option.

CORRB
produces the approximate correlation matrix of the fixed-effects parameter estimates. For ODS purposes, the label for this table is “CorrB.”

COVB
produces the approximate variance-covariance matrix of the fixed-effects parameter estimates \( \hat{\beta} \). By default, this matrix equals \( (X' \hat{V}^{-1} X)^{-1} \) and results from sweeping \( (X \ y)' \hat{V}^{-1} (X \ y) \) on all but its last pivot and removing the \( y \) border. The EMPIRICAL option in the PROC MIXED statement changes this matrix into “empirical sandwich” form, as described on page 2676. For ODS purposes, the label for this table is “CovB.”
produces the inverse of the approximate variance-covariance matrix of the fixed-effects parameter estimates. For ODS purposes, the label for this table is “InvCovB.”

enables you to specify your own denominator degrees of freedom for the fixed effects. The value-list specification is a list of numbers or missing values (.) separated by commas. The degrees of freedom should be listed in the order in which the effects appear in the “Tests of Fixed Effects” table. If you want to retain the default degrees of freedom for a particular effect, use a missing value for its location in the list. For example,

```latex
model Y = A B A*B / ddf=3,.,4.7;
```

assigns 3 denominator degrees of freedom to A and 4.7 to A*B, while those for B remain the same. If you specify DDFM=SATTERTH or DDFM=KENWARDROGER the DDF= option has no effect.

specifies the method for computing the denominator degrees of freedom for the tests of fixed effects resulting from the MODEL, CONTRAST, ESTIMATE, and LSMEANS statements.

The DDFM=CONTAIN option invokes the containment method to compute denominator degrees of freedom, and it is the default when you specify a RANDOM statement. The containment method is carried out as follows: Denote the fixed effect in question A, and search the RANDOM effect list for the effects that syntactically contain A. For example, the RANDOM effect B(A) contains A, but the RANDOM effect C does not, even if it has the same levels as B(A).

Among the RANDOM effects that contain A, compute their rank contribution to the (X Z) matrix. The DDF assigned to A is the smallest of these rank contributions. If no effects are found, the DDF for A is set equal to the residual degrees of freedom, \( N - \text{rank}(X Z) \). This choice of DDF matches the tests performed for balanced split-plot designs and should be adequate for moderately unbalanced designs.

Caution: If you have a Z matrix with a large number of columns, the overall memory requirements and the computing time after convergence can be substantial for the containment method. If it is too large, you may want to use the DDFM=BETWITHIN option.

The DDFM=BETWITHIN option is the default for REPEATED statement specifications (with no RANDOM statements). It is computed by dividing the residual degrees of freedom into between-subject and within-subject portions. PROC MIXED then checks whether a fixed effect changes within any subject. If so, it assigns within-subject degrees of freedom to the effect; otherwise, it assigns the between-subject
degrees of freedom to the effect (refer to Schluchter and Elashoff 1990). If there are multiple within-subject effects containing classification variables, the within-subject degrees of freedom is partitioned into components corresponding to the subject-by-effect interactions.

One exception to the preceding method is the case when you have specified no RANDOM statements and a REPEATED statement with the TYPE=UN option. In this case, all effects are assigned the between-subject degrees of freedom to provide for better small-sample approximations to the relevant sampling distributions. DDFM=KENWARDROGER may be a better option to try for this case.

The DDFM=RESIDUAL option performs all tests using the residual degrees of freedom, \( n - \text{rank}(X) \), where \( n \) is the number of observations.

The DDFM=SATTERTH option performs a general Satterthwaite approximation for the denominator degrees of freedom, computed as follows. Suppose \( \theta \) is the vector of unknown parameters in \( V \) and suppose \( C = (X'V^{-1}X)^{-} \), where \( - \) denotes a generalized inverse. Let \( \hat{C} \) and \( \hat{\theta} \) be the corresponding estimates.

Consider the one-dimensional case, and consider \( \ell \) to be a vector defining an estimable linear combination of \( \beta \). The Satterthwaite degrees of freedom for the \( t \)-statistic

\[
t = \frac{\ell \hat{\beta}}{\sqrt{\ell C \ell'}}
\]

is computed as

\[
\nu = \frac{2(\ell \hat{C} \ell')^2}{g'Ag}
\]

where \( g \) is the gradient of \( \ell C \ell' \) with respect to \( \theta \), evaluated at \( \hat{\theta} \), and \( A \) is the asymptotic variance-covariance matrix of \( \hat{\theta} \) obtained from the second derivative matrix of the likelihood equations.

For the multi-dimensional case, let \( L \) be an estimable contrast matrix of rank \( q > 1 \). The Satterthwaite denominator degrees of freedom for the \( F \)-statistic

\[
F = \frac{\hat{\beta}'L'(L \hat{C} L')^{-1}L\hat{\beta}}{q}
\]

is computed by first performing the spectral decomposition \( L \hat{C} L' = P'DP \) where \( P \) is an orthogonal matrix of eigenvectors and \( D \) is a diagonal matrix of eigenvalues, both of dimension \( q \times q \). Define \( \ell_m \) to be the \( m \)th row of \( PL \), and let

\[
\nu_m = \frac{2(D_m)^2}{g'_mAg_m}
\]

where \( D_m \) is the \( m \)th diagonal element of \( D \) and \( g_m \) is the gradient of \( \ell_m C \ell'_m \) with respect to \( \theta \), evaluated at \( \hat{\theta} \). Then let

\[
E = \sum_{m=1}^{q} \frac{\nu_m}{\nu_m - 2}I(\nu_m > 2)
\]
where the indicator function eliminates terms for which \( \nu_m \leq 2 \). The degrees of freedom for \( F \) are then computed as

\[
\nu = \frac{2E}{E - q}
\]

provided \( E > q \); otherwise \( \nu \) is set to zero.

This method is a generalization of the techniques described in Giesbrecht and Burns (1985), McLean and Sanders (1988), and Fai and Cornelius (1996). The method can also include estimated random effects. In this case, append \( \hat{\gamma} \) to \( \hat{\beta} \) and change \( \hat{C} \) to be the inverse of the coefficient matrix in the mixed model equations. The calculations require extra memory to hold \( c \) matrices that are the size of the mixed model equations, where \( c \) is the number of covariance parameters. In the notation of Table 46.12 on page 2773, this is approximately \( 8q(p+g)(p+g)/2 \) bytes. Extra computing time is also required to process these matrices. The Satterthwaite method implemented here is intended to produce an accurate \( F \)-approximation; however, the results may differ from those produced by PROC GLM. Also, the small sample properties of this approximation have not been extensively investigated for the various models available with PROC MIXED.

The DDFM=KENWARDROGER option performs the degrees-of-freedom calculations detailed by Kenward and Roger (1997). This approximation involves inflating the estimated variance-covariance matrix of the fixed and random effects by the method proposed by Prasad and Rao (1990) and Harville and Jeske (1992); refer also to Kackar and Harville (1984). Satterthwaite-type degrees of freedom are then computed based on this adjustment. By default, the observed information matrix of the covariance parameter estimates is used in the calculations.

When the asymptotic variance matrix of the covariance parameters is found to be singular, a generalized inverse is used. Covariance parameters with zero variance then do not contribute to the degrees-of-freedom adjustment for DDFM=SATTERTH and DDFM=KENWARDROGER, and a message is written to the LOG.

This method changes output in the following tables (listed in Table 46.8 on page 2752): Contrast, CorrB, CovB, Diffs, Estimates, InvCovB, LSMeans, MMEq, MMEqSol, Slices, SolutionF, SolutionR, Tests1–Tests3. The OUTP= and OUTPM= data sets are also affected.

\( E \)

requests that Type I, Type II, and Type III \( L \) matrix coefficients be displayed for all specified effects. For ODS purposes, the labels of the tables are “Coef.”

\( E1 \)

requests that Type I \( L \) matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coef.”

\( E2 \)

requests that Type II \( L \) matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coef.”
E3 requests that Type III $L$ matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coeff.”

FULLX requests that columns of the $X$ matrix that consist entirely of zeros not be eliminated from $X$; otherwise, they are eliminated by default. For a column corresponding to a missing cell to be added to $X$, its particular levels must be present in at least one observation in the analysis data set along with a missing dependent variable. The use of the FULLX option can impact coefficient specifications in the CONTRAST and ESTIMATE statements, as well as covariate coefficients from LSMEANS statements specified with the AT MEANS option.

HTYPE=value-list indicates the type of hypothesis test to perform on the fixed effects. Valid entries for value are 1, 2, and 3; the default value is 3. You can specify several types by separating the values with a comma or a space. The ODS table names are “Tests1” for the Type 1 tests, “Tests2” for the Type 2 tests, and “Tests3” for Type 3 tests.

INFLUENCE<(<EFFECT=effect> <ESTIMATES|EST> <ITER=number> <KEEP=number> <SELECT=value-list> <SIZE=number>)>

specifies that influence and case deletion diagnostics are to be computed.

The INFLUENCE option of the MODEL statement in the MIXED procedure computes influence diagnostics by noniterative or iterative methods. The noniterative diagnostics rely on recomputation formulas under the assumption that covariance parameters or their ratios remain fixed. With the possible exception of a profiled residual variance, no covariance parameters are updated. This is the default behavior because of its computational efficiency. However, the impact of an observation on the overall analysis can be underestimated if its effect on covariance parameters is not assessed. Toward this end, iterative methods can be applied to gauge the overall impact of observations and to obtain influence diagnostics for the covariance parameter estimates.

If you specify the INFLUENCE option without further suboptions, PROC MIXED computes single-case deletion diagnostics and influence statistics for each observation in the data set by updating estimates for the fixed effects parameter estimates, and also the residual variance, if it is profiled. The EFFECT=, SELECT=, ITER=, SIZE=, and KEEP= suboptions provide additional flexibility in the computation and reporting of influence statistics.
The modifiers and their default values are discussed in the following paragraphs. The set of computed influence diagnostics varies with the suboptions. The most extensive set of influence diagnostics is obtained when `ITER=n` with `n > 0`.

You can produce statistical graphics of influence diagnostics when the experimental ODS GRAPHICS statement is specified. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.

`EFFECT=effect` specifies an effect according to which observations are grouped. Observations sharing the same level of the `effect` are removed from the analysis as a group. The `effect` must contain only class variables, but need not be contained in the model.

Removing observations can change the rank of the $(X'V^{-1}X)^{-1}$ matrix. This is particularly likely to happen when multiple observations are eliminated from the analysis. If the rank of the estimated variance-covariance matrix of $\hat{\beta}$ changes or its singularity pattern is altered, no influence diagnostics are computed.

`ESTIMATES` specifies that the updated parameter estimates should be written to the ODS output data set. The values are not displayed in the “Influence” table, but if you use ODS OUTPUT to create a data set from the listing, the estimates are added to the data set. If `ITER=0`, only the fixed effects estimates are saved. In iterative influence
analyses, fixed effects and covariance parameters are stored. The $p$ fixed effects parameter estimates are named Parm1–Parm$p$, and the $q$ covariance parameter estimates are named CovP1–CovP$q$. The order corresponds to that in the “Solution for Fixed Effects” and “Covariance Parameter Estimates” tables. If parameter updates fail, for example, because of a loss of rank or a nonpositive definite Hessian, missing values are reported.

ITER=$n$ controls the maximum number of additional iterations PROC MIXED performs to update the fixed effects and covariance parameter estimates following data point removal. If you specify $n > 0$, then statistics such as DFFITS, MDFFITS, and the likelihood distances measure the impact of observation(s) on all aspects of the analysis. Typically, the influence will grow compared to values at ITER=0. In models without RANDOM or REPEATED effects, the ITER= option has no effect.

This documentation refers to analyses when $n > 0$ simply as iterative influence analysis, even if final covariance parameter estimates can be updated in a single step (for example, when METHOD=MIVQUE0 or METHOD=TYPE3). This nomenclature reflects the fact that only if $n > 0$ will all model parameters be updated, which may require additional iterations. If $n > 0$ and METHOD=REML (default) or METHOD=ML, the procedure updates fixed effects and variance-covariance parameters after removing the selected observations with additional Newton-Raphson iterations, starting from the converged estimates for the entire data. The process stops for each observation or set of observations if the convergence criterion is satisfied or the number of further iterations exceeds $n$. If $n > 0$ and METHOD=TYPE1, TYPE2, or TYPE3, ANOVA estimates of the covariance parameters are recomputed in a single step.

Compared to noniterative updates the computations are more involved. In particular for large data sets and/or a large number of random effects, iterative updates require considerably more resources. A one-step (ITER=1) or two-step update may be a good compromise. The output includes the number of iterations performed, which is less than $n$ if the iteration converges. If the process does not converge in $n$ iterations, you should be careful in interpreting the results, especially if $n$ is fairly large.

Bounds and other restrictions on the covariance parameters carry over from the full-data model. Covariance parameters that are not iterated in the model fit to the full data (the NOITER or HOLD option of the PARMS statement) are likewise not updated in the refit. In certain models, for example, random effects models, the ratios between the covariance parameters and the residual variance are maintained rather than the actual value of the covariance parameter estimate (see the section “Influence Diagnostics” on page 2765
KEEP= determines how many observations are retained for display and in
the output data set or how many tuples if you specify SIZE=. The
output is sorted by an influence statistic as discussed for the SIZE=
suboption.

SELECT = value-list specifies which observations or effect levels are chosen for in-
flluence calculations. If SELECT= is not specified, diagnostics are
computed for all possible subsets, that is

- all observations, if EFFECT= or SIZE= are not given
- all levels of the specified effect, if EFFECT= is specified
- all tuples of size \( k \) formed from the observations in value-list,
  if SIZE=\( k \) is specified

When you specify an effect with the EFFECT= option, the values in value-list represent indices of the levels in the order in which PROC MIXED builds classification effects. Which observations in the data set correspond to this index depends on the order of the variables in the CLASS statement, not the order in which the variables appear in the interaction effect. See the section “Parameterization of Mixed Models” on page 2743 on precisely how the procedure indexes nested and crossed effects and how lev-
els of classification variables are ordered. The actual values of the
classification variables involved in the effect are shown on the out-
put so you can determine which observations were removed.

If the EFFECT= suboption is not specified, the SELECT= value
list refers to the sequence in which observations are read from the
input data set or from the current BY group if there is a BY state-
ment. This indexing is not necessarily the same as the observation
numbers in the input data set, for example, if a WHERE clause is
specified or during BY processing.

SIZE= \( n \) instructs PROC MIXED to remove groups of observations formed
as tuples of size \( n \). For example, SIZE=2 specifies all \( n \times (n-1)/2 \)
unique pairs of observations. The number of tuples for SIZE=\( k \) is
\( n!/(k!(n-k)!) \) and grows quickly with \( n \) and \( k \). Using the SIZE=
option can result in considerable computing time. The MIXED
procedure displays by default only the 50 tuples with the greatest
influence. Use the KEEP= option to override this default and to re-
tain a different number of tuples in the listing or ODS output data
set. Regardless of the KEEP= specification, all tuples are eval-
uated and the results are ordered according to an influence statistic.
This statistic is the (restricted) likelihood distance as a measure of
overall influence if ITER = \( n > 0 \) or when a residual variance is
profiled. When likelihood distances are unavailable, the results are
ordered by the PRESS statistic.

To reduce computational burden, the SIZE= option can be com-
bined with the SELECT=value-list modifier. For example,
proc mixed data=aerosol;
  class aerosol manufacturer filter;
  model penetration = aerosol manufacturer / influence(size=2 keep=5
                     select=13,14,18,30,31,33);
  random filter(manuf);
run;

evaluates all 15 = 6 × 5/2 pairs formed from observations 13, 14, 18, 30, 31, and 33 and displays the five pairs with the greatest influence. If any observation in a tuple contains missing values or has otherwise not contributed to the analysis, the tuple is not evaluated. This guarantees that the displayed results refer to the same number of observations, so that meaningful statistics are available by which to order the results. If computations fail for a particular tuple, for example, because the \(X'V^{-1}X\) matrix changes rank or the \(G\) matrix is not positive definite, no results are produced. Results are retained when the maximum number of iterative updates is exceeded in iterative influence analyses.

The \texttt{SIZE=} suboption cannot be combined with the \texttt{EFFECT=} suboption.

As in the case of the \texttt{EFFECT=} suboption, the statistics being computed are those appropriate for removal of multiple data points, even if \texttt{SIZE=} = 1.

For ODS purposes the label of the “Influence Diagnostics” table is “Influence.” The variables in this table depend on whether you specify the \texttt{EFFECT=} , \texttt{SIZE=} , or \texttt{KEEP=} suboption and whether covariance parameters are iteratively updated. When \texttt{ITER=} = 0 (the default) certain influence diagnostics are only meaningful if the residual variance is profiled. \textit{Table 46.3} and \textit{Table 46.4} summarize the statistics obtained depending on the model and modifiers. The last column in these tables gives the variable name in the ODS OUTPUT INFLUENCE= data set. Restricted likelihood distances are reported instead of the likelihood distance unless METHOD=ML. See the “Influence Diagnostics” section beginning on page 2765 for details on the individual statistics.

**INTERCEPT**

adds a row to the tables for Type 1, 2, and 3 tests corresponding to the overall intercept.

**LCOMPONENTS**

requests an estimate for each row of the L matrix used to form tests of fixed effects. Components corresponding to Type 3 tests are the default; you can produce the Type 1 and Type 2 component estimates with the HTYPE= option.

Tests of fixed effects involve testing of linear hypotheses of the form $\mathbf{L}\beta = 0$. The matrix $\mathbf{L}$ is constructed from Type 1, 2, or 3 estimable functions. By default the MIXED procedure constructs Type 3 tests. In many situations, the individual rows of the matrix $\mathbf{L}$ represent contrasts of interest. For example, in a one-way classification model, the Type 3 estimable functions define differences of factor level means. In a balanced two-way layout, the rows of $\mathbf{L}$ correspond to differences of cell means.

For example, if factors A and B have a and b levels, respectively, the statements

```plaintext
   class A B;
   model y = A B x / htype=1,3 lcomponents;
```

produce $(a - 1)$ one degree of freedom tests for the rows of $\mathbf{L}$ associated with the Type 1 and Type 3 estimable functions for factor A, $(b - 1)$ tests for the rows of $\mathbf{L}$ associated with factor B, and a single test for the Type 1 and Type 3 coefficients associated with regressor $X$.

The denominator degrees of freedom associated with a row of $\mathbf{L}$ are the same as those in the corresponding “Tests of Fixed Effects” table, except for DDFM=KENWARDROGER and DDFM=SATTERTH. For these degree of freedom methods, the denominator degrees of freedom are computed separately for each row of $\mathbf{L}$.

For ODS purposes, the name of the table containing all requested component tests is “LComponents.” See Example 46.9 on page 2839 for examples incorporating the LCOMPONENTS option.
NOCONTAIN
has the same effect as the DDFM=RESIDUAL option.

NOINT
requests that no intercept be included in the model. An intercept is included by default.

NOTEST
specifies that no hypothesis tests be performed for the fixed effects.

OUTP=SAS-data-set
OUTPRED=SAS-data-set
specifies an output data set containing predicted values and related quantities. This option replaces the P option from Version 6.

Predicted values are formed by using the rows from \((X Z)\) as \(L\) matrices. Thus, predicted values from the original data are \(X\hat{β} + Z\hat{γ}\). Their approximate standard errors of prediction are formed from the quadratic form of \(L\) with \(C\) defined in the “Statistical Properties” section on page 2740. The L95 and U95 variables provide a \(t\)-type confidence interval for the predicted values, and they correspond to the L95M and U95M variables from the GLM and REG procedures for fixed-effect models. The residuals are the observed minus the predicted values. Predicted values for data points other than those observed can be obtained by using missing dependent variables in your input data set.

Specifications that have a REPEATED statement with the SUBJECT= option and missing dependent variables compute predicted values using empirical best linear unbiased prediction (EBLUP). Using hats (\(^\hat{\cdot}\)) to denote estimates, the EBLUP formula is

\[
\hat{m} = X_m\hat{β} + \hat{C}_m\hat{V}^{-1}(y - X\hat{β})
\]

where \(\hat{m}\) represents a hypothetical realization of a missing data vector with associated design matrix \(X_m\). The matrix \(C_m\) is the model-based covariance matrix between \(\hat{m}\) and the observed data \(y\), and other notation is as presented in the “Mixed Models Theory” section beginning on page 2731.

The estimated prediction variance is as follows:

\[
\hat{V}ar(\hat{m} - m) = \hat{V}_m - \hat{C}_m\hat{V}^{-1}\hat{C}_m^T + [X_m - \hat{C}_m\hat{V}^{-1}X](X^T\hat{V}^{-1}X)^{-1}[X_m - \hat{C}_m\hat{V}^{-1}X]^T
\]

where \(V_m\) is the model-based variance matrix of \(m\). For further details, refer to Henderson (1984) and Harville (1990). This feature can be useful for forecasting time series or for computing spatial predictions.

By default, all variables from the input data set are included in the OUTP= data set. You can select a subset of these variables using the ID statement.
**OUTPM=** SAS-data-set
**OUTPREDM=** SAS-data-set

specifies an output data set containing predicted means and related quantities. This option replaces the PM option from Version 6.

The output data set is of the same form as that resulting from the OUTP= option, except that the predicted values do not incorporate the EBLUP values $\hat{\gamma}$. They also do not use the EBLUPs for specifications that have a REPEATED statement with the SUBJECT= option and missing dependent variables. The predicted values are formed as $X\hat{\beta}$ in the OUTPM= data set, and standard errors are quadratic forms in the approximate variance-covariance matrix of $\hat{\beta}$ as displayed by the COVB option.

By default, all variables from the input data set are included in the OUTPM= data set. You can select a subset of these variables using the ID statement.

**RESIDUAL**

requests that Pearson-type and (internally) studentized residuals be added to the OUTP= and OUTPM= data sets. Studentized residuals are raw residuals standardized by their estimated standard error. When residuals are internally studentized, the data point in question has contributed to the estimation of the covariance parameter estimates on which the standard error of the residual is based. Externally studentized residuals can be computed with the INFLUENCE option. Pearson-type residuals scale the residual by the standard deviation of the response.

The RESIDUAL option adds the variables PearsonResid and StudentResid to the OUTP= and OUTPM= data sets. In the former case, the standardization draws on the variance of the conditional distribution (given the random effects). The standardization of residuals in the OUTPM= data set draws on the variance of the marginal distribution of the response.

The option has no effect unless the OUTP= or OUTPM= option are specified or you request statistical graphics with the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757. For computational details about studentized and Pearson residuals in MIXED, see the “Residual Diagnostics” section beginning on page 2763.

**SINGULAR=** number

tunes the sensitivity in sweeping. If a diagonal pivot element is less than $D \times \text{number}$ as PROC MIXED sweeps a matrix, the associated column is declared to be linearly dependent upon previous columns, and the associated parameter is set to 0. The value $D$ is the original diagonal element of the matrix. The default is 1E4 times the machine epsilon; this product is approximately 1E\text{-12} on most computers.

**SINGCHOL=** number

tunes the sensitivity in computing Cholesky roots. If a diagonal pivot element is less than $D \times \text{number}$ as PROC MIXED performs the Cholesky decomposition on a matrix, the associated column is declared to be linearly dependent upon previous columns and is set to 0. The value $D$ is the original diagonal element of the matrix. The default
for number is 1E4 times the machine epsilon; this product is approximately 1E\(-12\) on most computers.

**SINGRES=number**

sets the tolerance for which the residual variance is considered to be zero. The default is 1E4 times the machine epsilon; this product is approximately 1E\(-12\) on most computers.

**SOLUTION**

requests that a solution for the fixed-effects parameters be produced. Using notation from the “Mixed Models Theory” section beginning on page 2731, the fixed-effects parameter estimates are \(\hat{b}\) and their approximate standard errors are the square roots of the diagonal elements of \((X'\hat{\Omega}^{-1}X)^{-1}\). You can output this approximate variance matrix with the COVB option or modify it with the EMPIRICAL option in the PROC MIXED statement.

Along with the estimates and their approximate standard errors, a \(t\)-statistic is computed as the estimate divided by its standard error. The degrees of freedom for this \(t\)-statistic matches the one appearing in the “Tests of Fixed Effects” table under the effect containing the parameter. The “Pr > |t|” column contains the two-tailed \(p\)-value corresponding to the \(t\)-statistic and associated degrees of freedom. You can use the CL option to request confidence intervals for all of the parameters; they are constructed around the estimate by using a radius of the standard error times a percentage point from the \(t\)-distribution.

**VCIRY**

requests that responses and marginal residuals be scaled by the inverse Cholesky root of the marginal variance-covariance matrix. The variables ScaledDep and ScaledResid are added to the OUTPM= data set. These quantities can be important in bootstrapping of data or residuals. Examination of the scaled residuals is also helpful in diagnosing departures from normality. Notice that the results of this scaling operation can depend on the order in which the MIXED procedure processes the data.

The VCIRY option has no effect unless you also use the OUTPM= option or you request statistical graphics with the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.

**XPVIX**

is an alias for the COVBI option.

**XPVIXI**

is an alias for the COVB option.

**ZETA=number**

 tunes the sensitivity in forming Type III functions. Any element in the estimable function basis with an absolute value less than number is set to 0. The default is 1E\(-8\).
PARMS Statement

PARMS (value-list) . . . < / options > ;

The PARMS statement specifies initial values for the covariance parameters, or it requests a grid search over several values of these parameters. You must specify the values in the order in which they appear in the “Covariance Parameter Estimates” table.

The value-list specification can take any of several forms:

- \( m \) a single value
- \( m_1, m_2, \ldots, m_n \) several values
- \( m \) to \( n \) a sequence where \( m \) equals the starting value, \( n \) equals the ending value, and the increment equals 1
- \( m \) to \( n \) by \( i \) a sequence where \( m \) equals the starting value, \( n \) equals the ending value, and the increment equals \( i \)
- \( m_1, m_2 \) to \( m_3 \) mixed values and sequences

You can use the PARMS statement to input known parameters. Referring to the split-plot example (Example 46.1 on page 2777), suppose the three variance components are known to be 60, 20, and 6. The SAS statements to fix the variance components at these values is as follows:

```sas
proc mixed data=sp noprofile;
  class Block A B;
  model Y = A B A*B;
  random Block A*Block;
  parms (60) (20) (6) / noiter;
run;
```

The NOPROFILE option requests PROC MIXED to refrain from profiling the residual variance parameter during its calculations, thereby enabling its value to be held at 6 as specified in the PARMS statement. The NOITER option prevents any Newton-Raphson iterations so that the subsequent results are based on the given variance components. You can also specify known parameters of \( G \) using the GDATA= option in the RANDOM statement.

If you specify more than one set of initial values, PROC MIXED performs a grid search of the likelihood surface and uses the best point on the grid for subsequent analysis. Specifying a large number of grid points can result in long computing times. The grid search feature is also useful for exploring the likelihood surface. See Example 46.3 on page 2795.

The results from the PARMS statement are the values of the parameters on the specified grid (denoted by CovP1–CovPn), the residual variance (possibly estimated) for models with a residual variance parameter, and various functions of the likelihood.

For ODS purposes, the label of the “Parameter Search” table is “ParmSearch.”
You can specify the following options in the PARMS statement after a slash (/).

- **HOLD=value-list**
  specifies which parameter values PROC MIXED should hold to equal the specified values. For example, the statement

  ```
  parms (5) (3) (2) (3) / hold=1,3;
  ```

  constrains the first and third covariance parameters to equal 5 and 2, respectively.

- **LOGDETH**
  evaluates the log determinant of the Hessian matrix for each point specified in the PARMS statement. A Log Det H column is added to the “Parameter Search” table.

- **LOWERB=value-list**
  enables you to specify lower boundary constraints on the covariance parameters. The value-list specification is a list of numbers or missing values (.) separated by commas. You must list the numbers in the order that PROC MIXED uses for the covariance parameters, and each number corresponds to the lower boundary constraint. A missing value instructs PROC MIXED to use its default constraint, and if you do not specify numbers for all of the covariance parameters, PROC MIXED assumes the remaining ones are missing.

  An example for which this option is useful is when you want to constrain the G matrix to be positive definite in order to avoid the more computationally intensive algorithms required when G becomes singular. The corresponding code for a random coefficients model is as follows:

  ```
  proc mixed;
    class person;
    model y = time;
    random int time / type=fa0(2) sub=person;
    parms / lowerb=1e-4,.,1e-4;
  run;
  ```

  Here the FA0(2) structure is used in order to specify a Cholesky root parameterization for the 2 x 2 unstructured blocks in G. This parameterization ensures that the G matrix is nonnegative definite, and the PARMS statement then ensures that it is positive definite by constraining the two diagonal terms to be greater than or equal to 1E−4.

- **NOBOUND**
  requests the removal of boundary constraints on covariance parameters. For example, variance components have a default lower boundary constraint of 0, and the NOBOUND option allows their estimates to be negative.
NOITER
requests that no Newton-Raphson iterations be performed and that PROC MIXED use the best value from the grid search to perform inferences. By default, iterations begin at the best value from the PARMS grid search.

NOPROFILE
specifies a different computational method for the residual variance during the grid search. By default, PROC MIXED estimates this parameter using the profile likelihood when appropriate. This estimate is displayed in the Variance column of the “Parameter Search” table. The NOPROFILE option suppresses the profiling and uses the actual value of the specified variance in the likelihood calculations.

OLS
requests starting values corresponding to the usual general linear model. Specifically, all variances and covariances are set to zero except for the residual variance, which is set equal to its ordinary least-squares (OLS) estimate. This option is useful when the default MIVQUE0 procedure produces poor starting values for the optimization process.

PARMSDATA=SAS-data-set
PDATA=SAS-data-set
reads in covariance parameter values from a SAS data set. The data set should contain the EST or COVP1–COVPN variables.

RATIOS
indicates that ratios with the residual variance are specified instead of the covariance parameters themselves. The default is to use the individual covariance parameters.

UPPERB=value-list
enables you to specify upper boundary constraints on the covariance parameters. The value-list specification is a list of numbers or missing values (.) separated by commas. You must list the numbers in the order that PROC MIXED uses for the covariance parameters, and each number corresponds to the upper boundary constraint. A missing value instructs PROC MIXED to use its default constraint, and if you do not specify numbers for all of the covariance parameters, PROC MIXED assumes that the remaining ones are missing.

PRIOR Statement

PRIOR < distribution > / options ;

The PRIOR statement enables you to carry out a sampling-based Bayesian analysis in PROC MIXED. It currently operates only with variance component models. The analysis produces a SAS data set containing a pseudo-random sample from the joint posterior density of the variance components and other parameters in the mixed model.

The posterior analysis is performed after all other PROC MIXED computations. It begins with the “Posterior Sampling Information” table, which provides basic information about the posterior sampling analysis, including the prior densities, sampling
algorithm, sample size, and random number seed. For ODS purposes, the name of this table is “Posterior.”

By default, PROC MIXED uses an independence chain algorithm in order to generate the posterior sample (Tierney 1994). This algorithm works by generating a pseudo-random proposal from a convenient base distribution, chosen to be as close as possible to the posterior. The proposal is then retained in the sample with probability proportional to the ratio of weights constructed by taking the ratio of the true posterior to the base density. If a proposal is not accepted, then a duplicate of the previous observation is added to the chain.

In selecting the base distribution, PROC MIXED makes use of the fact that the fixed-effects parameters can be analytically integrated out of the joint posterior, leaving the marginal posterior density of the variance components. In order to better approximate the marginal posterior density of the variance components, PROC MIXED transforms them using the MIVQUE(0) equations. You can display the selected transformation with the PTRANS option or specify your own with the TDATA= option. The density of the transformed parameters is then approximated by a product of inverted gamma densities (refer to Gelfand et al. 1990).

To determine the parameters for the inverted gamma densities, PROC MIXED evaluates the logarithm of the posterior density over a grid of points in each of the transformed parameters, and you can display the results of this search with the PSEARCH option. PROC MIXED then performs a linear regression of these values on the logarithm of the inverted gamma density. The resulting base densities are displayed in the “Base Densities” table; for ODS purposes, the name of this table is “BaseDen.” You can input different base densities with the BDATA= option.

At the end of the sampling, the “Acceptance Rates” table displays the acceptance rate computed as the number of accepted samples divided by the total number of samples generated. For ODS purposes, the label of the “Acceptance Rates” table is “AcceptanceRates.”

The OUT= option specifies the output data set containing the posterior sample. PROC MIXED automatically includes all variance component parameters in this data set (labeled COVP1–COVPN), the Type III $F$-statistics constructed as in Ghosh (1992) discussing Schervish (1992) (labeled T3F1), the log values of the posterior (labeled LOGF), the log of the base sampling density (labeled LOGG), and the log of their ratio (labeled LOGRATIO). If you specify the SOLUTION option in the MODEL statement, the data set also contains a random sample from the posterior density of the fixed-effects parameters (labeled BETAN), and if you specify the SOLUTION option in the RANDOM statement, the table contains a random sample from the posterior density of the random-effects parameters (labeled GAMN). PROC MIXED also generates additional variables corresponding to any CONTRAST, ESTIMATE, or LSMEANS statement that you specify.

Subsequently, you can use SAS/INSIGHT, or the UNIVARIATE, CAPABILITY, or KDE procedures to analyze the posterior sample.

The prior density of the variance components is, by default, a noninformative version of Jeffreys’ prior (Box and Tiao 1973). You can also specify informative pri-
ors with the DATA= option or a flat (equal to 1) prior for the variance components. The prior density of the fixed-effects parameters is assumed to be flat (equal to 1), and the resulting posterior is conditionally multivariate normal (conditioning on the variance component parameters) with mean \((X'V^{-1}X)^{-1}X'V^{-1}y\) and variance \((X'V^{-1}X)^{-1}\).

The distribution argument in the PRIOR statement determines the prior density for the variance component parameters of your mixed model. Valid values are as follows.

**DATA=**

enables you to input the prior densities of the variance components used by the sampling algorithm. This data set must contain the TYPE and PARM1–PARM\(n\) variables, where \(n\) is the largest number of parameters among each of the base densities. The format of the DATA= data set matches that created by PROC MIXED in the “Base Densities” table, so you can output the densities from one run and use them as input for a subsequent run.

**JEFFREYS**

specifies a noninformative reference version of Jeffreys’ prior constructed using the square root of the determinant of the expected information matrix as in (1.3.92) of Box and Tiao (1973). This is the default prior.

**FLAT**

specifies a prior density equal to 1 everywhere, making the likelihood function the posterior.

You can specify the following options in the PRIOR statement after a slash (/).

**ALG=IC | INDCHAIN**

**ALG=IS | IMPSAMP**

**ALG=RS | REJSAMP**

**ALG=RWC | RWCHAIN**

specifies the algorithm used for generating the posterior sample. The ALG=IC option requests an independence chain algorithm, and it is the default. The option ALG=IS requests importance sampling, ALG=RS requests rejection sampling, and ALG=RWC requests a random walk chain. For more information on these techniques, refer to Ripley (1987), Smith and Gelfand (1992), and Tierney (1994).

**BDATA=**

enables you to input the base densities used by the sampling algorithm. This data set must contain the TYPE and PARM1–PARM\(n\) variables, where \(n\) is the largest number of parameters among each of the base densities. The format of the BDATA= data set matches that created by PROC MIXED in the “Base Densities” table, so you can output the densities from one run and use them as input for a subsequent run.

**GRID=(value-list)**

specifies a grid of values over which to evaluate the posterior density. The value-list syntax is the same as in the PARMS statement (see page 2706), and you must specify an output data set name with the OUTG= option.
GRIDT=(value-list)
specifies a transformed grid of values over which to evaluate the posterior density. The value-list syntax is the same as in the PARMS statement (see page 2706), and you must specify an output data set name with the OUTGT= option.

IFACTOR=number
is an alias for the SFACTOR= option.

LOGNOTE=number
instructs PROC MIXED to write a note to the SAS log after it generates the sample corresponding to each multiple of number. This is useful for monitoring the progress of CPU-intensive runs.

LOGRBOUND=number
specifies the bounding constant for rejection sampling. The value of number equals the maximum of \( \log(f/g) \) over the variance component parameter space, where \( f \) is the posterior density and \( g \) is the product inverted gamma densities used to perform rejection sampling.

When performing the rejection sampling, you may encounter the message

\[
\text{WARNING: The log ratio bound of LL was violated at sample XX.}
\]

When this occurs, PROC MIXED reruns an optimization algorithm to determine a new log upper bound and then restarts the rejection sampling. The resulting OUT= data set contains all observations that have been generated; therefore, assuming that you have requested N samples, you should retain only the final N observations in this data set for analysis purposes.

NSAMPLE=number
specifies the number of posterior samples to generate. The default is 1000, but more accurate results are obtained with larger samples such as 10000.

NSEARCH=number
specifies the number of posterior evaluations PROC MIXED makes for each transformed parameter in determining the parameters for the inverted gamma densities. The default is 20.

OUT=SAS-data-set
creates an output data set containing the sample from the posterior density.

OUTG=SAS-data-set
creates an output data set from the grid evaluations specified in the GRID= option.

OUTGT=SAS-data-set
creates an output data set from the transformed grid evaluations specified in the GRIDT= option.

PSEARCH
displays the search used to determine the parameters for the inverted gamma densities. For ODS purposes, the name of the table is “Search.”
PTTRANS displays the transformation of the variance components. For ODS purposes, the name of the table is “Trans.”

SEED=number specifies an integer used to start the pseudo-random number generator for the simulation. If you do not specify a seed, or specify a value less than or equal to zero, the seed is by default generated from reading the time of day from the computer clock. You should use a positive seed (less than $2^{31} - 1$) whenever you want to duplicate the sample in another run of PROC MIXED.

SFACTOR=number enables you to adjust the range over which PROC MIXED searches the transformed parameters in order to determine the parameters for the inverted gamma densities. PROC MIXED determines the range by first transforming the estimates from the standard PROC MIXED analysis (REML, ML, or MIVQUE0, depending upon which estimation method you select). It then multiplies and divides the transformed estimates by $2 \times number$ to obtain upper and lower bounds, respectively. Transformed values that produce negative variance components in the original scale are not included in the search. The default value is 1; number must be greater than 0.5.

TDATA= enables you to input the transformation of the covariance parameters used by the sampling algorithm. This data set should contain the CovP1–CovPn variables. The format of the TDATA= data set matches that created by PROC MIXED in the “Trans” table, so you can output the transformation from one run and use it as input for a subsequent run.

TRANS=EXPECTED
TRANS=MIVQUE0
TRANS=OBSERVED specifies the particular algorithm used to determine the transformation of the covariance parameters. The default is MIVQUE0, indicating a transformation based on the MIVQUE(0) equations. The other two options indicate the type of Hessian matrix used in constructing the transformation via a Cholesky root.

UPDATE=number is an alias for the LOGNOTE= option.

RANDOM Statement

```
RANDOM random-effects < / options > ;
```

The RANDOM statement defines the random effects constituting the $\gamma$ vector in the mixed model. It can be used to specify traditional variance component models (as in the VARCOMP procedure) and to specify random coefficients. The random effects can be classification or continuous, and multiple RANDOM statements are possible.

Using notation from the “Mixed Models Theory” section beginning on page 2731, the purpose of the RANDOM statement is to define the $Z$ matrix of the mixed model, the random effects in the $\gamma$ vector, and the structure of $G$. The $Z$ matrix is constructed
exactly as the X matrix for the fixed effects, and the G matrix is constructed to correspond with the effects constituting Z. The structure of G is defined by using the TYPE= option described on page 2715.

You can specify INTERCEPT (or INT) as a random effect to indicate the intercept. PROC MIXED does not include the intercept in the RANDOM statement by default as it does in the MODEL statement.

You can specify the following options in the RANDOM statement after a slash (/).

**ALPHA=number**
requests that a t-type confidence interval be constructed for each of the random effect estimates with confidence level $1 - number$. The value of number must be between 0 and 1; the default is 0.05.

**CL**
requests that t-type confidence limits be constructed for each of the random effect estimates. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.

**G**
requests that the estimated G matrix be displayed. PROC MIXED displays blanks for values that are 0. If you specify the SUBJECT= option, then the block of the G matrix corresponding to the first subject is displayed. For ODS purposes, the name of the table is “G.”

**GC**
displays the lower-triangular Cholesky root of the estimated G matrix according to the rules listed under the G option. For ODS purposes, the name of the table is “CholG.”

**GCI**
displays the inverse Cholesky root of the estimated G matrix according to the rules listed under the G option. For ODS purposes, the name of the table is “InvCholG.”

**GCorr**
displays the correlation matrix corresponding to the estimated G matrix according to the rules listed under the G option. For ODS purposes, the name of the table is “GCorr.”

**GDATA=SAS-data-set**
requests that the G matrix be read in from a SAS data set. This G matrix is assumed to be known; therefore, only R-side parameters from effects in the REPEATED statement are included in the Newton-Raphson iterations. If no REPEATED statement is specified, then only a residual variance is estimated.

The information in the GDATA= data set can appear in one of two ways. The first is a sparse representation for which you include ROW, COL, and VALUE variables to indicate the row, column, and value of G. All unspecified locations are assumed to be 0. The second representation is for dense matrices. In it you include ROW and COL1–COLn variables to indicate the row and columns of G, which is a symmetric matrix of order n. For both representations, you must specify effects in the RANDOM
statement that generate a \( Z \) matrix that contains \( n \) columns. See Example 46.4 on page 2802.

If you have more than one RANDOM statement, only one GDATA= option is required on any one of them, and the data set you specify must contain the entire \( G \) matrix defined by all of the RANDOM statements.

If the GDATA= data set contains variance ratios instead of the variances themselves, then use the RATIOS option.

Known parameters of \( G \) can also be input using the PARMS statement with the HOLD= option.

\( \text{GI} \)

displays the inverse of the estimated \( G \) matrix according to the rules listed under the \( G \) option. For ODS purposes, the name of the table is “InvG.”

\( \text{GROUP=} \text{effect} \)

\( \text{GRP=} \text{effect} \)

defines an effect specifying heterogeneity in the covariance structure of \( G \). All observations having the same level of the group effect have the same covariance parameters. Each new level of the group effect produces a new set of covariance parameters with the same structure as the original group. You should exercise caution in defining the group effect, as strange covariance patterns can result with its misuse. Also, the group effect can greatly increase the number of estimated covariance parameters, which may adversely affect the optimization process.

Continuous variables are permitted as arguments to the GROUP= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

\( \text{LDATA=} \text{SAS-data-set} \)

reads the coefficient matrices associated with the TYPE=LIN(\text{number}) option. The data set must contain the variables PARM, ROW, COL1–COLn, or PARM, ROW, COL, VALUE. The PARM variable denotes which of the \text{number} coefficient matrices is currently being constructed, and the ROW, COL1–COLn, or ROW, COL, VALUE variables specify the matrix values, as they do with the GDATA= option. Unspecified values of these matrices are set equal to 0.

\( \text{NOFULLZ} \)

eliminates the columns in \( Z \) corresponding to missing levels of random effects involving CLASS variables. By default, these columns are included in \( Z \).

\( \text{RATIOS} \)

indicates that ratios with the residual variance are specified in the GDATA= data set instead of the covariance parameters themselves. The default GDATA= data set contains the individual covariance parameters.
SOLUTION

requests that the solution for the random-effects parameters be produced. Using notation from the “Mixed Models Theory” section beginning on page 2731, these estimates are the empirical best linear unbiased predictors (EBLUPs) \( \hat{\gamma} = \hat{G}Z'\hat{V}^{-1}(y - X\hat{\beta}) \). They can be useful for comparing the random effects from different experimental units and can also be treated as residuals in performing diagnostics for your mixed model.

The numbers displayed in the SE Pred column of the “Solution for Random Effects” table are not the standard errors of the \( \hat{\gamma} \) displayed in the Estimate column; rather, they are the standard errors of predictions \( \hat{\gamma}_i - \gamma_i \), where \( \hat{\gamma}_i \) is the \( i \)th EBLUP and \( \gamma_i \) is the \( i \)th random-effect parameter.

SUBJECT=effect

identifies the subjects in your mixed model. Complete independence is assumed across subjects; thus, for the RANDOM statement, the SUBJECT= option produces a block-diagonal structure in \( G \) with identical blocks. The \( Z \) matrix is modified to accommodate this block-diagonality. In fact, specifying a subject effect is equivalent to nesting all other effects in the RANDOM statement within the subject effect.

Continuous variables are permitted as arguments to the SUBJECT= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

When you specify the SUBJECT= option and a classification random effect, computations are usually much quicker if the levels of the random effect are duplicated within each level of the SUBJECT= effect.

TYPE=covariance-structure

describes the covariance structure of \( G \). Valid values for covariance-structure and their descriptions are listed in Table 46.5 on page 2721 and Table 46.6 on page 2722. Although a variety of structures are available, most applications call for either TYPE=VC or TYPE=UN. The TYPE=VC (variance components) option is the default structure, and it models a different variance component for each random effect.

The TYPE=UN (unstructured) option is useful for correlated random coefficient models. For example,

\[
\text{random intercept age / type=un subject=person;}
\]

specifies a random intercept-slope model that has different variances for the intercept and slope and a covariance between them. You can also use TYPE=FA0(2) here to request a \( G \) estimate that is constrained to be nonnegative definite.
If you are constructing your own columns of $Z$ with continuous variables, you can use the TYPE=TOEP(1) structure to group them together to have a common variance component. If you desire to have different covariance structures in different parts of $G$, you must use multiple RANDOM statements with different TYPE= options.

$V<\text{value-list}>$
requests that blocks of the estimated $V$ matrix be displayed. The first block determined by the SUBJECT= effect is the default displayed block. PROC MIXED displays entries that are 0 as blanks in the table.

You can optionally use the value-list specification, which indicates the subjects for which blocks of $V$ are to be displayed. For example, the statement

$$\text{random int time / type=un subject=person v=1,3,7;}$$

displays block matrices for the first, third, and seventh persons. The table name for ODS purposes is “V.”

$VC<\text{value-list}>$
displays the Cholesky root of the blocks of the estimated $V$ matrix. The value-list specification is the same as in the $V=$ option. The table name for ODS purposes is “CholV.”

$VCI<\text{value-list}>$
displays the inverse of the Cholesky root of the blocks of the estimated $V$ matrix. The value-list specification is the same as in the $V=$ option. The table name for ODS purposes is “InvCholV.”

$VCORR<\text{value-list}>$
displays the correlation matrix corresponding to the blocks of the estimated $V$ matrix. The value-list specification is the same as in the $V=$ option. The table name for ODS purposes is “VCorr.”

$VI<\text{value-list}>$
displays the inverse of the blocks of the estimated $V$ matrix. The value-list specification is the same as in the $V=$ option. The table name for ODS purposes is “InvV.”

**REPEATED Statement**

$$\text{REPEATED < repeated-effect >> / options > ;}$$

The REPEATED statement is used to specify the $R$ matrix in the mixed model. Its syntax is different from that of the REPEATED statement in PROC GLM. If no REPEATED statement is specified, $R$ is assumed to be equal to $\sigma^2I$.

For many repeated measures models, no repeated effect is required in the REPEATED statement. Simply use the SUBJECT= option to define the blocks of $R$ and the TYPE= option to define their covariance structure. In this case, the repeated measures data must be similarly ordered for each subject, and you must indicate all missing response variables with periods in the input data set unless they all fall at the end of
a subject’s repeated response profile. These requirements are necessary in order to inform PROC MIXED of the proper location of the observed repeated responses.

Specifying a repeated effect is useful when you do not want to indicate missing values with periods in the input data set. The repeated effect must contain only classification variables. Make sure that the levels of the repeated effect are different for each observation within a subject; otherwise, PROC MIXED constructs identical rows in $R$ corresponding to the observations with the same level. This results in a singular $R$ and an infinite likelihood.

Whether you specify a REPEATED effect or not, the rows of $R$ for each subject are constructed in the order that they appear in the input data set.

You can specify the following options in the REPEATED statement after a slash (/).

**GROUP=**effect  
**GRP=**effect  

defines an effect specifying heterogeneity in the covariance structure of $R$. All observations having the same level of the GROUP effect have the same covariance parameters. Each new level of the GROUP effect produces a new set of covariance parameters with the same structure as the original group. You should exercise caution in properly defining the GROUP effect, as strange covariance patterns can result with its misuse. Also, the GROUP effect can greatly increase the number of estimated covariance parameters, which may adversely affect the optimization process.

Continuous variables are permitted as arguments to the GROUP= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

**HLM**  

produces a table of Hotelling-Lawley-McKeon statistics (McKeon 1974) for all fixed effects whose levels change across data having the same level of the SUBJECT= effect (the within-subject fixed effects). This option applies only when you specify a REPEATED statement with the TYPE=UN option and no RANDOM statements. For balanced data, this model is equivalent to the multivariate model for repeated measures in PROC GLM.

The Hotelling-Lawley-McKeon statistic has a slightly better $F$ approximation than the Hotelling-Lawley-Pillai-Samson statistic (see the description of the HLPS option, which follows). Both of the Hotelling-Lawley statistics can perform much better in small samples than the default $F$ statistic (Wright 1994).

Separate tables are produced for Type I, II, and III tests, according to the ones you select. For ODS purposes, the labels for these tables are “HLM1,” “HLM2,” and “HLM3,” respectively.
HLPS
produces a table of Hotelling-Lawley-Pillai-Samson statistics (Pillai and Samson 1959) for all fixed effects whose levels change across data having the same level of the SUBJECT= effect (the within-subject fixed effects). This option applies only when you specify a REPEATED statement with the TYPE=UN option and no RANDOM statements. For balanced data, this model is equivalent to the multivariate model for repeated measures in PROC GLM, and this statistic is the same as the Hotelling-Lawley Trace statistic produced by PROC GLM.

Separate tables are produced for Type I, II, and III tests, according to the ones you select. For ODS purposes, the labels for these tables are “HLPS1,” “HLPS2,” and “HLPS3,” respectively.

**LDATA=SAS-data-set**

reads the coefficient matrices associated with the TYPE=LIN(number) option. The data set must contain the variables PARM, ROW, COL1–COLn, or PARM, ROW, COL, VALUE. The PARM variable denotes which of the number coefficient matrices is currently being constructed, and the ROW, COL1–COLn, or ROW, COL, VALUE variables specify the matrix values, as they do with the RANDOM statement option GDATA=. Unspecified values of these matrices are set equal to 0.

**LOCAL**

**LOCAL=EXP(<effects>)**

**LOCAL=POM(POM-data-set)**

requests that a diagonal matrix be added to R. With just the LOCAL option, this diagonal matrix equals $\sigma^2 I$, and $\sigma^2$ becomes an additional variance parameter that PROC MIXED profiles out of the likelihood provided that you do not specify the NOPROFILE option in the PROC MIXED statement. The LOCAL option is useful if you want to add an observational error to a time series structure (Jones and Boadi-Boateng 1991) or a nugget effect to a spatial structure (Cressie 1991).

The LOCAL=EXP(<effects>) option produces exponential local effects, also known as dispersion effects, in a log-linear variance model. These local effects have the form

$$\sigma^2 \text{diag}[\exp(U\delta)]$$

where $U$ is the full-rank design matrix corresponding to the effects that you specify and $\delta$ are the parameters that PROC MIXED estimates. An intercept is not included in $U$ because it is accounted for by $\sigma^2$. PROC MIXED constructs the full-rank $U$ in terms of 1s and −1s for classification effects. Be sure to scale continuous effects in $U$ sensibly.

The LOCAL=POM(POM-data-set) option specifies the power-of-the-mean structure. This structure possesses a variance of the form $\sigma^2 |x_i^T\beta^*|^\theta$ for the $i$th observation, where $x_i$ is the $i$th row of $X$ (the design matrix of the fixed effects), and $\beta^*$ is an estimate of the fixed-effects parameters that you specify in POM-data-set.

The SAS data set specified by POM-data-set contains the numeric variable Estimate (in previous releases, the variable name was required to be EST), and it has at least as many observations as there are fixed-effects parameters. The first $p$ observations
of the Estimate variable in *POM-data-set* are taken to be the elements of $\beta^*$, where $p$ is the number of columns of $X$. You must order these observations according to the non-full-rank parameterization of the MIXED procedure. One easy way to set up *POM-data-set* for a $\beta^*$ corresponding to ordinary least squares is illustrated by the following code:

```plaintext
ods output SolutionF=sf;
proc mixed;
   class a;
   model y = a x / s;
run;

proc mixed;
   class a;
   model y = a x;
   repeated / local=pom(sf);
run;
```

Note that the generalized least-squares estimate of the fixed-effects parameters from the second PROC MIXED step usually is not the same as your specified $\beta^*$. However, you can iterate the POM fitting until the two estimates agree. Continuing from the previous example, the code for performing one step of this iteration is as follows.

```plaintext
ods output SolutionF=sf1;
proc mixed;
   class a;
   model y = a x / s;
   repeated / local=pom(sf);
run;

proc compare brief data=sf compare=sf1;
   var estimate;
run;

data sf;
   set sf1;
run;
```

Unfortunately, this iterative process does not always converge. For further details, refer to the description of pseudo-likelihood in Chapter 3 of Carroll and Ruppert (1988).

**LOCALW**

specifies that only the local effects and no others be weighted. By default, all effects are weighted. The LOCALW option is used in connection with the WEIGHT statement and the LOCAL option in the REPEATED statement.
Chapter 46. The MIXED Procedure

NONLOCALW
specifies that only the nonlocal effects and no others be weighted. By default, all effects are weighted. The NONLOCALW option is used in connection with the WEIGHT statement and the LOCAL option in the REPEATED statement.

R<value-list>
requests that blocks of the estimated R matrix be displayed. The first block determined by the SUBJECT= effect is the default displayed block. PROC MIXED displays blanks for value-lists that are 0.

The value-list indicates the subjects for which blocks of R are to be displayed. For example,

    repeated / type=cs subject=person r=1,3,5;

displays block matrices for the first, third, and fifth persons. See the “PARMS Statement” section on page 2706 for the possible forms of value-list. The table name for ODS purposes is “R.”

RC<value-list>
produces the Cholesky root of blocks of the estimated R matrix. The value-list specification is the same as with the R option. The table name for ODS purposes is “CholR.”

RCI<value-list>
produces the inverse Cholesky root of blocks of the estimated R matrix. The value-list specification is the same as with the R option. The table name for ODS purposes is “InvCholR.”

RCORR<value-list>
produces the correlation matrix corresponding to blocks of the estimated R matrix. The value-list specification is the same as with the R option. The table name for ODS purposes is “RCorr.”

RI<value-list>
produces the inverse of blocks of the estimated R matrix. The value-list specification is the same as with the R option. The table name for ODS purposes is “InvR.”

SSCP
requests that an unstructured R matrix be estimated from the sum-of-squares-and-crossproducts matrix of the residuals. It applies only when you specify TYPE=UN and have no RANDOM statements. Also, you must have a sufficient number of subjects for the estimate to be positive definite.

This option is useful when the size of the blocks of R are large (for example, greater than 10) and you want to use or inspect an unstructured estimate that is much quicker to compute than the default REML estimate. The two estimates will agree for certain balanced data sets when you have a classification fixed effect defined across all time points within a subject.
SUBJECT=effect

identifies the subjects in your mixed model. Complete independence is assumed across subjects; therefore, the SUBJECT= option produces a block-diagonal structure in R with identical blocks. When the SUBJECT= effect consists entirely of classification variables, the blocks of R correspond to observations sharing the same level of that effect. These blocks are sorted according to this effect as well.

Continuous variables are permitted as arguments to the SUBJECT= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

If you want to model nonzero covariance among all of the observations in your SAS data set, specify SUBJECT=INTERCEPT to treat the data as if they are all from one subject. Be aware though that, in this case, PROC MIXED manipulates an R matrix with dimensions equal to the number of observations. If no SUBJECT= effect is specified, then every observation is assumed to be from a different subject and R is assumed to be diagonal. For this reason, you usually want to use the SUBJECT= option in the REPEATED statement.

TYPE=covariance-structure

specifies the covariance structure of the R matrix. The SUBJECT= option defines the blocks of R, and the TYPE= option specifies the structure of these blocks. Valid values for covariance-structure and their descriptions are provided in Table 46.5 and Table 46.6. The default structure is VC.

In Table 46.5, “Parms” is the number of covariance parameters in the structure, \(t\) is the overall dimension of the covariance matrix, and \(1(A)\) equals 1 when \(A\) is true and 0 otherwise. For example, \(1(i = j)\) equals 1 when \(i = j\) and 0 otherwise, and \(1(|i - j| < q)\) equals 1 when \(|i - j| < q\) and 0 otherwise. For the TOEPH structures, \(\rho_0 = 1\), and for the UNR structures, \(\rho_{ii} = 1\) for all \(i\). For the direct product structures, the subscripts “1” and “2” refer to the first and second structure in the direct product, respectively, and \(i_1 = \text{int}((i + t_2 - 1)/t_2), j_1 = \text{int}((j + t_2 - 1)/t_2), i_2 = \text{mod}(i - 1, t_2) + 1\), and \(j_2 = \text{mod}(j - 1, t_2) + 1\).

</tr>
</tbody>
</table>

In Table 46.6, \(c\)-list contains the names of the numeric variables used as coordinates of the location of the observation in space, and \(d_{ij}\) is the Euclidean distance between the \(i\)th and \(j\)th vectors of these coordinates, which correspond to the \(i\)th and \(j\)th observations in the input data set. For SP(POWA) and SP(EXPA), \(c\) is the number of coordinates, and \(d(i, j, k)\) is the absolute distance between the \(k\)th coordinate,
\[ k = 1, \ldots, c, \] of the \( i \)th and \( j \)th observations in the input data set. For the geometrically anisotropic structures SP(EXPGA), SP(GAUGA), and SP(SPHGA), exactly two spatial coordinate variables must be specified as \( c_1 \) and \( c_2 \). Geometric anisotropy is corrected by applying a rotation \( \theta \) and scaling \( \lambda \) to the coordinate system, and \( d_{ij}(\theta, \lambda) \) represents the Euclidean distance between two points in the transformed space. SP(MATERN) and SP(MATHSW) represent covariance structures in a class defined by Matérn (refer to Matérn 1986, Handcock and Stein 1993, Handcock and Wallis 1994). The function \( K_\nu \) is the modified Bessel function of the second kind of (real) order \( \nu > 0 \); the parameter \( \nu \) governs the smoothness of the process (see below for more details).

Table 46.7 lists some examples of the structures in Table 46.5 and Table 46.6.

The following provides some further information about these covariance structures:

**TYPE=ANTE(1)** specifies the first-order antedependence structure (refer to Kenward 1987, Patel 1991, and Macchiavelli and Arnold 1994). In Table 46.5, $\sigma_i^2$ is the $i$th variance parameter, and $\rho_k$ is the $k$th autocorrelation parameter satisfying $|\rho_k| < 1$.

**TYPE=AR(1)** specifies a first-order autoregressive structure. PROC MIXED imposes the constraint $|\rho| < 1$ for stationarity.

**TYPE=ARH(1)** specifies a heterogeneous first-order autoregressive structure. As with **TYPE=AR(1)**, PROC MIXED imposes the constraint $|\rho| < 1$ for stationarity.

**TYPE=ARMA(1,1)** specifies the first-order autoregressive moving average structure. In Table 46.5, $\rho$ is the autoregressive parameter, $\gamma$ models a moving average component, and $\sigma^2$ is the residual variance. In the notation of Fuller (1976, p. 68), $\rho = \theta_1$ and

$$
\gamma = \frac{(1 + b_1 \theta_1)(\theta_1 + b_1)}{1 + b_1^2 + 2b_1 \theta_1}
$$

The example in Table 46.7 and $|b_1| < 1$ imply that

$$
b_1 = \frac{\beta - \sqrt{\beta^2 - 4\alpha^2}}{2\alpha}
$$

where $\alpha = \gamma - \rho$ and $\beta = 1 + \rho^2 - 2\gamma \rho$. PROC MIXED imposes the constraints $|\rho| < 1$ and $|\gamma| < 1$ for stationarity, although for some values of $\rho$ and $\gamma$ in this region the resulting covariance matrix is not positive definite. When the estimated value of $\rho$ becomes negative, the computed covariance is multiplied by $\cos(\pi d_{ij})$ to account for the negativity.

**TYPE=CS** specifies the compound-symmetry structure, which has constant variance and constant covariance.

**TYPE=CSH** specifies the heterogeneous compound-symmetry structure. This structure has a different variance parameter for each diagonal element, and it uses the square roots of these parameters in the off-diagonal entries. In Table 46.5, $\sigma_i^2$ is the $i$th variance parameter, and $\rho$ is the correlation parameter satisfying $|\rho| < 1$. 
TYPE=FA(q) specifies the factor-analytic structure with q factors (Jennrich and Schluchter 1986). This structure is of the form $\Lambda \Lambda' + D$, where $\Lambda$ is a $t \times q$ rectangular matrix and $D$ is a $t \times t$ diagonal matrix with $t$ different parameters. When $q > 1$, the elements of $\Lambda$ in its upper right-hand corner (that is, the elements in the $i$th row and $j$th column for $j > i$) are set to zero to fix the rotation of the structure.

TYPE=FA0(q) is similar to the FA(q) structure except that no diagonal matrix $D$ is included. When $q < t$, that is, when the number of factors is less than the dimension of the matrix, this structure is nonnegative definite but not of full rank. In this situation, you can use it for approximating an unstructured $G$ matrix in the RANDOM statement or for combining with the LOCAL option in the REPEATED statement. When $q = t$, you can use this structure to constrain $G$ to be nonnegative definite in the RANDOM statement.

TYPE=FA1(q) is similar to the FA(q) structure except that all of the elements in $D$ are constrained to be equal. This offers a useful and more parsimonious alternative to the full factor-analytic structure.

TYPE=HF specifies the Huynh-Feldt covariance structure (Huynh and Feldt 1970). This structure is similar to the CSH structure in that it has the same number of parameters and heterogeneity along the main diagonal. However, it constructs the off-diagonal elements by taking arithmetic rather than geometric means.

You can perform a likelihood ratio test of the Huynh-Feldt conditions by running PROC MIXED twice, once with TYPE=HF and once with TYPE=UN, and then subtracting their respective values of $-2$ times the maximized likelihood.

If PROC MIXED does not converge under your Huynh-Feldt model, you can specify your own starting values with the PARMS statement. The default MIVQUE(0) starting values can sometimes be poor for this structure. A good choice for starting values is often the parameter estimates corresponding to an initial fit using TYPE=CS.

TYPE=LIN(q) specifies the general linear covariance structure with q parameters (Helms and Edwards 1991). This structure consists of a linear combination of known matrices that are input with the LDATA= option. This structure is very general, and you need to make sure that the variance matrix is positive definite. By default, PROC MIXED sets the initial values of the parameters to 1. You can use the PARMS statement to specify other initial values.

TYPE=SIMPLE is an alias for TYPE=VC.

TYPE=SP(EXPA)(c-list) specifies the spatial anisotropic exponential structure, where c-list is a list of variables indicating the coordinates. This structure has $(i, j)$th element equal to

$$\sigma^2 \prod_{k=1}^{c} \exp[-\theta_k d(i, j, k)^{p_k}]$$
where \( c \) is the number of coordinates and \( d(i, j, k) \) is the absolute distance between the \( k \)th coordinate \((k = 1, \ldots, c)\) of the \( i \)th and \( j \)th observations in the input data set. There are \( 2c + 1 \) parameters to be estimated: \( \theta_k, p_k (k = 1, \ldots, c) \), and \( \sigma^2 \).

You may want to constrain some of the EXPA parameters to known values. For example, suppose you have three coordinate variables \( C_1, C_2 \), and \( C_3 \) and you want to constrain the powers \( p_k \) to equal 2, as in Sacks et al. (1989). Suppose further that you want to model covariance across the entire input data set and you suspect the \( \theta_k \) and \( \sigma^2 \) estimates are close to 3, 4, 5, and 1, respectively. Then specify

\[
\text{repeated} / \text{type}=\text{sp(expa)}(c_1 c_2 c_3) \\
\text{subject}=\text{intercept}; \\
\text{parms} (3) (4) (5) (2) (2) (2) (1) / \text{hold}=4,5,6;
\]

\( \text{TYPE=SP(EXPGA)}(c_1 c_2) \)

\( \text{TYPE=SP(GAUGA)}(c_1 c_2) \)

\( \text{TYPE=SP(SPHGA)}(c_1 c_2) \) specify modifications of the isotropic SP(EXP), SP(SPH), and SP(GAU) covariance structures that allow for geometric anisotropy in two dimensions. The coordinates are specified by the variables \( c_1 \) and \( c_2 \).

If the spatial process is geometrically anisotropic in \( c = [c_{i1}, c_{i2}] \), then it is isotropic in the coordinate system

\[
A c = \begin{bmatrix} 1 & 0 \\ 0 & \lambda \end{bmatrix} \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} c = c^*
\]

for a properly chosen angle \( \theta \) and scaling factor \( \lambda \). Elliptical iso-correlation contours are thereby transformed to spherical contours, adding two parameters to the respective isotropic covariance structures. Euclidean distances (see Table 46.6 on page 2722) are expressed in terms of \( c^* \).

The angle \( \theta \) of the clockwise rotation is reported in radians, \( 0 \leq \theta \leq 2\pi \). The scaling parameter \( \lambda \) represents the ratio of the range parameters in the direction of the major and minor axis of the correlation contours. In other words, following a rotation of the coordinate system by angle \( \theta \), isotropy is achieved by compressing or magnifying distances in one coordinate by the factor \( \lambda \).

Fixing \( \lambda = 1.0 \) reduces the models to isotropic ones for any angle of rotation. If the scaling parameter is held constant at 1.0, you should also hold constant the angle of rotation, e.g.,

\[
\text{repeated} / \text{type}=\text{sp(expga)}(gxc gyc) \\
\text{subject}=\text{intercept}; \\
\text{parms} (6) (1.0) (0.0) (1) / \text{hold}=2,3;
\]
If $\lambda$ is fixed at any other value than 1.0, the angle of rotation can be estimated. Specifying a starting grid of angles and scaling factors can considerably improve the convergence properties of the optimization algorithm for these models. Only a single random effect with geometrically anisotropic structure is permitted.

\textbf{TYPE=SP(MATERN)(c-list)}

\textbf{TYPE=SP(MATHSW)(c-list)} specifies covariance structures in the Matérn class of covariance functions (Matérn 1986). Two observations for the same subject (block of $\mathbf{R}$) that are Euclidean distance $d_{ij}$ apart have covariance

$$
\sigma^2 \frac{1}{\Gamma(\nu)} \left( \frac{d_{ij}}{2\rho} \right)^\nu 2K_\nu(d_{ij}/\rho) \quad \nu > 0, \rho > 0,
$$

where $K_\nu$ is the modified Bessel function of the second kind of (real) order $\nu > 0$. The smoothness (continuity) of a stochastic process with covariance function in this class increases with $\nu$. The Matérn class thus enables data-driven estimation of the smoothness properties. The covariance is identical to the exponential model for $\nu = 0.5$ (\texttt{TYPE=SP(EXP)(c-list)}), while for $\nu = 1$ the model advocated by Whittle (1954) results. As $\nu \to \infty$ the model approaches the gaussian covariance structure (\texttt{TYPE=SP(GAU)(c-list)}).

The MATHSW structure represents the Matérn class in the parameterization of Handcock and Stein (1993) and Handcock and Wallis (1994),

$$
\sigma^2 \frac{1}{\Gamma(\nu)} \left( \frac{d_{ij} \sqrt{\nu}}{\rho} \right)^\nu 2K_\nu \left( \frac{2d_{ij} \sqrt{\nu}}{\rho} \right)
$$

Since computation of the function $K_\nu$ and its derivatives is numerically very intensive, fitting models with Matérn covariance structures can be more time consuming than for other spatial covariance structures. Good starting values are essential.

\textbf{TYPE=SP(POW)(c-list)}

\textbf{TYPE=SP(POWA)(c-list)} specifies the spatial power structures. When the estimated value of $\rho$ becomes negative, the computed covariance is multiplied by $\cos(\pi d_{ij})$ to account for the negativity.

\textbf{TYPE=TOEP<(q)>} specifies a banded Toeplitz structure. This can be viewed as a moving-average structure with order equal to $q - 1$. The \texttt{TYPE=TOEP} option is a full Toeplitz matrix, which can be viewed as an autoregressive structure with order equal to the dimension of the matrix. The specification \texttt{TYPE=TOEP(1)} is the same as $\sigma^2 \mathbf{I}$, where $\mathbf{I}$ is an identity matrix, and it can be useful for specifying the same variance component for several effects.
TYPE=TOEPH\(<(q)\> \) specifies a heterogeneous banded Toeplitz structure. In Table 46.5, \( \sigma^2_i \) is the \( i \)th variance parameter and \( \rho_j \) is the \( j \)th correlation parameter satisfying \( |\rho_j| < 1 \). If you specify the order parameter \( q \), then PROC MIXED estimates only the first \( q \) bands of the matrix, setting all higher bands equal to 0. The option \( \text{TOEPH}(1) \) is equivalent to both the \( \text{UN}(1) \) and \( \text{UNR}(1) \) options.

TYPE=UN\(<(q)\> \) specifies a completely general (unstructured) covariance matrix parameterized directly in terms of variances and covariances. The variances are constrained to be nonnegative, and the covariances are unconstrained. This structure is not constrained to be nonnegative definite in order to avoid nonlinear constraints; however, you can use the FA0 structure if you want this constraint to be imposed by a Cholesky factorization. If you specify the order parameter \( q \), then PROC MIXED estimates only the first \( q \) bands of the matrix, setting all higher bands equal to 0.

TYPE=UNR\(<(q)\> \) specifies a completely general (unstructured) covariance matrix parameterized in terms of variances and correlations. This structure fits the same model as the \( \text{TYPE}=\text{UN}(q) \) option but with a different parameterization. The \( i \)th variance parameter is \( \sigma_i^2 \). The parameter \( \rho_{jk} \) is the correlation between the \( j \)th and \( k \)th measurements; it satisfies \( |\rho_{jk}| < 1 \). If you specify the order parameter \( r \), then PROC MIXED estimates only the first \( q \) bands of the matrix, setting all higher bands equal to zero.

TYPE=UN@AR(1)

TYPE=UN@CS

TYPE=UN@UN specify direct (Kronecker) product structures designed for multivariate repeated measures (refer to Galecki 1994). These structures are constructed by taking the Kronecker product of an unstructured matrix (modeling covariance across the multivariate observations) with an additional covariance matrix (modeling covariance across time or another factor). The upper left value in the second matrix is constrained to equal 1 to identify the model. Refer to \textit{SAS/IML User’s Guide, First Edition}, for more details on direct products.

To use these structures in the REPEATED statement, you must specify two distinct REPEATED effects, both of which must be included in the CLASS statement. The first effect indicates the multivariate observations, and the second identifies the levels of time or some additional factor. Note that the input data set must still be constructed in “univariate” format; that is, all dependent observations are still listed observation-wise in one single variable. Although this construction provides for general modeling possibilities, it forces you to construct variables indicating both dimensions of the Kronecker product.

For example, suppose your observed data consist of heights and weights of several children measured over several successive years.
Your input data set should then contain variables similar to the following:

- \( Y \), all of the heights and weights, with a separate observation for each
- \( \text{Var} \), indicating whether the measurement is a height or a weight
- \( \text{Year} \), indicating the year of measurement
- \( \text{Child} \), indicating the child on which the measurement was taken

Your PROC MIXED code for a Kronecker AR(1) structure across years would then be

```
proc mixed;
  class Var Year Child;
  model Y = Var Year Var*Year;
  repeated Var Year / type=un@ar(1) subject=Child;
run;
```

You should nearly always want to model different means for the multivariate observations, hence the inclusion of \( \text{Var} \) in the MODEL statement. The preceding mean model consists of cell means for all combinations of \( \text{VAR} \) and \( \text{YEAR} \).

\( \text{TYPE}=\text{VC} \) specifies standard variance components and is the default structure for both the RANDOM and REPEATED statements. In the RANDOM statement, a distinct variance component is assigned to each effect. In the REPEATED statement, this structure is usually used only with the GROUP= option to specify a heterogeneous variance model.

**WEIGHT Statement**

```
WEIGHT variable ;
```

If you do not specify a REPEATED statement, the WEIGHT statement operates exactly like the one in PROC GLM. In this case PROC MIXED replaces \( X'X \) and \( Z'Z \) with \( X'WX \) and \( Z'WZ \), where \( W \) is the diagonal weight matrix. If you specify a REPEATED statement, then the WEIGHT statement replaces \( R \) with \( LRL \), where \( L \) is a diagonal matrix with elements \( W^{1/2} \). Observations with nonpositive or missing weights are not included in the PROC MIXED analysis.
Details

Mixed Models Theory

This section provides an overview of a likelihood-based approach to general linear mixed models. This approach simplifies and unifies many common statistical analyses, including those involving repeated measures, random effects, and random coefficients. The basic assumption is that the data are linearly related to unobserved multivariate normal random variables. Extensions to nonlinear and nonnormal situations are possible but are not discussed here. Additional theory and examples are provided in Littell et al. (1996), Verbeke and Molenberghs (1997 2000), and Brown and Prescott (1999).

Matrix Notation

Suppose that you observe \( n \) data points \( y_1, \ldots, y_n \) and that you want to explain them using \( n \) values for each of \( p \) explanatory variables \( x_{11}, \ldots, x_{1p}, x_{21}, \ldots, x_{2p}, \ldots, x_{n1}, \ldots, x_{np} \). The \( x_{ij} \) values may be either regression-type continuous variables or dummy variables indicating class membership. The standard linear model for this setup is

\[
y_i = \sum_{j=1}^{p} x_{ij} \beta_j + \epsilon_i \quad i = 1, \ldots, n
\]

where \( \beta_1, \ldots, \beta_p \) are unknown fixed-effects parameters to be estimated and \( \epsilon_1, \ldots, \epsilon_n \) are unknown independent and identically distributed normal (Gaussian) random variables with mean 0 and variance \( \sigma^2 \).

The preceding equations can be written simultaneously using vectors and a matrix, as follows:

\[
\begin{bmatrix}
y_1 \\
y_2 \\
\vdots \\
y_n
\end{bmatrix} =
\begin{bmatrix}
x_{11} & x_{12} & \cdots & x_{1p} \\
x_{21} & x_{22} & \cdots & x_{2p} \\
\vdots & \vdots & \ddots & \vdots \\
x_{n1} & x_{n2} & \cdots & x_{np}
\end{bmatrix}
\begin{bmatrix}
\beta_1 \\
\beta_2 \\
\vdots \\
\beta_p
\end{bmatrix} +
\begin{bmatrix}
\epsilon_1 \\
\epsilon_2 \\
\vdots \\
\epsilon_n
\end{bmatrix}
\]

For convenience, simplicity, and extendibility, this entire system is written as

\[
y = X\beta + \epsilon
\]

where \( y \) denotes the vector of observed \( y_i \)'s, \( X \) is the known matrix of \( x_{ij} \)'s, \( \beta \) is the unknown fixed-effects parameter vector, and \( \epsilon \) is the unobserved vector of independent and identically distributed Gaussian random errors.

In addition to denoting data, random variables, and explanatory variables in the preceding fashion, the subsequent development makes use of basic matrix operators such as transpose (\( ' \)), inverse (\( ^{-1} \)), generalized inverse (\( \sim \)), determinant (\( | \cdot | \)), and matrix multiplication. Refer to Searle (1982) for details on these and other matrix techniques.
Formulation of the Mixed Model

The previous general linear model is certainly a useful one (Searle 1971), and it is the one fitted by the GLM procedure. However, many times the distributional assumption about \( \epsilon \) is too restrictive. The mixed model extends the general linear model by allowing a more flexible specification of the covariance matrix of \( \epsilon \). In other words, it allows for both correlation and heterogeneous variances, although you still assume normality.

The mixed model is written as

\[
y = X\beta + Z\gamma + \epsilon
\]

where everything is the same as in the general linear model except for the addition of the known design matrix, \( Z \), and the vector of unknown random-effects parameters, \( \gamma \). The matrix \( Z \) can contain either continuous or dummy variables, just like \( X \). The name *mixed model* comes from the fact that the model contains both fixed-effects parameters, \( \beta \), and random-effects parameters, \( \gamma \). Refer to Henderson (1990) and Searle, Casella, and McCulloch (1992) for historical developments of the mixed model.

A key assumption in the foregoing analysis is that \( \gamma \) and \( \epsilon \) are normally distributed with

\[
E\begin{bmatrix} \gamma \\ \epsilon \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}
\]

\[
\text{Var} \begin{bmatrix} \gamma \\ \epsilon \end{bmatrix} = \begin{bmatrix} G & 0 \\ 0 & R \end{bmatrix}
\]

The variance of \( y \) is, therefore, \( V = ZGZ' + R \). You can model \( V \) by setting up the random-effects design matrix \( Z \) and by specifying covariance structures for \( G \) and \( R \).

Note that this is a general specification of the mixed model, in contrast to many texts and articles that discuss only simple random effects. Simple random effects are a special case of the general specification with \( Z \) containing dummy variables, \( G \) containing variance components in a diagonal structure, and \( R = \sigma^2 I_n \), where \( I_n \) denotes the \( n \times n \) identity matrix. The general linear model is a further special case with \( Z = 0 \) and \( R = \sigma^2 I_n \).

The following two examples illustrate the most common formulations of the general linear mixed model.
Example: Growth Curve with Compound Symmetry

Suppose that you have three growth curve measurements for \( s \) individuals and that you want to fit an overall linear trend in time. Your \( X \) matrix is as follows:

\[
X = \begin{bmatrix}
1 & 1 \\
1 & 2 \\
1 & 3 \\
\vdots & \vdots \\
1 & 1 \\
1 & 2 \\
1 & 3
\end{bmatrix}
\]

The first column (coded entirely with 1s) fits an intercept, and the second column (coded with times of 1, 2, 3) fits a slope. Here, \( n = 3s \) and \( p = 2 \).

Suppose further that you want to introduce a common correlation among the observations from a single individual, with correlation being the same for all individuals. One way of setting this up in the general mixed model is to eliminate the \( Z \) and \( G \) matrices and let the \( R \) matrix be block diagonal with blocks corresponding to the individuals and with each block having the compound-symmetry structure. This structure has two unknown parameters, one modeling a common covariance and the other a residual variance. The form for \( R \) would then be as follows:

\[
R = \begin{bmatrix}
\sigma_1^2 + \sigma^2 & \sigma_1^2 & \sigma_1^2 \\
\sigma_1^2 & \sigma_1^2 + \sigma^2 & \sigma_1^2 \\
\sigma_1^2 & \sigma_1^2 & \sigma_1^2 + \sigma^2 \\
\vdots & \vdots & \vdots \\
\sigma_1^2 + \sigma^2 & \sigma_1^2 & \sigma_1^2 \\
\sigma_1^2 & \sigma_1^2 + \sigma^2 & \sigma_1^2 \\
\sigma_1^2 & \sigma_1^2 & \sigma_1^2 + \sigma^2
\end{bmatrix}
\]

where blanks denote zeroes. There are \( 3s \) rows and columns altogether, and the common correlation is \( \sigma_1^2 / (\sigma_1^2 + \sigma^2) \).

The PROC MIXED code to fit this model is as follows:

```plaintext
proc mixed;
    class indiv;
    model y = time;
    repeated / type=cs subject=indiv;
run;
```

Here, \( \text{indiv} \) is a classification variable indexing individuals. The MODEL statement fits a straight line for \( \text{time} \); the intercept is fit by default just as in PROC GLM. The REPEATED statement models the \( R \) matrix: TYPE=CS specifies the compound symmetry structure, and SUBJECT=INDIV specifies the blocks of \( R \).
An alternative way of specifying the common intra-individual correlation is to let

\[
Z = \begin{bmatrix}
1 \\
1 \\
1 \\
1 \\
1 \\
1 \\
\vdots \\
1 \\
1 \\
1 \\
1 \\
1 \\
\end{bmatrix}
\]

\[
G = \begin{bmatrix}
\sigma_1^2 \\
\sigma_1^2 \\
\vdots \\
\sigma_1^2
\end{bmatrix}
\]

and \( R = \sigma^2 I_n \). The \( Z \) matrix has \( 3s \) rows and \( s \) columns, and \( G \) is \( s \times s \).

You can set up this model in PROC MIXED in two different but equivalent ways:

```sas
proc mixed;
   class indiv;
   model y = time;
   random indiv;
run;

proc mixed;
   class indiv;
   model y = time;
   random intercept / subject=indiv;
run;
```

Both of these specifications fit the same model as the previous one that used the REPEATED statement; however, the RANDOM specifications constrain the correlation to be positive whereas the REPEATED specification leaves the correlation unconstrained.

**Example: Split-Plot Design**

The split-plot design involves two experimental treatment factors, \( A \) and \( B \), and two different sizes of experimental units to which they are applied (refer to Winer 1971, Snedecor and Cochran 1980, Milliken and Johnson 1992, and Steel, Torrie, and Dickey 1997). The levels of \( A \) are randomly assigned to the larger sized experimental unit, called *whole plots*, whereas the levels of \( B \) are assigned to the smaller sized experimental unit, the *subplots*. The subplots are assumed to be nested within the whole plots, so that a whole plot consists of a cluster of subplots and a level of \( A \) is applied to the entire cluster.
Such an arrangement is often necessary by nature of the experiment, the classical example being the application of fertilizer to large plots of land and different crop varieties planted in subdivisions of the large plots. For this example, fertilizer is the whole plot factor $A$ and variety is the subplot factor $B$.

The first example is a split-plot design for which the whole plots are arranged in a randomized block design. The appropriate PROC MIXED code is as follows:

```plaintext
proc mixed;
   class a b block;
   model y = a|b;
   random block a*block;
run;
```

Here

$$R = \sigma^2 I_{24}$$

and $X$, $Z$, and $G$ have the following form:

$$X = \begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
\vdots & \vdots & \vdots & \vdots \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 \\
\end{bmatrix}$$
$Z = \begin{bmatrix}
1 & 1 \\
1 & 1 \\
1 & 1 \\
1 & 1 \\
1 & 1 \\
& \ldots
\end{bmatrix}
$

$G = \begin{bmatrix}
\sigma_B^2 \\
\sigma_B^2 \\
\sigma_B^2 \\
\sigma_B^2 \\
\sigma_B^2 \\
\sigma_{AB}^2
\end{bmatrix}
$

where $\sigma_B^2$ is the variance component for Block and $\sigma_{AB}^2$ is the variance component for A*Block. Changing the RANDOM statement to

```
random int a / subject=block;
```

fits the same model, but with $Z$ and $G$ sorted differently.
Mixed Models Theory

Estimating $G$ and $R$ in the Mixed Model

Estimation is more difficult in the mixed model than in the general linear model. Not only do you have $\beta$ as in the general linear model, but you have unknown parameters in $\gamma$, $G$, and $R$ as well. Least squares is no longer the best method. Generalized least squares (GLS) is more appropriate, minimizing

$$(y - X\beta)'V^{-1}(y - X\beta)$$
However, it requires knowledge of $V$ and, therefore, knowledge of $G$ and $R$. Lacking such information, one approach is to use estimated GLS, in which you insert some reasonable estimate for $V$ into the minimization problem. The goal thus becomes finding a reasonable estimate of $G$ and $R$.

In many situations, the best approach is to use likelihood-based methods, exploiting the assumption that $\gamma$ and $\epsilon$ are normally distributed (Hartley and Rao 1967; Patterson and Thompson 1971; Harville 1977; Laird and Ware 1982; Jennrich and Schluchter 1986). PROC MIXED implements two likelihood-based methods: maximum likelihood (ML) and restricted/residual maximum likelihood (REML). A favorable theoretical property of ML and REML is that they accommodate data that are missing at random (Rubin 1976; Little 1995).

PROC MIXED constructs an objective function associated with ML or REML and maximizes it over all unknown parameters. Using calculus, it is possible to reduce this maximization problem to one over only the parameters in $G$ and $R$. The corresponding log-likelihood functions are as follows:

\[
ML: \quad l(G, R) = -\frac{1}{2} \log |V| - \frac{1}{2} r' V^{-1} r - \frac{n}{2} \log(2\pi)
\]
\[
REML: \quad l_R(G, R) = -\frac{1}{2} \log |V| - \frac{1}{2} \log |X' V^{-1} X| - \frac{1}{2} r' V^{-1} y - \frac{n - p}{2} \log(2\pi)
\]

where $r = y - X(X' V^{-1} X)^{-1} X' V^{-1} y$ and $p$ is the rank of $X$. PROC MIXED actually minimizes $-2$ times these functions using a ridge-stabilized Newton-Raphson algorithm. Lindstrom and Bates (1988) provide reasons for preferring Newton-Raphson to the Expectation-Maximum (EM) algorithm described in Dempster, Laird, and Rubin (1977) and Laird, Lange, and Stram (1987), as well as analytical details for implementing a QR-decomposition approach to the problem. Wolfinger, Tobias, and Sall (1994) present the sweep-based algorithms that are implemented in PROC MIXED.

One advantage of using the Newton-Raphson algorithm is that the second derivative matrix of the objective function evaluated at the optima is available upon completion. Denoting this matrix $H$, the asymptotic theory of maximum likelihood (refer to Serfling 1980) shows that $2H^{-1}$ is an asymptotic variance-covariance matrix of the estimated parameters of $G$ and $R$. Thus, tests and confidence intervals based on asymptotic normality can be obtained. However, these can be unreliable in small samples, especially for parameters such as variance components which have sampling distributions that tend to be skewed to the right.

If a residual variance $\sigma^2$ is a part of your mixed model, it can usually be profiled out of the likelihood. This means solving analytically for the optimal $\sigma^2$ and plugging this expression back into the likelihood formula (refer to Wolfinger, Tobias, and Sall 1994). This reduces the number of optimization parameters by one and can improve convergence properties. PROC MIXED profiles the residual variance out of the log likelihood whenever it appears reasonable to do so. This includes the case when $R$ equals $\sigma^2 I$ and when it has blocks with a compound symmetry, time series, or spatial
Mixed Models Theory ♦ 2739

structure. PROC MIXED does not profile the log likelihood when \( R \) has unstructured blocks, when you use the HOLD= or NOITER option in the PARMS statement, or when you use the NOPROFILE option in the PROC MIXED statement.

Instead of ML or REML, you can use the noniterative MIVQUE0 method to estimate \( G \) and \( R \) (Rao 1972; LaMotte 1973; Wolfinger, Tobias, and Sall 1994). In fact, by default PROC MIXED uses MIVQUE0 estimates as starting values for the ML and REML procedures. For variance component models, another estimation method involves equating Type I, II, or III expected mean squares to their observed values and solving the resulting system. However, Swallow and Monahan (1984) present simulation evidence favoring REML and ML over MIVQUE0 and other method-of-moment estimators.

**Estimating \( \beta \) and \( \gamma \) in the Mixed Model**

ML, REML, MIVQUE0, or Type1–Type3 provide estimates of \( G \) and \( R \), which are denoted \( \hat{G} \) and \( \hat{R} \), respectively. To obtain estimates of \( \beta \) and \( \gamma \), the standard method is to solve the *mixed model equations* (Henderson 1984):

\[
\begin{bmatrix}
X'\hat{R}^{-1}X & X'\hat{R}^{-1}Z \\
Z'\hat{R}^{-1}X & Z'\hat{R}^{-1}Z + \hat{G}^{-1}
\end{bmatrix}
\begin{bmatrix}
\hat{\beta} \\
\hat{\gamma}
\end{bmatrix}
= \begin{bmatrix}
X'\hat{R}^{-1}y \\
Z'\hat{R}^{-1}y
\end{bmatrix}
\]

The solutions can also be written as

\[
\hat{\beta} = (X'\hat{V}^{-1}X)^{-1}X'\hat{V}^{-1}y
\]

\[
\hat{\gamma} = \hat{G}Z'\hat{V}^{-1}(y - X\hat{\beta})
\]

and have connections with empirical Bayes estimators (Laird and Ware 1982, Carlin and Louis 1996).

Note that the mixed model equations are extended normal equations and that the preceding expression assumes that \( \hat{G} \) is nonsingular. For the extreme case when the eigenvalues of \( \hat{G} \) are very large, \( \hat{G}^{-1} \) contributes very little to the equations and \( \hat{\gamma} \) is close to what it would be if \( \gamma \) actually contained fixed-effects parameters. On the other hand, when the eigenvalues of \( \hat{G} \) are very small, \( \hat{G}^{-1} \) dominates the equations and \( \hat{\gamma} \) is close to 0. For intermediate cases, \( \hat{G}^{-1} \) can be viewed as shrinking the fixed-effects estimates of \( \gamma \) towards 0 (Robinson 1991).

If \( \hat{G} \) is singular, then the mixed model equations are modified (Henderson 1984) as follows:

\[
\begin{bmatrix}
X'\hat{R}^{-1}X & X'\hat{R}^{-1}Z\hat{L} \\
\hat{L}'Z'\hat{R}^{-1}X & \hat{L}'Z'\hat{R}^{-1}\hat{L} + \hat{I}
\end{bmatrix}
\begin{bmatrix}
\hat{\beta} \\
\hat{\gamma}
\end{bmatrix}
= \begin{bmatrix}
X'\hat{R}^{-1}y \\
\hat{L}'Z'\hat{R}^{-1}y
\end{bmatrix}
\]

where \( \hat{L} \) is the lower-triangular Cholesky root of \( \hat{G} \), satisfying \( \hat{G} = \hat{L}\hat{L}' \). Both \( \hat{\gamma} \) and a generalized inverse of the left-hand-side coefficient matrix are then transformed using \( \hat{L} \) to determine \( \hat{\gamma} \).

An example of when the singular form of the equations is necessary is when a variance component estimate falls on the boundary constraint of 0.
Model Selection

The previous section on estimation assumes the specification of a mixed model in terms of $X$, $Z$, $G$, and $R$. Even though $X$ and $Z$ have known elements, their specific form and construction is flexible, and several possibilities may present themselves for a particular data set. Likewise, several different covariance structures for $G$ and $R$ might be reasonable.

Space does not permit a thorough discussion of model selection, but a few brief comments and references are in order. First, subject matter considerations and objectives are of great importance when selecting a model; refer to Diggle (1988) and Lindsey (1993).

Second, when the data themselves are looked to for guidance, many of the graphical methods and diagnostics appropriate for the general linear model extend to the mixed model setting as well (Christensen, Pearson, and Johnson 1992).

Finally, a likelihood-based approach to the mixed model provides several statistical measures for model adequacy as well. The most common of these are the likelihood ratio test and Akaike’s and Schwarz’s criteria (Bozdogan 1987; Wolfinger 1993, Keselman et al. 1998, 1999).

Statistical Properties

If $G$ and $R$ are known, $\hat{\beta}$ is the best linear unbiased estimator (BLUE) of $\beta$, and $\hat{\gamma}$ is the best linear unbiased predictor (BLUP) of $\gamma$ (Searle 1971; Harville 1988, 1990; Robinson 1991; McLean, Sanders, and Stroup 1991). Here, “best” means minimum mean squared error. The covariance matrix of $(\hat{\beta} - \beta, \hat{\gamma} - \gamma)$ is

$$ C = \begin{bmatrix} X' R^{-1} X & X'R^{-1} Z \\ Z' R^{-1} X & Z' R^{-1} Z + G^{-1} \end{bmatrix} $$

where $-$ denotes a generalized inverse (refer to Searle 1971).

However, $G$ and $R$ are usually unknown and are estimated using one of the aforementioned methods. These estimates, $\hat{G}$ and $\hat{R}$, are therefore simply substituted into the preceding expression to obtain

$$ \hat{C} = \begin{bmatrix} X' \hat{R}^{-1} X & X' \hat{R}^{-1} Z \\ Z' \hat{R}^{-1} X & Z' \hat{R}^{-1} Z + \hat{G}^{-1} \end{bmatrix} $$

as the approximate variance-covariance matrix of $(\hat{\beta} - \beta, \hat{\gamma} - \gamma)$. In this case, the BLUE and BLUP acronyms no longer apply, but the word empirical is often added to indicate such an approximation. The appropriate acronyms thus become EBLUE and EBLUP.

McLean and Sanders (1988) show that $\hat{C}$ can also be written as

$$ \hat{C} = \begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} \\ \hat{C}_{21} & \hat{C}_{22} \end{bmatrix} $$
where
\[
\hat{C}_{11} = (X'\hat{V}^{-1}X)^{-1}
\]
\[
\hat{C}_{21} = -GZ'\hat{V}^{-1}X\hat{C}_{11}
\]
\[
\hat{C}_{22} = (Z'\hat{R}^{-1}Z + \hat{G}^{-1})^{-1} - \hat{C}_{21}X'\hat{V}^{-1}Z\hat{G}
\]

Note that \(\hat{C}_{11}\) is the familiar estimated generalized least-squares formula for the variance-covariance matrix of \(\beta\).

As a cautionary note, \(\hat{C}\) tends to underestimate the true sampling variability of \((\hat{\beta}, \hat{\gamma})\) because no account is made for the uncertainty in estimating \(G\) and \(R\). Although inflation factors have been proposed (Kackar and Harville 1984; Kass and Steffey 1989; Prasad and Rao 1990), they tend to be small for data sets that are fairly well balanced. PROC MIXED does not compute any inflation factors by default, but rather accounts for the downward bias by using the approximate \(t\) and \(F\) statistics described subsequently. The DDFM=KENWARDROGER option in the MODEL statement prompts PROC MIXED to compute a specific inflation factor along with Satterthwaite-based degrees of freedom.

**Inference and Test Statistics**

For inferences concerning the covariance parameters in your model, you can use likelihood-based statistics. One common likelihood-based statistic is the Wald \(Z\), which is computed as the parameter estimate divided by its asymptotic standard error. The asymptotic standard errors are computed from the inverse of the second derivative matrix of the likelihood with respect to each of the covariance parameters. The Wald \(Z\) is valid for large samples, but it can be unreliable for small data sets and for parameters such as variance components, which are known to have a skewed or bounded sampling distribution.

A better alternative is the likelihood ratio \(\chi^2\). This statistic compares two covariance models, one a special case of the other. To compute it, you must run PROC MIXED twice, once for each of the two models, and then subtract the corresponding values of \(-2\) times the log likelihoods. You can use either ML or REML to construct this statistic, which tests whether the full model is necessary beyond the reduced model.

As long as the reduced model does not occur on the boundary of the covariance parameter space, the \(\chi^2\) statistic computed in this fashion has a large-sample sampling distribution that is \(\chi^2\) with degrees of freedom equal to the difference in the number of covariance parameters between the two models. If the reduced model does occur on the boundary of the covariance parameter space, the asymptotic distribution becomes a mixture of \(\chi^2\) distributions (Self and Liang 1987). A common example of this is when you are testing that a variance component equals its lower boundary constraint of 0.

A final possibility for obtaining inferences concerning the covariance parameters is to simulate or resample data from your model and construct empirical sampling distributions of the parameters. The SAS macro language and the ODS system are useful tools in this regard.
For inferences concerning the fixed- and random-effects parameters in the mixed model, consider estimable linear combinations of the following form:

\[
L \begin{bmatrix}
\beta \\
\gamma
\end{bmatrix}
\]

The estimability requirement (Searle 1971) applies only to the \( \beta \)-portion of \( L \), as any linear combination of \( \gamma \) is estimable. Such a formulation in terms of a general \( L \) matrix encompasses a wide variety of common inferential procedures such as those employed with Type I–Type III tests and LS-means. The CONTRAST and ESTIMATE statements in PROC MIXED enable you to specify your own \( L \) matrices. Typically, inference on fixed-effects is the focus, and, in this case, the \( \gamma \)-portion of \( L \) is assumed to contain all 0s.

Statistical inferences are obtained by testing the hypothesis

\[
H : L \begin{bmatrix}
\beta \\
\gamma
\end{bmatrix} = 0
\]

or by constructing point and interval estimates.

When \( L \) consists of a single row, a general \( t \)-statistic can be constructed as follows (refer to McLean and Sanders 1988, Stroup 1989a):

\[
t = \frac{L \begin{bmatrix}
\hat{\beta} \\
\hat{\gamma}
\end{bmatrix}}{\sqrt{L\hat{C}L'}}
\]

Under the assumed normality of \( \gamma \) and \( \epsilon \), \( t \) has an exact \( t \)-distribution only for data exhibiting certain types of balance and for some special unbalanced cases. In general, \( t \) is only approximately \( t \)-distributed, and its degrees of freedom must be estimated. See the DDFM= option on page 2693 for a description of the various degrees-of-freedom methods available in PROC MIXED.

With \( \tilde{\nu} \) being the approximate degrees of freedom, the associated confidence interval is

\[
L \begin{bmatrix}
\hat{\beta} \\
\hat{\gamma}
\end{bmatrix} \pm t_{\tilde{\nu}, \alpha/2} \sqrt{L\hat{C}L'}
\]

where \( t_{\tilde{\nu}, \alpha/2} \) is the \((1 - \alpha/2)100\)th percentile of the \( t_{\tilde{\nu}} \)-distribution.

When the rank of \( L \) is greater than 1, PROC MIXED constructs the following general \( F \)-statistic:

\[
F = \left( \frac{L' (L\hat{C}L')^{-1} L \begin{bmatrix}
\hat{\beta} \\
\hat{\gamma}
\end{bmatrix}}{\text{rank}(L)} \right)
\]
Analogous to $t$, $F$ in general has an approximate $F$-distribution with $\text{rank}(L)$ numerator degrees of freedom and $\hat{\nu}$ denominator degrees of freedom.

The $t$- and $F$-statistics enable you to make inferences about your fixed effects, which account for the variance-covariance model you select. An alternative is the $\chi^2$ statistic associated with the likelihood ratio test. This statistic compares two fixed-effects models, one a special case of the other. It is computed just as when comparing different covariance models, although you should use ML and not REML here because the penalty term associated with restricted likelihoods depends upon the fixed-effects specification.

**Parameterization of Mixed Models**

Recall that a mixed model is of the form

$$y = X\beta + Z\gamma + \epsilon$$

where $y$ represents univariate data, $\beta$ is an unknown vector of fixed effects with known model matrix $X$, $\gamma$ is an unknown vector of random effects with known model matrix $Z$, and $\epsilon$ is an unknown random error vector.

PROC MIXED constructs a mixed model according to the specifications in the MODEL, RANDOM, and REPEA TED statements. Each effect in the MODEL statement generates one or more columns in the model matrix $X$, and each effect in the RANDOM statement generates one or more columns in the model matrix $Z$. Effects in the REPEA TED statement do not generate model matrices; they serve only to index observations within subjects. This section shows precisely how PROC MIXED builds $X$ and $Z$.

**Intercept**

By default, all models automatically include a column of 1s in $X$ to estimate a fixed-effect intercept parameter $\mu$. You can use the NOINT option in the MODEL statement to suppress this intercept. The NOINT option is useful when you are specifying a classification effect in the MODEL statement and you want the parameter estimate to be in terms of the mean response for each level of that effect, rather than in terms of a deviation from an overall mean.

By contrast, the intercept is not included by default in $Z$. To obtain a column of 1s in $Z$, you must specify in the RANDOM statement either the INTERCEPT effect or some effect that has only one level.

**Regression Effects**

Numeric variables, or polynomial terms involving them, may be included in the model as regression effects (covariates). The actual values of such terms are included as columns of the model matrices $X$ and $Z$. You can use the bar operator with a regression effect to generate polynomial effects. For instance, $X|X|X$ expands to $X \times X \times X \times X \times X$, a cubic model.
Main Effects

If a class variable has \( m \) levels, PROC MIXED generates \( m \) columns in the model matrix for its main effect. Each column is an indicator variable for a given level. The order of the columns is the sort order of the values of their levels and can be controlled with the ORDER= option in the PROC MIXED statement. The following table is an example.

<table>
<thead>
<tr>
<th>Data</th>
<th>I</th>
<th>A</th>
<th>B</th>
</tr>
</thead>
<tbody>
<tr>
<td>A B</td>
<td>μ</td>
<td>A1</td>
<td>A2</td>
</tr>
<tr>
<td>1 1</td>
<td>1</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>1 2</td>
<td>1</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>1 3</td>
<td>1</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>2 1</td>
<td>1</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>2 2</td>
<td>1</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>2 3</td>
<td>1</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

Typically, there are more columns for these effects than there are degrees of freedom for them. In other words, PROC MIXED uses an over-parameterized model.

Interaction Effects

Often a model includes interaction (crossed) effects. With an interaction, PROC MIXED first reorders the terms to correspond to the order of the variables in the CLASS statement. Thus, \( B*A \) becomes \( A*B \) if \( A \) precedes \( B \) in the CLASS statement. Then, PROC MIXED generates columns for all combinations of levels that occur in the data. The order of the columns is such that the rightmost variables in the cross index faster than the leftmost variables. Empty columns (that would contain all 0s) are not generated for \( X \), but they are for \( Z \).
In the preceding matrix, main-effects columns are not linearly independent of crossed-effect columns; in fact, the column space for the crossed effects contains the space of the main effect.

When your model contains many interaction effects, you may be able to code them more parsimoniously using the bar operator ( | ). The bar operator generates all possible interaction effects. For example, $A|B|C$ expands to $A B A^*B C A^*C B^*C A^*B^*C$. To eliminate higher-order interaction effects, use the at sign ( @ ) in conjunction with the bar operator. For instance, $A|B|C|D@2$ expands to $A B A^*B C A^*C B^*C D A^*D B^*D C^*D$.

**Nested Effects**

Nested effects are generated in the same manner as crossed effects. Hence, the design columns generated by the following two statements are the same (but the ordering of the columns is different):

```plaintext
model Y=A B(A);
model Y=A A*B;
```

The nesting operator in PROC MIXED is more a notational convenience than an operation distinct from crossing. Nested effects are typically characterized by the property that the nested variables never appear as main effects. The order of the variables within nesting parentheses is made to correspond to the order of these variables in the CLASS statement. The order of the columns is such that variables outside the parentheses index faster than those inside the parentheses, and the rightmost nested variables index faster than the leftmost variables.

<table>

</tbody>
</table>

Note that nested effects are often distinguished from interaction effects by the implied randomization structure of the design. That is, they usually indicate random effects within a fixed-effects framework. The fact that random effects can be modeled directly in the RANDOM statement may make the specification of nested effects in the MODEL statement unnecessary.

**Continuous-Nesting-Class Effects**

When a continuous variable nests with a class variable, the design columns are constructed by multiplying the continuous values into the design columns for the class effect.
Chapter 46. The MIXED Procedure

Data | I | A | X(A)
--- | --- | --- | ---
X A μ | A1 | A2 | X(A1) | X(A2)
21 1 | 1 | 1 | 0 | 21 | 0
24 1 | 1 | 1 | 0 | 24 | 0
22 1 | 1 | 1 | 0 | 22 | 0
28 2 | 1 | 0 | 1 | 0 | 28
19 2 | 1 | 0 | 1 | 0 | 19
23 2 | 1 | 0 | 1 | 0 | 23

This model estimates a separate slope for X within each level of A.

Continuous-by-Class Effects

Continuous-by-class effects generate the same design columns as continuous-nesting-class effects. The two models are made different by the presence of the continuous variable as a regressor by itself, as well as a contributor to a compound effect.

Data | I | X | A | X*A
--- | --- | --- | --- | ---
X A μ | X | A1 | A2 | X*A | X*A
21 1 | 1 | 21 | 1 | 0 | 21 | 0
24 1 | 1 | 24 | 1 | 0 | 24 | 0
22 1 | 1 | 22 | 1 | 0 | 22 | 0
28 2 | 1 | 28 | 0 | 1 | 0 | 28
19 2 | 1 | 19 | 0 | 1 | 0 | 19
23 2 | 1 | 23 | 0 | 1 | 0 | 23

You can use continuous-by-class effects to test for homogeneity of slopes.

General Effects

An example that combines all the effects is X1*X2*A*B*C(D E). The continuous list comes first, followed by the crossed list, followed by the nested list in parentheses. You should be aware of the sequencing of parameters when you use the CONTRAST or ESTIMATE statements to compute some function of the parameter estimates.

Effects may be renamed by PROC MIXED to correspond to ordering rules. For example, B*A(E D) may be renamed A*B(D E) to satisfy the following:

- Class variables that occur outside parentheses (crossed effects) are sorted in the order in which they appear in the CLASS statement.
- Variables within parentheses (nested effects) are sorted in the order in which they appear in the CLASS statement.

The sequencing of the parameters generated by an effect can be described by which variables have their levels indexed faster:

- Variables in the crossed list index faster than variables in the nested list.
Within a crossed or nested list, variables to the right index faster than variables to the left.

For example, suppose a model includes four effects—A, B, C, and D—each having two levels, 1 and 2. If the CLASS statement is

```plaintext
class A B C D;
```

then the order of the parameters for the effect B*A(C D), which is renamed A*B(C D), is

```plaintext
A1B1C1D1 → A1B2C1D1 → A2B1C1D1 → A2B2C1D1 →
A1B1C1D2 → A1B2C1D2 → A2B1C1D2 → A2B2C1D2 →
A1B1C2D1 → A1B2C2D1 → A2B1C2D1 → A2B2C2D1 →
```

Note that first the crossed effects B and A are sorted in the order in which they appear in the CLASS statement so that A precedes B in the parameter list. Then, for each combination of the nested effects in turn, combinations of A and B appear. The B effect moves fastest because it is rightmost in the cross list. Then A moves next fastest, and D moves next fastest. The C effect is the slowest since it is leftmost in the nested list.

When numeric levels are used, levels are sorted by their character format, which may not correspond to their numeric sort sequence (for example, noninteger levels). Therefore, it is advisable to include a desired format for numeric levels or to use the ORDER=INTERNAL option in the PROC MIXED statement to ensure that levels are sorted by their internal values.

### Implications of the Non-Full-Rank Parameterization

For models with fixed-effects involving class variables, there are more design columns in X constructed than there are degrees of freedom for the effect. Thus, there are linear dependencies among the columns of X. In this event, all of the parameters are not estimable; there is an infinite number of solutions to the mixed model equations. PROC MIXED uses a generalized (g2) inverse to obtain values for the estimates (Searle 1971). The solution values are not displayed unless you specify the SOLUTION option in the MODEL statement. The solution has the characteristic that estimates are 0 whenever the design column for that parameter is a linear combination of previous columns. With this parameterization, hypothesis tests are constructed to test linear functions of the parameters that are estimable.

Some procedures (such as the CATMOD procedure) reparameterize models to full rank using restrictions on the parameters. PROC GLM and PROC MIXED do not reparameterize, making the hypotheses that are commonly tested more understandable. Refer to Goodnight (1978) for additional reasons for not reparameterizing.
**Missing Level Combinations**

PROC MIXED handles missing level combinations of classification variables similarly to the way PROC GLM does. Both procedures delete fixed-effects parameters corresponding to missing levels in order to preserve estimability. However, PROC MIXED does not delete missing level combinations for random-effects parameters because linear combinations of the random-effects parameters are always estimable. These conventions can affect the way you specify your CONTRAST and ESTIMATE coefficients.

---

**Default Output**

The following sections describe the output PROC MIXED produces by default. This output is organized into various tables, and they are discussed in order of appearance.

**Model Information**

The “Model Information” table describes the model, some of the variables it involves, and the method used in fitting it. It also lists the method (profile, fit, factor, or none) for handling the residual variance in the model. The profile method concentrates the residual variance out of the optimization problem, whereas the fit method retains it as a parameter in the optimization. The factor method keeps the residual fixed, and none is displayed when a residual variance is not a part of the model.

The “Model Information” table also has a row labeled Fixed Effects SE Method. This row describes the method used to compute the approximate standard errors for the fixed-effects parameter estimates and related functions of them. The two possibilities for this row are Model-Based, which is the default method, and Empirical, which results from using the EMPIRICAL option in the PROC MIXED statement.

For ODS purposes, the label of the “Model Information” table is “ModelInfo.”

**Class Level Information**

The “Class Level Information” table lists the levels of every variable specified in the CLASS statement. You should check this information to make sure the data are correct. You can adjust the order of the CLASS variable levels with the ORDER= option in the PROC MIXED statement. For ODS purposes, the label of the “Class Level Information” table is “ClassLevels.”

**Dimensions**

The “Dimensions” table lists the sizes of relevant matrices. This table can be useful in determining CPU time and memory requirements. For ODS purposes, the label of the “Dimensions” table is “Dimensions.”

**Number of Observations**

The “Number of Observations” table shows the number of observations read from the data set and the number of observations used in fitting the model.
The “Iteration History” table describes the optimization of the residual log likelihood or log likelihood described on page 2738. The function to be minimized (the objective function) is $-2l$ for ML and $-2l_R$ for REML; the column name of the objective function in the “Iteration History” table is “-2 Log Like” for ML and “-2 Res Log Like” for REML. The minimization is performed using a ridge-stabilized Newton-Raphson algorithm, and the rows of this table describe the iterations that this algorithm takes in order to minimize the objective function.

The Evaluations column of the “Iteration History” table tells how many times the objective function is evaluated during each iteration.

The Criterion column of the “Iteration History” table is, by default, a relative Hessian convergence quantity given by

$$\frac{g_k' H_k^{-1} g_k}{|f_k|}$$

where $f_k$ is the value of the objective function at iteration $k$, $g_k$ is the gradient (first derivative) of $f_k$, and $H_k$ is the Hessian (second derivative) of $f_k$. If $H_k$ is singular, then PROC MIXED uses the following relative quantity:

$$\frac{g_k' g_k}{|f_k|}$$

To prevent the division by $|f_k|$, use the ABSOLUTE option in the PROC MIXED statement. To use a relative function or gradient criterion, use the CONVF or CONVG options, respectively.

The Hessian criterion is considered superior to function and gradient criteria because it measures orthogonality rather than lack of progress (Bates and Watts 1988). Provided the initial estimate is feasible and the maximum number of iterations is not exceeded, the Newton-Raphson algorithm is considered to have converged when the criterion is less than the tolerance specified with the CONVF, CONVG, or CONVH option in the PROC MIXED statement. The default tolerance is $1E^{-8}$. If convergence is not achieved, PROC MIXED displays the estimates of the parameters at the last iteration.

A convergence criterion that is missing indicates that a boundary constraint has been dropped; it is usually not a cause for concern.

If you specify the ITDETAILS option in the PROC MIXED statement, then the covariance parameter estimates at each iteration are included as additional columns in the “Iteration History” table.

For ODS purposes, the label of the “Iteration History” table is “IterHistory.”
Covariance Parameter Estimates

The “Covariance Parameter Estimates” table contains the estimates of the parameters in $G$ and $R$ (see the “Estimating $G$ and $R$ in the Mixed Model” section on page 2737). Their values are labeled in the “Cov Parm” table along with Subject and Group information if applicable. The estimates are displayed in the Estimate column and are the results of one of the following estimation methods: REML, ML, MIVQUE0, SSCP, Type1, Type2, or Type3.

If you specify the RATIO option in the PROC MIXED statement, the Ratio column is added to the table listing the ratios of each parameter estimate to that of the residual variance.

Requesting the COVTEST option in the PROC MIXED statement produces the Std Error, Z Value, and Pr Z columns. The Std Error column contains the approximate standard errors of the covariance parameter estimates. These are the square roots of the diagonal elements of the observed inverse Fisher information matrix, which equals $2H^{-1}$, where $H$ is the Hessian matrix. The $H$ matrix consists of the second derivatives of the objective function with respect to the covariance parameters; refer to Wolfinger, Tobias, and Sall (1994) for formulas. When you use the SCORING= option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute the covariance matrix instead of the observed Hessian. The observed or expected inverse Fisher information matrix can be viewed as an asymptotic covariance matrix of the estimates.

The Z Value column is the estimate divided by its approximate standard error, and the Pr Z column is the one- or two-tailed area of the standard Gaussian density outside of the Z-value. The MIXED procedure computes one-sided p-values for the residual variance and for covariance parameters with a lower bound of 0. The procedure computes two-sided p-values otherwise. These statistics constitute Wald tests of the covariance parameters, and they are valid only asymptotically.

Caution: Wald tests can be unreliable in small samples.

For ODS purposes, the label of the “Covariance Parameter Estimates” table is “CovParms.”

Fit Statistics

The “Fit Statistics” table provides some statistics about the estimated mixed model. Expressions for the $-2$ times the log likelihood are provided in the “Estimating $G$ and $R$ in the Mixed Model” section on page 2737. If the log likelihood is an extremely large number, then PROC MIXED has deemed the estimated $V$ matrix to be singular. In this case, all subsequent results should be viewed with caution.

In addition, the “Fit Statistics” table lists three information criteria: AIC, AICC, and BIC, all in smaller-is-better form. Expressions for these criteria are described under the IC option on page 2676.

For ODS purposes, the label of the “Model Fitting Information” table is “FitStatistics.”
Null Model Likelihood Ratio Test

If one covariance model is a submodel of another, you can carry out a likelihood ratio test for the significance of the more general model by computing \(-2 \times \text{difference between their log likelihoods}\). Then compare this statistic to the \(\chi^2\) distribution with degrees of freedom equal to the difference in the number of parameters for the two models.

This test is reported in the “Null Model Likelihood Ratio Test” table to determine whether it is necessary to model the covariance structure of the data at all. The “Chi-Square” value is \(-2 \times \text{log likelihood from the null model minus } -2 \times \text{log likelihood from the fitted model}\), where the null model is the one with only the fixed effects listed in the MODEL statement and \(R = \sigma^2 I\). This statistic has an asymptotic \(\chi^2\)-distribution with \(q - 1\) degrees of freedom, where \(q\) is the effective number of covariance parameters (those not estimated to be on a boundary constraint). The Pr > ChiSq column contains the upper-tail area from this distribution. This \(p\)-value can be used to assess the significance of the model fit.

This test is not produced for cases where the null hypothesis lies on the boundary of the parameter space, which is typically for variance component models. This is because the standard asymptotic theory does not apply in this case (Self and Liang 1987, Case 5).

If you specify a PARMS statement, PROC MIXED constructs a likelihood ratio test between the best model from the grid search and the final fitted model and reports the results in the “Parameter Search” table.

For ODS purposes, the label of the “Null Model Likelihood Ratio Test” table is “LRT.”

Type 3 Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table contains hypothesis tests for the significance of each of the fixed effects, that is, those effects you specify in the MODEL statement. By default, PROC MIXED computes these tests by first constructing a Type III \(L\) matrix (see Chapter 11, “The Four Types of Estimable Functions,”) for each effect. This \(L\) matrix is then used to compute the following \(F\)-statistic:

\[
F = \frac{\hat{\beta}'L'[L'(X'\hat{V}^{-1}X)^{-1}L']^{-1}L\hat{\beta}}{\text{rank}(L)}
\]

A \(p\)-value for the test is computed as the tail area beyond this statistic from an \(F\)-distribution with NDF and DDF degrees of freedom. The numerator degrees of freedom (NDF) is the row rank of \(L\), and the denominator degrees of freedom is computed using one of the methods described under the DDFM= option on page 2693. Small values of the \(p\)-value (typically less than 0.05 or 0.01) indicate a significant effect.

You can use the HTYPE= option in the MODEL statement to obtain tables of Type I (sequential) tests and Type II (adjusted) tests in addition to or instead of the table of Type III (partial) tests.
You can use the CHISQ option in the MODEL statement to obtain Wald \( \chi^2 \) tests of the fixed effects. These are carried out by using the numerator of the \( F \)-statistic and comparing it with the \( \chi^2 \) distribution with NDF degrees of freedom. It is more liberal than the \( F \)-test because it effectively assumes an infinite denominator degrees of freedom.

For ODS purposes, the label of the “Type 1 Tests of Fixed Effects” through the “Type 3 Tests of Fixed Effects” tables are “Tests1” through “Tests3,” respectively.

**ODS Table Names**

Each table created by PROC MIXED has a name associated with it, and you must use this name to reference the table when using ODS statements. These names are listed in Table 46.8.

</table>

In Table 46.8, “Coef” refers to multiple tables produced by the E, E1, E2, or E3 options in the MODEL statement and the E option in the CONTRAST, ESTIMATE, and LSMEANS statements. You can create one large data set of these tables with a statement similar to

```plaintext
ods output Coef=c;
```

To create separate data sets, use

```plaintext
ods output Coef(match_all)=c;
```

Here the resulting data sets are named C, C1, C2, etc. The same principles apply to data sets created from the “R,” “CholR,” “InvCholR,” “RCorr,” “InvR,” “V,” “CholV,” “InvCholV,” “VCorr,” and “InvV” tables.

In Table 46.8, the following changes have occurred from Version 6. The “Predicted,” “PredMeans,” and “Sample” tables from Version 6 no longer exist and have been replaced by output data sets; see descriptions of the MODEL statement options OUTPRED= on page 2703 and OUTPREDM= on page 2704 and the PRIOR statement option OUT= on page 2711 for more details. The “ML” and “REML” tables from Version 6 have been replaced by the “IterHistory” table. The “Tests,” “HLM,” and “HLPS” tables from Version 6 have been renamed “Tests3,” “HLM3,” and “HLPS3.”
Table 46.9 lists the variable names associated with the data sets created when you use the ODS OUTPUT option in conjunction with the preceding tables. In Table 46.9, \( n \) is used to denote a generic number that is dependent upon the particular data set and model you select, and it can assume a different value each time it is used (even within the same table). The phrase `model specific` appears in rows of the affected tables to indicate that columns in these tables depend upon the variables you specify in the model.

**Caution:** There exists a danger of name collisions with the variables in the `model specific` tables in Table 46.9 and variables in your input data set. You should avoid using input variables with the same names as the variables in these tables.

</table>
Some of the variables listed in Table 46.9 are created only when you have specified certain options in the relevant PROC MIXED statements.

Converting from Previous Releases

The following changes have occurred in variables listed in Table 46.9 from Version 6. Nearly all underscores have been removed from variable names in order to be compatible and consistent with other procedures. Some of the variable names have been changed (for example, T has been changed to tValue and PT to Probt) for the same reason. You may have to modify some of your Version 6 code to accommodate these changes.

In Version 6, PROC MIXED used a MAKE statement to save displayed output as data sets. The MAKE statement is now obsolete and may not be supported in future releases. Use the ODS OUTPUT statement instead. The following table shows typical conversions in order to replace the MAKE statement in Version 6 code with ODS statements.

Table 46.10. ODS Conversions for PROC MIXED

ODS Graphics (Experimental)

This section describes the use of ODS for creating diagnostic plots with the MIXED procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement. In addition you must specify the relevant options of the PROC MIXED or MODEL statement (Table 46.11). To request plots of studentized residuals, for example, specify the experimental RESIDUAL option of the MODEL statement. To obtain graphical displays of leave-one-out parameter estimates, specify the experimental INFLUENCE option with the ESTIMATES suboption.
Residual Plots

With the experimental graphics features the MIXED procedure can generate panels of residual diagnostics. Each panel consists of a plot of residuals versus predicted values, a histogram with Normal density overlaid, a Q-Q plot, and summary residual and fit statistics (Figure 46.15). The plots are produced even if the OUTP= and OUTPM= options of the MODEL statement are not specified. Three such panels are produced for the marginal residuals which would be added to the OUTPM= data set. The panels display the raw, studentized, and Pearson residuals (see “Residual Diagnostics”). In models with random effects where EBLUPs can be used for prediction, the raw, studentized and Pearson conditional residuals are also plotted.

Recall the example in the “Getting Started” section on page 2665. The following statements generate six $2 \times 2$ panels of residual graphs.

```latex
ods html;
ods graphics on;

proc mixed;
  class Family Gender;
  model Height = Gender / residual;
  random Family Family*Gender;
run;

ods graphics off;
ods html close;
```

The graphical displays are requested by specifying the experimental ODS GRAPHICS statement. The panel for the marginal studentized residuals is shown in Figure 46.15 and the panel for the conditional studentized residuals in Figure 46.16.
Figure 46.15. Marginal Studentized Residual Panel (Experimental)

Figure 46.16. Conditional Studentized Residual Panel (Experimental)
A similar panel display for the scaled residuals is produced when you specify the experimental VCIRY option of the MODEL statement; see option VCIRY on page 2705 for more details.

The “Residual Statistics” in the lower right-hand corner inset provides descriptive statistics for the set of residuals that is displayed. Note that residuals in a mixed model do not necessarily sum to zero, even if the model contains an intercept.

**Influence Plots**

With the experimental graphics features the MIXED procedure can generate one or more panels of influence graphics. The type and number of panels produced depends on the modifiers of the INFLUENCE option. Plots related to covariance parameters are produced when diagnostics are computed by iterative methods (ITER=). The estimates of the fixed effects—and covariance parameters when updates are iterative—are plotted when the ESTIMATES modifier is specified.

The two types of panel graphs produced by the INFLUENCE option are shown in Figure 46.17 and Figure 46.18. The diagnostics panel shows an overall influence statistic (likelihood distance) and diagnostics for the fixed effects (CookD and COVRATIO). The statistics produced depend on suboptions of the INFLUENCE option (see Example 46.8 for the statements and options that produced Figure 46.17). Reference lines are drawn at zero for PRESS residuals and COVTRACE, and at one for COVRATIO. A reference line for likelihood distances is drawn at the 75th percentile of a chi-square distribution with \( m \) degrees of freedom if the largest displacement value in the “Influence” table is close to or larger than that percentile. The number \( m \) equals the number of parameters being updated.
Figure 46.17. Influence Diagnostics (Experimental)

Figure 46.18. Delete Estimates (Experimental)
The second type of influence panel plot is obtained when you specify the
ESTIMATES suboption (Figure 46.18). It shows the delete-estimates for each
updated model parameter. Reference lines are drawn at the full data estimates. For
noniterative influence analyses with profiled residual variance, the delete-case root
mean square error is also plotted.

For the SAS statements that produce influence plots and for variations of these graphs
see Example 46.7 and Example 46.8.

**Box Plots**

You can specify the BOXPLOT option in the PROC MIXED statement.

**BOXPLOT**<suboptions>

requests box plots of observed and residual values $Y - X\hat{\beta}$ for effects that consist of
single CLASS variables. This includes SUBJECT= and GROUP= effects.

For models with a RANDOM statement you also obtain box plots of the conditional
residuals $Y - X\hat{\beta} - Z\hat{\gamma}$. The box plots are constructed from studentized residuals
when the RESIDUAL option of the MODEL statement is specified.

The following suboptions modify the appearance of the plots:

**DATALABEL | NODATALABEL**

determines whether to place observation labels next to far outliers. Far outliers
are labeled by default.

**FILL | NOFILL**

determines whether the boxes are filled. The default is FILL.

**NPANEL=n**

limits the number of boxes per plot. The default is to place box plots for all
levels of a factor in a common panel.

See Example 46.8 for an application.

**ODS Graph Names**

The MIXED procedure assigns a name to each graph it creates using ODS. You can
use these names to reference the graphs when using ODS. The names are listed in
Table 46.11.

To request these graphs, you must specify the ODS GRAPHICS statement in ad-
dition to the options indicated in Table 46.11. For more information on the ODS
GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

Residual Diagnostics

Consider a residual vector of the form $\tilde{e} = PY$, where $P$ is a projection matrix, possibly an oblique projector. A typical element $\tilde{e}_i$ with variance $v_i$ and estimated variance $\hat{v}_i$ is said to be standardized as

$$\frac{\tilde{e}_i}{\sqrt{\text{var}[\tilde{e}_i]}} = \frac{\tilde{e}_i}{\sqrt{\hat{v}_i}}$$

and studentized as

$$\frac{\tilde{e}_i}{\sqrt{\hat{v}_i}}$$

External studentization uses an estimate of $\text{var}[\tilde{e}_i]$ which does not involve the $i$th observation. Externally studentized residuals are often preferred over studentized residuals because they have well-known distributional properties in standard linear models for independent data.

Residuals that are scaled by the estimated variance of the response, i.e., $\tilde{e}_i/\sqrt{\text{var}[Y_i]}$, are referred to as Pearson-type residuals.
Marginal and Conditional Residuals

The marginal and conditional means in the linear mixed model are \( E[Y] = X\beta \) and \( E[Y|\gamma] = X\beta + Z\gamma \), respectively. Accordingly, the vector \( r_m \) of marginal residuals is defined as

\[
r_m = Y - X\hat{\beta}
\]

and the vector \( r_c \) of conditional residuals is

\[
r_c = Y - X\hat{\beta} - Z\hat{\gamma} = r_m - Z\hat{\gamma}
\]

Following Gregoire, Schabenberger, and Barrett (1995), let \( Q = X(X'\hat{V}^{-1}X)^{-1}X' \) and \( K = I - ZGZ'\hat{V}^{-1} \). Then

\[
\hat{\text{var}}[r_m] = \hat{V} - Q
\]
\[
\hat{\text{var}}[r_c] = K(\hat{V} - Q)K'
\]

For an individual observation the raw, studentized, and Pearson residuals computed by the RESIDUAL option of the MODEL statement are given in the following table.

<table>
<thead>
<tr>
<th>Type of Residual</th>
<th>Marginal</th>
<th>Conditional</th>
</tr>
</thead>
<tbody>
<tr>
<td>Raw</td>
<td>( r_{mi} = Y_i - x_i'\hat{\beta} )</td>
<td>( r_{ci} = r_{mi} - z_i'\hat{\gamma} )</td>
</tr>
<tr>
<td>Studentized</td>
<td>( r_{mi}^{\text{student}} = \frac{r_{mi}}{\sqrt{\hat{\text{var}}[r_{mi}]} )</td>
<td>( r_{ci}^{\text{student}} = \frac{r_{ci}}{\sqrt{\hat{\text{var}}[r_{ci}]} )</td>
</tr>
<tr>
<td>Pearson</td>
<td>( r_{mi}^{\text{pearson}} = \frac{r_{mi}}{\sqrt{\hat{\text{var}}[Y_i]} )</td>
<td>( r_{ci}^{\text{pearson}} = \frac{r_{ci}}{\sqrt{\hat{\text{var}}[Y_i</td>
</tr>
</tbody>
</table>

When the OUTPM= option of the MODEL statement is specified in addition to the RESIDUAL option, \( r_{mi}, r_{mi}^{\text{student}}, \) and \( r_{mi}^{\text{pearson}} \) are added to the data set as variables Resid, StudentResid, and PearsonResid, respectively. When the OUTP= option is specified, \( r_{ci}, r_{ci}^{\text{student}}, \) and \( r_{ci}^{\text{pearson}} \) are added to the data set.

Scaled Residuals

For correlated data, a set of scaled quantities can be defined through the Cholesky decomposition of the variance-covariance matrix. Since fitted residuals in linear models are rank-deficient, it is customary to draw on the variance-covariance matrix of the data. If \( \text{var}[Y] = V \) and \( C'C = V \), then \( C'^{-1}Y \) has uniform dispersion and its elements are uncorrelated.

Scaled residuals in a mixed model are meaningful for quantities based on the marginal distribution of the data. Let \( \hat{C} \) denote the Cholesky root of \( \hat{V} \), so that \( \hat{C}'\hat{C} = \hat{V} \), and define

\[
Y_c = \hat{C}'^{-1}Y
\]
\[
r_{m(c)} = \hat{C}'^{-1}r_m
\]
By analogy with other scalings, the inverse Cholesky decomposition can also be applied to the residual vector, $\hat{C}^{-1}r_m$, although $V$ is not the variance-covariance matrix of $r_m$.

To diagnose whether the covariance structure of the model has been specified correctly can be difficult based on $Y_c$, since the inverse Cholesky transformation affects the expected value of $Y_c$. You can draw on $r_{m(c)}$ as a vector of (approximately) uncorrelated data with constant mean.

When the OUTPM= option of the MODEL statement is specified in addition to the VCIRY option, $Y_c$ is added as variable ScaledDep and $r_{m(c)}$ is added as ScaledResid to the data set.

**Influence Diagnostics**

**The Basic Idea and Statistics**

The general idea of quantifying the influence of one or more observations relies on computing parameter estimates based on all data points, removing the cases in question from the data, refitting the model, and computing statistics based on the change between full-data and reduced-data estimation. Influence statistics can be coarsely grouped by the aspect of estimation which is their primary target:

- overall measures compare changes in objective functions: (restricted) likelihood distance (Cook and Weisberg 1982, Ch. 5.2)
- influence on parameter estimates: Cook’s $D$ (Cook 1977, 1979), MDFFITS (Belsley, Kuh, and Welsch 1980, p. 32)
- influence on precision of estimates: CovRatio and CovTrace
- influence on fitted and predicted values: PRESS residual, PRESS statistic (Allen 1974), DFFITS (Belsley, Kuh, and Welsch 1980, p. 15)
- outlier properties: Internally and externally studentized residuals, leverage

For linear models for uncorrelated data, it is not necessary to refit the model after removing a data point in order to measure the impact of an observation on the model. The change in fixed effect estimates, residuals, residual sums of squares, and the variance-covariance matrix of the fixed effects can be computed based on the fit to the full data alone. By contrast, in mixed models several important complications arise. Data points can impact not only the fixed effects but also the covariance parameter estimates on which the fixed effects estimates depend. Furthermore, closed-form expressions for computing the change in important model quantities may not be available.

This section provides background material for the various influence diagnostics available with the MIXED procedure. See the section “Mixed Models Theory” beginning on page 2731 for relevant expressions and definitions. The parameter vector $\theta$ denotes all unknown parameters in the $R$ and $G$ matrix.

The observations whose influence is being ascertained are represented by the set $U$ and referred to simply as “the observations in $U$.” The estimate of a parameter vector,
for example, \( \beta \), obtained from all observations except those in the set \( U \) is denoted \( \hat{\beta}_{(U)} \). In case of a matrix \( A \), the notation \( A_{(U)} \) represents the matrix with the rows in \( U \) removed; these rows are collected in \( A_U \). If \( A \) is symmetric, then notation \( A_{(U)} \) implies removal of rows and columns. The vector \( Y_U \) comprises the responses of the data points being removed, and \( V_{(U)} \) is the variance-covariance matrix of the remaining observations. When \( k = 1 \), lowercase notation emphasizes that single points are removed, e.g., \( A_{(u)} \).

### Managing the Covariance Parameters

An important component of influence diagnostics in the mixed model is the estimated variance-covariance matrix \( V = ZGZ' + R \). To make the dependence on the vector of covariance parameters explicit, write it as \( V(\theta) \). If one parameter, \( \sigma^2 \), is profiled or factored out of \( V \), the remaining parameters are denoted as \( \theta^* \). Notice that in a model where \( G \) is diagonal and \( R = \sigma^2 I \), the parameter vector \( \theta^* \) contains the ratios of each variance component and \( \sigma^2 \) (see Wolfinger, Tobias, and Sall 1994). When ITER=0, two scenarios are distinguished:

1. If the residual variance is not profiled, either because the model does not contain a residual variance or because it is part of the Newton-Raphson iterations, then \( \hat{\theta}_{(U)} \equiv \hat{\theta} \).

2. If the residual variance is profiled then \( \hat{\theta}^*_{(U)} \equiv \hat{\theta}^* \) and \( \hat{\sigma}^2_{(U)} \neq \hat{\sigma}^2 \). Influence statistics such as Cook’s \( D \) and internally studentized residuals are based on \( V(\hat{\theta}) \) whereas externally studentized residuals and the DFFITS statistic are based on \( V(\hat{\theta}_{(U)}) = \hat{\sigma}^2_{(U)} V(\theta^*) \). In a random components model with uncorrelated errors, for example, the computation of \( V(\hat{\theta}_{(U)}) \) involves scaling of \( \hat{G} \) and \( \hat{R} \) by the full data estimate \( \hat{\sigma}^2 \) and multiplying the result with the reduced-data estimate \( \hat{\sigma}^2_{(U)} \).

Certain statistics, such as MDFFITS, COVRATIO, and COVTRACE, require an estimate of the variance of the fixed effects that is based on the reduced number of observations. For example, \( V(\hat{\theta}_{(U)}) \) is evaluated at the reduced-data parameter estimates but computed for the entire data set. The matrix \( V_{(U)}(\hat{\theta}_{(U)}) \), on the other hand, has rows and columns corresponding to the points in \( U \) removed. The resulting matrix is evaluated at the delete-case estimates.

When influence analysis is iterative, the entire vector \( \theta \) is updated, whether the residual variance is profiled or not. The matrices to be distinguished here are \( V(\hat{\theta}) \), \( V(\hat{\theta}_{(U)}) \), and \( V_{(U)}(\hat{\theta}_{(U)}) \), with unambiguous notation.

### Predicted Values, PRESS Residual, and PRESS Statistic

An unconditional predicted value is \( \hat{y}_i = x_i' \hat{\beta} \), where the vector \( x_i \) is the \( i \)th row of \( X \). The (raw) residual is given as \( \hat{\epsilon}_i = y_i - \hat{y}_i \) and the PRESS residual is

\[
\hat{\epsilon}_{i(U)} = y_i - x_i' \hat{\beta}_{(U)}
\]
The **PRESS statistic** is the sum of the squared PRESS residuals,

\[ \text{PRESS} = \sum_{i \in U} \hat{\epsilon}_i^2(U) \]

where the sum is over the observations in \( U \).

If \text{EFFECT=}, \text{SIZE=}, or \text{KEEP=} are not specified, PROC MIXED computes the PRESS residual for each observation selected through \text{SELECT=} (or all observations if \text{SELECT=} is not given). If \text{EFFECT=}, \text{SIZE=}, or \text{KEEP=} are specified, the procedure computes \text{PRESS}.

**Leverage**

For the general mixed model, leverage can be defined through the projection matrix that results from a transformation of the model with the inverse of the Cholesky decomposition of \( V \), or through an oblique projector. The MIXED procedure follows the latter path in the computation of influence diagnostics. The leverage value reported for the \( i \)th observation is the \( i \)th diagonal entry of the matrix

\[ H = X(X'V(\hat{\theta})^{-1}X)^{-1}X'V(\hat{\theta})^{-1} \]

which is the weight of the observation in contributing to its own predicted value, \( H = d\hat{Y}/dY \).

While \( H \) is idempotent, it is generally not symmetric and thus not a projection matrix in the narrow sense.

The properties of these leverages are generalizations of the properties in models with diagonal variance-covariance matrices. For example, \( \hat{Y} = HY \), and in a model with intercept and \( V = \sigma^2I \), the leverage values

\[ h_{ii} = x_i'(X'X)^{-1}x_i \]

are \( h_{ii}^l = 1/n \leq h_{ii} \leq 1 = h_{ii}^u \) and \( \sum_{i=1}^n h_{ii} = \text{rank}(X) \). The lower bound for \( h_{ii} \) is achieved in an intercept-only model, the upper bound in a saturated model. The trace of \( H \) equals the rank of \( X \).

If \( \nu_{ij} \) denotes the element in row \( i \), column \( j \) of \( V^{-1} \), then for a model containing only an intercept the diagonal elements of \( H \) are

\[ h_{ii} = \frac{\sum_{j=1}^n \nu_{ij}}{\sum_{i=1}^n \sum_{j=1}^n \nu_{ij}} \]

Because \( \sum_{j=1}^n \nu_{ij} \) is a sum of elements in the \( i \)th row of the inverse variance-covariance matrix \( h_{ii} \) can be negative, even if the correlations among data points are nonnegative. In case of a saturated model with \( X = I \), \( h_{ii} = 1.0 \).
Internally and Externally Studentized Residuals

See the section “Residual Diagnostics” on page 2763 for the distinction between standardization, studentization, and scaling of residuals. Internally studentized marginal and conditional residuals are computed with the RESIDUAL option of the MIXED procedure (p. 2763). The INFLUENCE option computes internally and externally studentized marginal residuals.

The computation of internally studentized residuals relies on the diagonal entries of $V(\hat{\theta}) - Q(\hat{\theta}) = X(X'V(\hat{\theta})^{-1}X)^{-}X'$. Externally studentized residuals require iterative influence analysis or a profiled residual variance. In the former case the studentization is based on $V(\hat{\theta}_U)$; in the latter case it is based on $\sigma^2(U) \text{V}(\hat{\theta}^*)$.

Cook’s $D$

Cook’s $D$ statistic is an invariant norm that measures the influence of observations in $U$ on a vector of parameter estimates (Cook 1977). In case of the fixed effects coefficients, let

$$\delta(U) = \hat{\beta} - \hat{\beta}_U$$

Then the MIXED procedure computes

$$D(\beta) = \delta'(U) \text{var}[\hat{\beta}]^{-} \delta(U)/\text{rank}(X)$$

where $\text{var}[\hat{\beta}]^{-}$ is the matrix that results from sweeping $(X'V(\hat{\theta})^{-1}X)^{-}$.

If $V$ is known, Cook’s $D$ can be calibrated according to a chi-square distribution with degrees of freedom equal to the rank of $X$ (Christensen, Pearson, and Johnson 1992). For estimated $V$ the calibration can be carried out according to an $F(\text{rank}(X), n - \text{rank}(X))$ distribution. To interpret $D$ on a familiar scale, Cook (1979) and Cook and Weisberg (1982, p. 116) refer to the 50th percentile of the reference distribution. If $D$ is equal to that percentile, then removing the points in $U$ moves the fixed effects coefficient vector from the center of the confidence region to the 50% confidence ellipsoid (Myers 1990, p. 262).

In the case of iterative influence analysis, the MIXED procedure also computes a $D$-type statistic for the covariance parameters. If $\Gamma$ is the asymptotic variance-covariance matrix of $\hat{\theta}$, then MIXED computes

$$D_\theta = (\hat{\theta} - \hat{\theta}_U)'\Gamma^{-1}(\hat{\theta} - \hat{\theta}_U)$$

DFFITS and MDFFITS

A DFFIT measures the change in predicted values due to removal of data points. If this change is standardized by the externally estimated standard error of the predicted value in the full data, the DFFITS statistic of Belsley, Kuh, and Welsch (1980, p. 15) results:

$$\text{DFFITS}_i = (\hat{y}_i - \hat{y}_{i(u)})/\text{ese}(\hat{y}_i)$$
The MIXED procedure computes DFFITS when the EFFECT= or SIZE= modifiers of the INFLUENCE option are not in effect. In general, an external estimate of the estimated standard error is used. When ITER > 0, the estimate is

$$ese(y_i) = \sqrt{x_i'(X'V(\hat{\theta}_u)^{-1}X)x_i}$$

When ITER=0 and $\sigma^2$ is profiled, then

$$ese(y_i) = \hat{\sigma}(u) \sqrt{x_i'(X'V(\hat{\theta}_*)^{-1}X)x_i}$$

When the EFFECT=, SIZE=, or KEEP= modifiers are specified, the MIXED procedure computes a multivariate version suitable for the deletion of multiple data points. The statistic, termed MDFFITS after the MDFFIT statistic of Belsley, Kuh, and Welsch (1980, p. 32), is closely related to Cook’s $D$. Consider the case $V = \sigma^2 V(\theta^*)$ so that

$$\text{var}[^{\hat{\beta}}] = \sigma^2 (X'V(\theta^*)^{-1}X)^{-1}$$

and let $\tilde{\text{var}}[^{\hat{\beta}(U)}]$ be an estimate of $\text{var}[^{\hat{\beta}(U)}]$ that does not use the observations in $U$. The MDFFITS statistic is then computed as

$$\text{MDFFITS}(\beta) = \delta'(U) \tilde{\text{var}}[^{\hat{\beta}(U)}]^{-1} \delta(U)/\text{rank}(X)$$

If ITER=0 and $\sigma^2$ is profiled, then $\tilde{\text{var}}[^{\hat{\beta}(U)}]$ is obtained by sweeping

$$\hat{\sigma}^2(U)(X'_U V(U)(\hat{\theta}_*)^{-1}X(U))^{-1}$$

The underlying idea is that if $\theta^*$ were known, then

$$(X'_U V(U)(\theta^*)^{-1}X(U))^{-1}$$

would be $\text{var}[^{\hat{\beta}}]/\sigma^2$ in a generalized least squares regression with all but the data in $U$.

In the case of iterative influence analysis, $\tilde{\text{var}}[^{\hat{\beta}(U)}]$ is evaluated at $\hat{\theta}(U)$. Furthermore, a MDFFITS-type statistic is then computed for the covariance parameters:

$$\text{MDFFITS}(\theta) = (\hat{\theta} - \hat{\theta}(U))'\tilde{\text{var}}[^{\hat{\theta}(U)}]^{-1}(\hat{\theta} - \hat{\theta}(U))$$
Covariance Ratio and Trace

These statistics depend on the availability of an external estimate of \( V \), or at least of \( \sigma^2 \). Whereas Cook’s \( D \) and MDFFITS measure the impact of data points on a vector of parameter estimates, the covariance-based statistics measure impact on their precision. Following Christensen, Pearson, and Johnson (1992), the MIXED procedure computes

\[
\text{COVTRACE}(\beta) = |\text{trace}(\hat{\text{var}}[\beta] - \hat{\text{var}}[\beta(U)])| - \text{rank}(X)
\]

\[
\text{COVRATIO}(\beta) = \frac{\text{det}_{ns}(\hat{\text{var}}[\beta(U)])}{\text{det}_{ns}(\hat{\text{var}}[\beta])}
\]

where \( \text{det}_{ns}(M) \) denotes the determinant of the nonsingular part of matrix \( M \).

In the case of iterative influence analysis these statistics are also computed for the covariance parameter estimates. If \( q \) denotes the rank of \( \text{var}[\hat{\theta}] \), then

\[
\text{COVTRACE}(\theta) = |\text{trace}(\hat{\text{var}}[\theta] - \hat{\text{var}}[\theta(U)])| - q
\]

\[
\text{COVRATIO}(\theta) = \frac{\text{det}_{ns}(\hat{\text{var}}[\theta(U)])}{\text{det}_{ns}(\hat{\text{var}}[\theta])}
\]

Likelihood Distances

The log-likelihood function \( l \) and restricted log-likelihood function \( l_R \) of the linear mixed model are given in the section “Estimating G and R in the Mixed Model” beginning on page 2737. Denote as \( \psi \) the collection of all parameters, i.e., the fixed effects \( \beta \) and the covariance parameters \( \theta \). Twice the difference between the (restricted) log-likelihood evaluated at the full-data estimates \( \hat{\psi} \) and at the reduced-data estimates \( \hat{\psi}(U) \) is known as the (restricted) likelihood distance:

\[
\text{RLD}(U) = 2\{l_R(\hat{\psi}) - l_R(\hat{\psi}(U))\}
\]

\[
\text{LD}(U) = 2\{l(\hat{\psi}) - l(\hat{\psi}(U))\}
\]

Cook and Weisberg (1982, Ch. 5.2) refer to these differences as likelihood distances, Beckman, Nachtsheim, and Cook (1987) term the measures likelihood displacements. If the number of elements in \( \psi \) that are subject to updating following point removal is \( q \), then likelihood displacements can be compared against cutoffs from a chi-square distribution with \( q \) degrees of freedom. Notice that this reference distribution does not depend on the number of observations removed from the analysis, but rather on the number of model parameters that are updated. The likelihood displacement gives twice the amount by which the log-likelihood of the full data changes if one were to utilize an estimate based on fewer data points. It is thus a global, summary measure of the influence of the observations in \( U \) jointly on all parameters.

Unless METHOD=ML, the MIXED procedure computes the likelihood displacement based on the residual (=restricted) log likelihood, even if METHOD=MIVQUE0 or METHOD=TYPE1, TYPE2, or TYPE3.
Noniterative Update Formulas

Update formulas that do not require refitting of the model are available for the cases where $V = \sigma^2 I$, $V$ is known, or $V^*$ is known. When ITER=0 and these update formulas can be invoked, the MIXED procedure uses the computational devices that are outlined in the following paragraphs. It is then assumed that the variance-covariance matrix of the fixed effects has the form $(X'V^{-1}X)^{-1}$. When DDFM=KENWARDROGER, this is not the case; the estimated variance-covariance matrix is then inflated to better represent the uncertainty in the estimated covariance parameters. Influence statistics when DDFM=KENWARDROGER should iteratively update the covariance parameters (ITER > 0). The dependence of $V$ on $\theta$ is suppressed in the sequel for brevity.

Updating the Fixed Effects

Denote by $U$ the $(n \times k)$ matrix that is assembled from $k$ columns of the identity matrix. Each column of $U$ corresponds to the removal of one data point. The point being targeted by the $i$th column of $U$ corresponds to the row in which a 1 appears. Furthermore, define

\[ \Omega = (X'V^{-1}X)^{-1} \]
\[ Q = X\Omega X' \]
\[ P = V^{-1}(V - Q)V^{-1} \]

The change in the fixed effects estimates following removal of the observations in $U$ is

\[ \hat{\beta} - \hat{\beta}_{(U)} = \Omega X'V^{-1}U(U'PU)^{-1}U'V^{-1}(y - X\hat{\beta}) \]

Using results in Cook and Weisberg (1982, A2) you can further compute

\[ \tilde{\Omega} = (X'_{(U)}V^{-1}_{(U)}X_{(U)})^{-1} = \Omega + \Omega X'V^{-1}U(U'PU)^{-1}U'V^{-1}X\Omega \]

If $X$ is $(n \times p)$ of rank $m < p$, then $\Omega$ is deficient in rank and the MIXED procedure computes needed quantities in $\tilde{\Omega}$ by sweeping (Goodnight 1979). If the rank of the $(k \times k)$ matrix $U'PU$ is less than $k$, the removal of the observations introduces a new singularity, whether $X$ is of full rank or not. The solution vectors $\hat{\beta}$ and $\hat{\beta}_{(U)}$ then do not have the same expected values and should not be compared. When the MIXED procedure encounters this situation, influence diagnostics that depend on the choice of generalized inverse are not computed. The procedure also monitors the singularity criteria when sweeping the rows of $(X'V^{-1}X)^{-1}$ and of $(X'_{(U)}V^{-1}_{(U)}X_{(U)})^{-1}$. If a new singularity is encountered or a former singularity disappears, no influence statistics are computed.
Residual Variance

When $\sigma^2$ is profiled out of the marginal variance-covariance matrix, a closed-form estimate of $\sigma^2$ that is based on only the remaining observations can be computed provided $V^* = V(\hat{\theta}^*)$ is known. Hurtado (1993, Thm. 5.2) shows that

$$(n - q - r)\hat{\sigma}^2_{(U)} = (n - q)\hat{\sigma}^2 - \hat{e}_U'(\hat{\sigma}^2 U'PU)^{-1}\hat{e}_U,$$

and $\hat{e}_U = U'V^*-1(y - X\hat{\beta})$. In the case of maximum likelihood estimation $q = 0$ and for REML estimation $q = \text{rank}(X)$. The constant $r$ equals the rank of $(U'PU)$ for REML estimation and the number of effective observations that are removed if METHOD=ML.

Likelihood Distances

For noniterative methods the following computational devices are used to compute (restricted) likelihood distances provided that the residual variance $\sigma^2$ is profiled.

The log-likelihood function $l(\hat{\theta})$ evaluated at the full-data and reduced-data estimates can be written as

$$l(\hat{\psi}) = -\frac{n}{2} \log(\hat{\sigma}^2) - \frac{1}{2} \log |V^*| - \frac{1}{2} (y - X\hat{\beta})'V^*-1(y - X\hat{\beta})/\hat{\sigma}^2 - \frac{n}{2} \log(2\pi)$$

$$l(\hat{\psi}_{(U)}) = -\frac{n}{2} \log(\hat{\sigma}^2_{(U)}) - \frac{1}{2} \log |V^*| - \frac{1}{2} (y - X\hat{\beta}_{(U)})'V^*-1(y - X\hat{\beta}_{(U)})/\hat{\sigma}^2_{(U)} - \frac{n}{2} \log(2\pi)$$

Notice that $l(\hat{\theta}_{(U)})$ evaluates the log-likelihood for $n$ data points at the reduced-data estimates. It is not the log-likelihood obtained by fitting the model to the reduced data. The likelihood distance is then

$$LD_{(U)} = n \log(\frac{\hat{\sigma}^2_{(U)}}{\hat{\sigma}^2}) - n + (y - X\hat{\beta}_{(U)})'V^*-1(y - X\hat{\beta}_{(U)})/\hat{\sigma}^2_{(U)}$$

Expressions for $RLD_{(U)}$ in noniterative influence analysis are derived along the same lines.

Computational Issues

Computational Method

In addition to numerous matrix-multiplication routines, PROC MIXED frequently uses the sweep operator (Goodnight 1979) and the Cholesky root (Golub and Van Loan 1989). The routines perform a modified W transformation (Goodnight and Hemmerle 1979) for G-side likelihood calculations and a direct method for R-side likelihood calculations. For the Type III F-tests, PROC MIXED uses the algorithm described in Chapter 32, “The GLM Procedure.”
PROC MIXED uses a ridge-stabilized Newton-Raphson algorithm to optimize either a full (ML) or residual (REML) likelihood function. The Newton-Raphson algorithm is preferred to the EM algorithm (Lindstrom and Bates 1988). PROC MIXED profiles the likelihood with respect to the fixed effects and also with respect to the residual variance whenever it appears reasonable to do so. The residual profiling can be avoided by using the NOPROFILE option of the PROC MIXED statement. PROC MIXED uses the MIVQUE0 method (Rao 1972; Giesbrecht 1989) to compute initial values.

The likelihoods that PROC MIXED optimizes are usually well-defined continuous functions with a single optimum. The Newton-Raphson algorithm typically performs well and finds the optimum in a few iterations. It is a quadratically converging algorithm, meaning that the error of the approximation near the optimum is squared at each iteration. The quadratic convergence property is evident when the convergence criterion drops to zero by factors of 10 or more.

</tr>
</tbody>
</table>

Using the notation from Table 46.12, the following are estimates of the computational speed of the algorithms used in PROC MIXED. For likelihood calculations, the crossproducts matrix construction is of order $N(p + g)^2$ and the sweep operations are of order $(p + g)^3$. The first derivative calculations for parameters in $G$ are of order $qg^3$ for ML and $q(g^3 + pg^2 + p^2g)$ for REML. If you specify a subject effect in the RANDOM statement and if you are not using the REPEATED statement, then replace $g$ by $g/S$ and $q$ by $qS$ in these calculations. The first derivative calculations for parameters in $R$ are of order $qS(t^3 + gt^2 + g^2t)$ for ML and $qS(t^3 + (p + g)t^2 + (p^2 + g^2)t)$ for REML. For the second derivatives, replace $q$ by $q(q + 1)/2$ in the first derivative expressions. When you specify both $G$- and $R$-side parameters (that is, when you use both the RANDOM and REPEATED statements), then additional calculations are required of an order equal to the sum of the orders for $G$ and $R$. Considerable execution times may result in this case.

For further details about the computational techniques used in PROC MIXED, refer to Wolfinger, Tobias, and Sall (1994).

### Parameter Constraints

By default, some covariance parameters are assumed to satisfy certain boundary constraints during the Newton-Raphson algorithm. For example, variance components are constrained to be nonnegative and autoregressive parameters are constrained to be between $-1$ and 1. You can remove these constraints with the NOBOUND option in the PARMs statement, but this may lead to estimates that produce an infinite likelihood. You can also introduce or change boundary constraints with the LOWERB= and UPPERB= options in the PARMs statement.
During the Newton-Raphson algorithm, a parameter may be set equal to one of its boundary constraints for a few iterations and then it may move away from the boundary. You see a missing value in the Criterion column of the “Iteration History” table whenever a boundary constraint is dropped.

For some data sets the final estimate of a parameter may equal one of its boundary constraints. This is usually not a cause for concern, but it may lead you to consider a different model. For instance, a variance component estimate can equal zero; in this case, you may want to drop the corresponding random effect from the model. However, be aware that changing the model in this fashion can impact degrees of freedom calculations.

**Convergence Problems**

For some data sets, the Newton-Raphson algorithm can fail to converge. Non-convergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data.

It is also possible for PROC MIXED to converge to a point that is not the global optimum of the likelihood, although this usually occurs only with the spatial covariance structures.

If you experience convergence problems, the following points may be helpful:

- One useful tool is the PARMS statement, which lets you input initial values for the covariance parameters and performs a grid search over the likelihood surface.

- Sometimes the Newton-Raphson algorithm does not perform well when two of the covariance parameters are on a different scale; that is, they are several orders of magnitude apart. This is because the Hessian matrix is processed jointly for the two parameters, and elements of it corresponding to one of the parameters can become close to internal tolerances in PROC MIXED. In this case, you can improve stability by rescaling the effects in the model so that the covariance parameters are on the same scale.

- Data that is extremely large or extremely small can adversely affect results because of the internal tolerances in PROC MIXED. Rescaling it can improve stability.

- For stubborn problems, you may want to specify ODS OUTPUT COVPARMS= data-set-name to output the “CovParms” table as a precautionary measure. That way, if the problem does not converge, you can read the final parameter values back into a new run with the PARMSDATA= option in the PARMS statement.

- Fisher scoring can be more robust than Newton-Raphson to poor MIVQUE(0) starting values. Specifying a SCORING= value of 5 or so may help to recover from poor starting values.

- Tuning the singularity options SINGULAR=, SINGCHOL=, and SINGRES= in the MODEL statement may improve the stability of the optimization process.
- Tuning the MAXITER= and MAXFUNC= options in the PROC MIXED statement can save resources. Also, the ITDETAILS option displays the values of all of the parameters at each iteration.
- Using the NOPROFILE and NOBOUND options in the PROC MIXED statement may help convergence, although they can produce unusual results.
- Although the CONVH convergence criterion usually gives the best results, you may want to try CONVF or CONVG, possibly along with the ABSOLUTE option.
- If the convergence criterion bottoms out at a relatively small value such as 1E−7 but never gets less than 1E−8, you may want to specify CONVH=1E−6 in the PROC MIXED statement to get results; however, interpret the results with caution.
- An infinite likelihood during the iteration process means that the Newton-Raphson algorithm has stepped into a region where either the R or V matrix is nonpositive definite. This is usually no cause for concern as long as iterations continue. If PROC MIXED stops because of an infinite likelihood, recheck your model to make sure that no observations from the same subject are producing identical rows in R or V and that you have enough data to estimate the particular covariance structure you have selected. Any time that the final estimated likelihood is infinite, subsequent results should be interpreted with caution.
- A nonpositive definite Hessian matrix can indicate a surface saddlepoint or linear dependencies among the parameters.
- A warning message about the singularities of X changing indicates that there is some linear dependency in the estimate of $X'\hat{V}^{-1}X$ that is not found in $X'X$. This can adversely affect the likelihood calculations and optimization process. If you encounter this problem, make sure that your model specification is reasonable and that you have enough data to estimate the particular covariance structure you have selected. Rearranging effects in the MODEL statement so that the most significant ones are first can help because PROC MIXED sweeps the estimate of $X'\hat{V}^{-1}X$ in the order of the MODEL effects and the sweep is more stable if larger pivots are dealt with first. If this does not help, specifying starting values with the PARMS statement can place the optimization on a different and possibly more stable path.
- Lack of convergence may indicate model misspecification or a violation of the normality assumption.

**Memory**

Let $p$ be the number of columns in X, and let $g$ be the number of columns in Z. For large models, most of the memory resources are required for holding symmetric matrices of order $p$, $g$, and $p + g$. The approximate memory requirement in bytes is

$$40(p^2 + g^2) + 32(p + g)^2$$

If you have a large model that exceeds the memory capacity of your computer, see the suggestions listed under “Computing Time.”
**Computing Time**

PROC MIXED is computationally intensive, and execution times can be long. In addition to the CPU time used in collecting sums and cross products and in solving the mixed model equations (as in PROC GLM), considerable CPU time is often required to compute the likelihood function and its derivatives. These latter computations are performed for every Newton-Raphson iteration.

If you have a model that takes too long to run, the following suggestions may be helpful:

- Examine the “Model Information” table to find out the number of columns in the $X$ and $Z$ matrices. A large number of columns in either matrix can greatly increase computing time. You may want to eliminate some higher order effects if they are too large.
- If you have a $Z$ matrix with a lot of columns, use the `DDFM=BW` option in the `MODEL` statement to eliminate the time required for the containment method.
- If possible, “factor out” a common effect from the effects in the `RANDOM` statement and make it the `SUBJECT=` effect. This creates a block-diagonal $G$ matrix and can often speed calculations.
- If possible, use the same or nested `SUBJECT=` effects in all `RANDOM` and `REPEATED` statements.
- If your data set is very large, you may want to analyze it in pieces. The `BY` statement can help implement this strategy.
- In general, specify random effects with a lot of levels in the `REPEATED` statement and those with a few levels in the `RANDOM` statement.
- The `METHOD=MIVQUE0` option runs faster than either the `METHOD=REML` or `METHOD=ML` option because it is noniterative.
- You can specify known values for the covariance parameters using the `HOLD=` or `NOITER` option in the `PARMS` statement or the `GDATA=` option in the `RANDOM` statement. This eliminates the need for iteration.
- The `LOGNOTE` option in the PROC MIXED statement writes periodic messages to the SAS log concerning the status of the calculations. It can help you diagnose where the slow down is occurring.
Examples

The following are basic examples of the use of PROC MIXED. More examples and details can be found in Littell et al. (1996), Wolfinger (1997), Verbeke and Molenberghs (1997, 2000), Murray (1998), Singer (1998), Sullivan, Dukes, and Losina (1999), and Brown and Prescott (1999).

Example 46.1. Split-Plot Design

PROC MIXED can fit a variety of mixed models. One of the most common mixed models is the split-plot design. The split-plot design involves two experimental factors, A and B. Levels of A are randomly assigned to whole plots (main plots), and levels of B are randomly assigned to split plots (subplots) within each whole plot. The design provides more precise information about B than about A, and it often arises when A can be applied only to large experimental units. An example is where A represents irrigation levels for large plots of land and B represents different crop varieties planted in each large plot.

Consider the following data from Stroup (1989a), which arise from a balanced split-plot design with the whole plots arranged in a randomized complete-block design. The variable A is the whole-plot factor, and the variable B is the subplot factor. A traditional analysis of these data involves the construction of the whole-plot error (A*Block) to test A and the pooled residual error (B*Block and A*B*Block) to test B and A*B. To carry out this analysis with PROC GLM, you must use a TEST statement to obtain the correct F-test for A.

Performing a mixed model analysis with PROC MIXED eliminates the need for the error term construction. PROC MIXED estimates variance components for Block, A*Block, and the residual, and it automatically incorporates the correct error terms into test statistics.

```plaintext
data sp;
   input Block A B Y @@;
datalines;
1 1 1 56 1 1 2 41
1 2 1 50 1 2 2 36
1 3 1 39 1 3 2 35
2 1 1 30 2 1 2 25
2 2 1 36 2 2 2 28
2 3 1 33 2 3 2 30
3 1 1 32 3 1 2 24
3 2 1 31 3 2 2 27
3 3 1 15 3 3 2 19
4 1 1 30 4 1 2 25
4 2 1 35 4 2 2 30
4 3 1 17 4 3 2 18
;
```
proc mixed;
class A B Block;
model Y = A B A*B;
random Block A*Block;
run;

The variables A, B, and Block are listed as classification variables in the CLASS statement. The columns of model matrix X consist of indicator variables corresponding to the levels of the fixed effects A, B, and A*B listed on the right-hand side in the MODEL statement. The dependent variable Y is listed on the left-hand side in the MODEL statement.

The columns of the model matrix Z consist of indicator variables corresponding to the levels of the random effects Block and A*Block. The G matrix is diagonal and contains the variance components of Block and A*Block. The R matrix is also diagonal and contains the residual variance.

The SAS code produces Output 46.1.1.

**Output 46.1.1.** Split-Plot Example

<table>

<tr>
<td>Class: Levels</td>
</tr>
<tr>
<td>A: 3</td>
</tr>
<tr>
<td>B: 2</td>
</tr>
<tr>
<td>Block: 4</td>
</tr>
</tbody>
</table>

The “Class Level Information” table lists the levels of all variables specified in the CLASS statement. You can check this table to make sure that the data are correct.
The “Dimensions” table lists the magnitudes of various vectors and matrices. The X matrix is seen to be $24 \times 12$, and the Z matrix is $24 \times 16$.

The “Number of Observations” table shows that all observations read from the data set are used in the analysis.

PROC MIXED estimates the variance components for Block, A*Block, and the residual by REML. The REML estimates are the values that maximize the likelihood of a set of linearly independent error contrasts, and they provide a correction for the downward bias found in the usual maximum likelihood estimates. The objective function is $-2$ times the logarithm of the restricted likelihood, and PROC MIXED minimizes this objective function to obtain the estimates.

The minimization method is the Newton-Raphson algorithm, which uses the first and second derivatives of the objective function to iteratively find its minimum. The “Iteration History” table records the steps of that optimization process. For this example, only one iteration is required to obtain the estimates. The Evaluations column reveals that the restricted likelihood is evaluated once for each of the iterations. A criterion of 0 indicates that the Newton-Raphson algorithm has converged.
The REML estimates for the variance components of Block, A*Block, and the residual are 62.40, 15.38, and 9.36, respectively, as listed in the Estimate column of the “Covariance Parameter Estimates” table.

The “Fitting Information” table lists several pieces of information about the fitted mixed model, including the residual log likelihood. Akaike’s and Schwarz’s criteria can be used to compare different models; the ones with smaller values are preferred.

Finally, the fixed effects are tested using Type III estimable functions. The tests match the one obtained from the following PROC GLM code:

```r
proc glm data=sp;
class A B Block;
model Y = A B A*B Block A*Block;
test h=A e=A*Block;
run;
```

You can continue this analysis by producing solutions for the fixed and random effects and then testing various linear combinations of them by using the CONTRAST...
and ESTIMATE statements. If you use the same CONTRAST and ESTIMATE statements with PROC GLM, the test statistics correspond to the fixed-effects-only model. The test statistics from PROC MIXED incorporate the random effects.

The various “inference space” contrasts given by Stroup (1989a) can be implemented via the ESTIMATE statement. Consider the following examples:

\[
\text{estimate 'a1 mean narrow'} \\
\quad \text{intercept 1 A 1 B .5 .5 A*B .5 .5 |} \\
\quad \text{Block .25 .25 .25 .25} \\
\quad \text{A*Block .25 .25 .25 .25 0 0 0 0 0 0 0 0;}
\]

\[
\text{estimate 'a1 mean intermed'} \\
\quad \text{intercept 1 A 1 B .5 .5 A*B .5 .5 |} \\
\quad \text{Block .25 .25 .25 .25;}
\]

\[
\text{estimate 'a1 mean broad'} \\
\quad \text{intercept 1 a 1 b .5 .5 A*B .5 .5;}
\]

These statements result in Output 46.1.2.

**Output 46.1.2.** Inference Space Results

| Label             | Estimate | Standard Error | DF | t Value | Pr > |t| |
|-------------------|----------|----------------|----|---------|-------|-------|
| a1 mean narrow    | 32.8750  | 1.0817         | 9  | 30.39   | <.0001|
| a1 mean intermed  | 32.8750  | 2.2396         | 9  | 14.68   | <.0001|
| a1 mean broad     | 32.8750  | 4.5403         | 9  | 7.24    | <.0001|

Note that all the estimates are equal, but their standard errors increase with the size of the inference space. The narrow inference space consists of the observed levels of Block and A*Block, and the \( t \)-statistic value of 30.39 applies only to these levels. This is the same \( t \)-statistic computed by PROC GLM, because it computes standard errors from the narrow inference space. The intermediate inference space consists of the observed levels of Block and the entire population of levels from which A*Block are sampled. The \( t \)-statistic value of 14.68 applies to this intermediate space. The broad inference space consists of arbitrary random levels of both Block and A*Block, and the \( t \)-statistic value of 7.24 is appropriate. Note that the larger the inference space, the weaker the conclusion. However, the broad inference space is usually the one of interest, and even in this space conclusive results are common. The highly significant \( p \)-value for ‘a1 mean broad’ is an example. You can also obtain the ‘a1 mean broad’ result by specifying A in an LSMEANS statement. For more discussion of the inference space concept, refer to McLean, Sanders, and Stroup (1991).

The following statements illustrate another feature of the RANDOM statement. Recall that the basic code for a split-plot design with whole plots arranged in randomized blocks is as follows.
Chapter 46. The MIXED Procedure

```sas
proc mixed;
class A B Block;
model Y = A B A*B;
random Block A*Block;
run;
```

An equivalent way of specifying this model is

```sas
proc mixed data=sp;
class A B Block;
model Y = A B A*B;
random intercept A / subject=Block;
run;
```

In general, if all of the effects in the RANDOM statement can be nested within one effect, you can specify that one effect using the SUBJECT= option. The subject effect is, in a sense, “factored out” of the random effects. The specification using the SUBJECT= effect can result in quicker execution times for large problems because PROC MIXED is able to perform the likelihood calculations separately for each subject.

Example 46.2. Repeated Measures

The following data are from Pothoff and Roy (1964) and consist of growth measurements for 11 girls and 16 boys at ages 8, 10, 12, and 14. Some of the observations are suspect (for example, the third observation for person 20); however, all of the data are used here for comparison purposes.

The analysis strategy employs a linear growth curve model for the boys and girls as well as a variance-covariance model that incorporates correlations for all of the observations arising from the same person. The data are assumed to be Gaussian, and their likelihood is maximized to estimate the model parameters. Refer to Jennrich and Schluchter (1986), Louis (1988), Crowder and Hand (1990), Diggle, Liang, and Zeger (1994), and Everitt (1995) for overviews of this approach to repeated measures. Jennrich and Schluchter present results for the Pothoff and Roy data from various covariance structures. The PROC MIXED code to fit an unstructured variance matrix (their Model 2) is as follows:
data pr;
   input Person Gender $ y1 y2 y3 y4;
   y=y1; Age=8; output;
   y=y2; Age=10; output;
   y=y3; Age=12; output;
   y=y4; Age=14; output;
   drop y1-y4;
datalines;
   1 F 21.0 20.0 21.5 23.0
   2 F 21.0 21.5 24.0 25.5
   3 F 20.5 24.0 24.5 26.0
   4 F 23.5 24.5 25.0 26.5
   5 F 21.5 23.0 22.5 23.5
   6 F 20.0 21.0 21.0 22.5
   7 F 21.5 22.5 23.0 25.0
   8 F 23.0 23.0 23.5 24.0

  11 F 24.5 25.0 28.0 28.0
  12 M 26.0 25.0 29.0 31.0
  13 M 21.5 22.5 23.0 26.5
  14 M 23.0 22.5 24.0 27.5
  15 M 25.5 27.5 26.5 27.0
  16 M 20.0 23.5 22.5 26.0
  17 M 24.5 25.5 27.0 28.5
  18 M 22.0 22.0 24.5 26.5
  19 M 24.0 21.5 24.5 25.5
  20 M 23.0 20.5 31.0 26.0
  21 M 27.5 28.0 31.0 31.5
  22 M 23.0 23.0 23.5 25.0
  23 M 21.5 23.5 24.0 28.0
  24 M 17.0 24.5 26.0 29.5
  25 M 22.5 25.5 25.5 26.0
  26 M 23.0 24.5 26.0 30.0
  27 M 22.0 21.5 23.5 25.0;

proc mixed data=pr method=ml covtest;
   class Person Gender;
   model y = Gender Age Gender*Age / s;
   repeated / type=un subject=Person r;
run;

To follow Jennrich and Schluchter, this example uses maximum likelihood (METHOD=ML) instead of the default REML to estimate the unknown covariance parameters. The COVTEST option requests asymptotic tests of all of the covariance parameters.

The MODEL statement first lists the dependent variable Y. The fixed effects are then listed after the equals sign. The variable Gender requests a different intercept for the girls and boys. Age models an overall linear growth trend, and Gender*Age makes the slopes different over time. It is actually not necessary to specify Age separately, but doing so enables PROC MIXED to carry out a test for heterogeneous slopes. The S option requests the display of the fixed-effects solution vector.
The REPEATED statement contains no effects, taking advantage of the default assumption that the observations are ordered similarly for each subject. The TYPE=UN option requests an unstructured block for each SUBJECT=Person. The R matrix is, therefore, block diagonal with 27 blocks, each block consisting of identical $4 \times 4$ unstructured matrices. The 10 parameters of these unstructured blocks make up the covariance parameters estimated by maximum likelihood. The R option requests that the first block of R be displayed.

The results from this analysis are shown in Output 46.2.1.

**Output 46.2.1.** Repeated Measures with Unstructured Covariance Matrix

<td>419.47704812</td>
<td>0.00000000</td>
</tr>
</tbody>
</table>

Convergence criteria met.

Three Newton-Raphson iterations are required to find the maximum likelihood estimates. The default relative Hessian criterion has a final value less than $1E−8$, indicating the convergence of the Newton-Raphson algorithm and the attainment of an optimum.

The Mixed Procedure

Estimated R Matrix for Person 1

</table>

The preceding table lists the 10 estimated covariance parameters in order; note their correspondence to the first block of $R$ displayed previously. The parameter estimates are labeled according to their location in the block in the Cov Parm column, and all of these estimates are associated with Person as the subject effect. The Std Error column lists approximate standard errors of the covariance parameters obtained from the inverse Hessian matrix. These standard errors lead to approximate Wald $Z$-statistics, which are compared with the standard normal distribution. The results of these tests indicate that all the parameters are significantly different from 0; however, the Wald test can be unreliable in small samples.

To carry out Wald tests of various linear combinations of these parameters, use the following procedure. First, run the code again, adding the ASYCOV option and an ODS statement:

```sas
ods output CovParms=cp AsyCov=asy;
proc mixed data=pr method=ml covtest asycov;
   class Person Gender;
   model y = Gender Age Gender*Age / s;
   repeated / type=un subject=Person r;
run;
```

This creates two data sets, `cp` and `asy`, which contain the covariance parameter estimates and their asymptotic variance covariance matrix, respectively. Then read these data sets into the SAS/IML matrix programming language as follows:

```sas
proc iml;
   use cp;
   read all var {Estimate} into est;
   use asy;
   read all var ('CovP1'..'CovP10') into asy;
```

You can then construct your desired linear combinations and corresponding quadratic forms with the `asy` matrix.
The null model likelihood ratio test (LRT) is highly significant for this model, indicating that the unstructured covariance matrix is preferred to the diagonal one of the ordinary least-squares null model. The degrees of freedom for this test is 9, which is the difference between 10 and the 1 parameter for the null model’s diagonal matrix.

The preceding table lists the solution vector for the fixed effects. The estimate of the boys’ intercept is 15.84, while that for the girls is $15.84 + 1.58 = 17.42$. Similarly, the estimate for the boys’ slope is 0.827, while that for the girls is $0.827 - 0.350 = 0.477$. Thus the girls’ starting point is larger than that for the boys, but their growth rate is about half that of the boys.

Note that two of the estimates equal 0; this is a result of the overparameterized model used by PROC MIXED. You can obtain a full-rank parameterization by using the following MODEL statement:

```
model y = Gender Gender*Age / noint s;
```

Here, the NOINT option causes the different intercepts to be fit directly as the two levels of Gender. However, this alternative specification results in different tests for these effects.
The “Type 3 Tests of Fixed Effects” table displays Type III tests for all of the fixed effects. These tests are partial in the sense that they account for all of the other fixed effects in the model. In addition, you can use the HTYPE= option in the MODEL statement to obtain Type I (sequential) or Type II (also partial) tests of effects.

It is usually best to consider higher-order terms first, and in this case the Age*Gender test reveals a difference between the slopes that is statistically significant at the 1% level. Note that the \( p \)-value for this test (0.0091) is the same as the \( p \)-value in the “Age*Gender F” row in the “Solution for Fixed Effects” table and that the \( F \)-statistic (7.99) is the square of the \( t \)-statistic (–2.83), ignoring rounding error. Similar connections are evident among the other rows in these two tables.

The Age test is one for an overall growth curve accounting for possible heterogeneous slopes, and it is highly significant. Finally, the Gender row tests the null hypothesis of a common intercept, and this hypothesis cannot be rejected from these data.

As an alternative to the \( F \)-tests shown here, you can carry out likelihood ratio tests of various hypotheses by fitting the reduced models, subtracting \(-2\log\) likelihoods, and comparing the resulting statistics with \( \chi^2 \) distributions.

Since the different levels of the repeated effect represent different years, it is natural to try fitting a time series model to the data within each subject. To obtain time series structures in \( \mathbf{R} \), you can replace TYPE=UN with TYPE=AR(1) or TYPE=TOEP to obtain the first- or \( n \)th-order autoregressive covariance matrices, respectively. For example, the code to fit an AR(1) structure is

```plaintext
proc mixed data=pr method=ml;
class Person Gender;
model y = Gender Age Gender*Age / s;
repeated / type=ar(1) sub=Person r;
run;
```

To fit a random coefficients model, use the following code:
proc mixed data=pr method=ml;
   class Person Gender;
   model y = Gender Age Gender*Age / s;
   random intercept Age / type=un sub=Person g;
run;

This specifies an unstructured covariance matrix for the random intercept and slope. In mixed model notation, G is block diagonal with identical $2 \times 2$ unstructured blocks for each person. By default, R becomes $\sigma^2 I$. See Example 46.5 for further information on this model.

Finally, you can fit a compound symmetry structure by using TYPE=CS.

proc mixed data=pr method=ml covtest;
   class Person Gender;
   model y = Gender Age Gender*Age / s;
   repeated / type=cs subject=Person r;
run;

The results from this analysis are shown in Output 46.2.2.

<tr>
<td>Residual</td>
<td></td>
<td>1.8746</td>
<td>0.2946</td>
<td>6.36</td>
<td>&lt;.0001</td>
</tr>
</tbody>
</table>

The common covariance is estimated to be 3.0306, as listed in the CS row of the preceding table, and the residual variance is estimated to be 1.8746, as listed in the Residual row. You can use these two numbers to estimate the intraclass correlation coefficient (ICC) for this model. Here, the ICC estimate equals 3.0306/(3.0306 + 1.8746) = 0.6178. You can also obtain this number by adding the RCORR option to the REPEATED statement.

The Mixed Procedure

Fit Statistics

-2 Log Likelihood 428.6
AIC (smaller is better) 440.6

<td>6.46</td>
<td>0.0130</td>
</tr>
</tbody>
</table>

The $F$-tests are also similar to those from the preceding unstructured example. Again, the slopes are significantly different but the intercepts are not.

You can fit the same compound symmetry model with the following specification using the RANDOM statement:

```r
proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  random Person;
run;
```

Compound symmetry is the structure that Jennrich and Schluchter deemed best among the ones they fit. To carry the analysis one step further, you can use the GROUP= option to specify heterogeneity of this structure across girls and boys.

```r
proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=cs subject=Person group=Gender;
run;
```

The results from this analysis are shown in Output 46.2.3.
Output 46.2.3. Repeated Measures with Heterogeneous Structures

<th>Pr &gt; ChiSq</th>
</tr>
</thead>
<tbody>
<tr>
<td>3</td>
<td>69.43</td>
<td>&lt;.0001</td>
</tr>
</tbody>
</table>

Both Akaike’s Information Criterion (424.8) and Schwarz’s Bayesian Criterion (435.2) are smaller for this model than for the homogeneous compound symmetry model (440.6 and 448.4, respectively). This indicates that the heterogeneous model is more appropriate. To construct the likelihood ratio test between the two models, subtract the \(-2\) log likelihood values: 428.6 – 408.8 = 19.8. Comparing this value with the \(\chi^2\) distribution with two degrees of freedom yields a \(p\)-value less than 0.0001, again favoring the heterogeneous model.
Example 46.3. Plotting the Likelihood

The Mixed Procedure

Solution for Fixed Effects

| Effect   | Gender | Estimate | Error  | DF | t Value | Pr > |t| |
|----------|--------|----------|--------|----|---------|------|---|
| Intercept|        | 16.3406  | 1.1130 | 25 | 14.68   | <.0001 |
| Gender   | F      | 1.0321   | 1.3890 | 25 | 0.74    | 0.4644 |
| Gender   | M      | 0        |        |    |         |      |   |
| Age      |        | 0.7844   | 0.09283| 79 | 8.45    | <.0001 |
| Age*Gender| F    | -0.3048  | 0.1063 | 79 | -2.87   | 0.0053 |
| Age*Gender| M    | 0        |        |    |         |      |   |

Note that the fixed effects estimates are the same as in the homogeneous case, but the standard errors are different.

</tr>
</tbody>
</table>

The fixed effects tests are similar to those from previous models, although the p-values do change as a result of specifying a different covariance structure. It is important for you to select a reasonable covariance structure in order to obtain valid inferences for your fixed effects.

Example 46.3. Plotting the Likelihood

The data for this example are from Hemmerle and Hartley (1973) and are also used as an example for the VARCOMP procedure. The response variable consists of measurements from an oven experiment, and the model contains a fixed effect A and random effects B and A*B.

The SAS code is as follows:

```
data hh;
  input a b y @@;
datalines;
1 1 237 1 1 254 1 1 246
1 2 178 1 2 179
2 1 208 2 1 178 2 1 187
2 2 146 2 2 145 2 2 141
3 1 186 3 1 183
3 2 142 3 2 125 3 2 136
;```
ods output ParmSearch=parms;
proc mixed data=hh asycov mmeq mmeqsol covtest;
   class a b;
   model y = a / outp=predicted;
   random b a*b;
   lsmeans a;
   parms (17 to 20 by .1) (.3 to .4 by .005) (1.0);
run;

proc print data=predicted;
run;

The ASYCOV option in the PROC statement requests the asymptotic variance matrix of the covariance parameter estimates. This matrix is the observed inverse Fisher information matrix, which equals $2H^{-1}$, where $H$ is the Hessian matrix of the objective function evaluated at the final covariance parameter estimates. The MMEQ and MMEQSOL options in the PROC statement request that the mixed model equations and their solution be displayed.

The OUTP= option in the MODEL statement produces the data set predicted, containing the predicted values. Least-squares means (LSMEANS) are requested for A. The PARMS and ODS statements are used to construct a data set containing the likelihood surface.

The results from this analysis are shown in Output 46.3.1.

**Output 46.3.1.** Plotting the Likelihood

<table>
<thead>
<tr>

The “Model Information” table lists details about this variance components model.

<table>
<thead>
<tr>
<th>The Mixed Procedure</th>
</tr>
</thead>
<tbody>
<tr>
<td>Class Level Information</td>
</tr>
<tr>
<td>Class</td>
</tr>
<tr>
<td>a</td>
</tr>
<tr>
<td>b</td>
</tr>
</tbody>
</table>

The “Class Level Information” table lists the levels for A and B.
The “Dimensions” table reveals that $X$ is $16 \times 4$ and $Z$ is $16 \times 8$. Since there are no SUBJECT= effects, PROC MIXED considers the data effectively to be from one subject with 16 observations.

Only a portion of the “Parameter Search” table is shown because the full listing has 651 rows.
Convergence is quick because PROC MIXED starts from the best value from the grid search.

The preceding table lists the variance components estimates. Note that B is much more variable than A*B.

The asymptotic covariance matrix also reflects the large variability of B relative to A*B.
Example 46.3. Plotting the Likelihood

The Mixed Procedure

Fit Statistics

-2 Res Log Likelihood 104.9
AIC (smaller is better) 110.9
AICC (smaller is better) 113.6
BIC (smaller is better) 107.0

PARMS Model Likelihood Ratio Test

</table>

This solution matrix results from sweeping all but the last row of the mixed model equations matrix. The final column contains a solution vector for the fixed and random effects. The first four rows correspond to fixed effects and the last eight to random effects.

#### Type 3 Tests of Fixed Effects

<table>
<thead>
<tr>
<th>Effect</th>
<th>Num DF</th>
<th>Den DF</th>
<th>F Value</th>
<th>Pr &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>a</td>
<td>2</td>
<td>2</td>
<td>28.00</td>
<td>0.0345</td>
</tr>
</tbody>
</table>

The A factor is significant at the 5% level.
Example 46.3. Plotting the Likelihood

The Mixed Procedure

Least Squares Means

</tbody>
</table>

The preceding output lists the predicted values from the model. These values are the sum of the fixed effects estimates and the empirical best linear unbiased predictors (EBLUPs) of the random effects. It is often useful to plot predicted values and residuals to assess the adequacy of the model, using another SAS procedure to generate plots and diagnostic measures.

To plot the likelihood surface using the G3D procedure from SAS/GRAPH software, use the following source:

```sas
proc g3d data=parms;
   plot CovP1*CovP2 = ResLogLike
      / ctop=red cbottom=blue caxis=black;
run;
```

The results from this plot are shown in Output 46.3.2. The peak of the surface is the REML estimates for the B and A*B variance components.
Example 46.4. Known G and R

This animal breeding example from Henderson (1984, p. 53) considers multiple traits. The data are artificial and consist of measurements of two traits on three animals, but the second trait of the third animal is missing. Assuming an additive genetic model, you can use PROC MIXED to predict the breeding value of both traits on all three animals and also to predict the second trait of the third animal. The data are as follows:

```
data h;
  input Trait Animal Y;
datalines;
  1 1 6
  1 2 8
  1 3 7
  2 1 9
  2 2 5
  2 3 .
;
```

Output 46.3.2. Plot of Likelihood Surface
Both \( G \) and \( R \) are known.

\[
G = \begin{bmatrix}
2 & 1 & 1 & 2 & 1 & 1 \\
1 & 2 & .5 & 1 & 2 & .5 \\
1 & .5 & 2 & 1 & .5 & 2 \\
2 & 1 & 1 & 3 & 1.5 & 1.5 \\
1 & 2 & .5 & 1.5 & 3 & .75 \\
1 & .5 & 2 & 1.5 & .75 & 3
\end{bmatrix}
\]

\[
R = \begin{bmatrix}
4 & 0 & 0 & 1 & 0 & 0 \\
0 & 4 & 0 & 0 & 1 & 0 \\
0 & 0 & 4 & 0 & 0 & 1 \\
1 & 0 & 0 & 5 & 0 & 0 \\
0 & 1 & 0 & 0 & 5 & 0 \\
0 & 0 & 1 & 0 & 0 & 5
\end{bmatrix}
\]

In order to read \( G \) into PROC MIXED using the GDATA= option in the RANDOM statement, perform the following DATA step:

```plaintext
data g;
   input Row Col1-Col6;
datalines;
   1 2 1 1 2 1 1
   2 1 2 .5 1 2 .5
   3 1 .5 2 1 .5 2
   4 2 1 1 3 1.5 1.5
   5 1 2 .5 1.5 3 .75
   6 1 .5 2 1.5 .75 3
;
```

The preceding data are in the dense representation for a GDATA= data set. You can also construct a data set with the sparse representation using Row, Col, and Value variables, although this would require 21 observations instead of 6 for this example.

The PROC MIXED code is as follows:

```plaintext
proc mixed data=h mmeq mmeqsol;
   class Trait Animal;
   model Y = Trait / noint s outp=predicted;
   random Trait*Animal / type=un gdata=g g gi s;
   repeated / type=un sub=Animal r ri;
   parms (4) (1) (5) / noiter;
run;

proc print data=predicted;
run;
```

The MMEQ and MMEQSOL options request the mixed model equations and their solution. The variables Trait and Animal are classification variables, and Trait defines
the entire \( X \) matrix for the fixed-effects portion of the model, since the intercept is omitted with the NOINT option. The fixed-effects solution vector and predicted values are also requested using the \( S \) and \( OUTP= \) options, respectively.

The random effect Trait*Animal leads to a \( Z \) matrix with six columns, the first five corresponding to the identity matrix and the last consisting of 0s. An unstructured \( G \) matrix is specified using the \( \text{TYPE}=\text{UN} \) option, and it is read into PROC MIXED from a SAS data set using the \( \text{GDATA}=G \) specification. The \( G \) and \( G^{-1} \) options request the display of \( G \) and \( G^{-1} \), respectively. The \( S \) option requests that the random-effects solution vector be displayed.

Note that the preceding \( R \) matrix is block diagonal if the data are sorted by animals. The REPEATED statement exploits this fact by requesting \( R \) to have unstructured \( 2 \times 2 \) blocks corresponding to animals, which are the subjects. The \( R \) and \( RI \) options request that the estimated \( 2 \times 2 \) blocks for the first animal and its inverse be displayed.

The PARMS statement lists the parameters of this \( 2 \times 2 \) matrix. Note that the parameters from \( G \) are not specified in the PARMS statement because they have already been assigned using the \( \text{GDATA}= \) option in the RANDOM statement. The NOITER option prevents PROC MIXED from computing residual (restricted) maximum likelihood estimates; instead, the known values are used for inferences.

The results from this analysis are shown in Output 46.4.1.

**Output 46.4.1.** Known \( G \) and \( R \)

```
The Mixed Procedure

Model Information

  Data Set            WORK.H
  Dependent Variable  Y
  Covariance Structure Unstructured
  Subject Effect      Animal
  Estimation Method   REML
  Residual Variance Method None
  Fixed Effects SE Method Model-Based
  Degrees of Freedom Method Containment
```

The “Unstructured” covariance structure applies to both \( G \) and \( R \) here.
The Mixed Procedure

Class Level Information

<table>
<thead>
<tr>
<th>Class</th>
<th>Levels</th>
<th>Values</th>
</tr>
</thead>
<tbody>
<tr>
<td>Trait</td>
<td>2</td>
<td>1 2</td>
</tr>
<tr>
<td>Animal</td>
<td>3</td>
<td>1 2 3</td>
</tr>
</tbody>
</table>

The levels of Trait and Animal have been specified correctly.

The Mixed Procedure

Dimensions

- Covariance Parameters: 3
- Columns in X: 2
- Columns in Z: 6
- Subjects: 1
- Max Obs Per Subject: 6

Number of Observations

- Number of Observations Read: 6
- Number of Observations Used: 5
- Number of Observations Not Used: 1

The three covariance parameters indicated here correspond to those from the R matrix. Those from G are considered fixed and known because of the GDATA= option.

The Mixed Procedure

</table>
The solution to the mixed model equations also matches that given by Henderson (1984, p. 55).

The estimates for the two traits are nearly identical, but the standard error of the second one is larger because of the missing observation.

The Estimate column lists the best linear unbiased predictions (BLUPs) of the breeding values of both traits for all three animals. The \( p \)-values are missing because the default containment method for computing degrees of freedom results in zero degrees of freedom for the random effects parameter tests.

The two estimated traits are significantly different from zero at the 5\% level.
The preceding table contains the predicted values of the observations based on the trait and breeding value estimates, that is, the fixed and random effects. The predicted values are not the predictions of future records in the sense that they do not contain a component corresponding to a new observational error. Refer to Henderson (1984) for information on predicting future records. The L95 and U95 columns usually contain confidence limits for the predicted values; they are missing here because the random-effects parameter degrees of freedom equals 0.

**Example 46.5. Random Coefficients**

This example comes from a pharmaceutical stability data simulation performed by Obenchain (1990). The observed responses are replicate assay results, expressed in percent of label claim, at various shelf ages, expressed in months. The desired mixed model involves three batches of product that differ randomly in intercept (initial potency) and slope (degradation rate). This type of model is also known as a hierarchical or multilevel model (Singer 1998; Sullivan, Dukes, and Losina 1999).

The SAS code is as follows:

```sas
data rc;
  input Batch Month @@;
  Monthc = Month;
  do i = 1 to 6;
    input Y @@;
    output;
  end;
  datalines;
  1 0 101.2 103.3 103.3 102.1 104.4 102.4
  1 1 98.8 99.4 99.7 99.5 . .

```
Example 46.5. Random Coefficients

In the DATA step, Monthc is created as a duplicate of Month in order to enable both a continuous and classification version of the same variable. The variable Monthc is used in a subsequent analysis on page 2814.

In the PROC MIXED code, Batch is listed as the only classification variable. The fixed effect Month in the MODEL statement is not declared a classification variable; thus it models a linear trend in time. An intercept is included as a fixed effect by default, and the S option requests that the fixed-effects parameter estimates be produced.

The two RANDOM effects are Int and Month, modeling random intercepts and slopes, respectively. Note that Intercept and Month are used as both fixed and random effects. The TYPE=UN option in the RANDOM statement specifies an unstructured covariance matrix for the random intercept and slope effects. In mixed model notation, G is block diagonal with unstructured 2×2 blocks. Each block corresponds to a different level of Batch, which is the SUBJECT= effect. The unstructured type provides a mechanism for estimating the correlation between the random coefficients. The S option requests the production of the random-effects parameter estimates.

The results from this analysis are shown in Output 46.5.1.

Output 46.5.1. Random Coefficients Analysis

<tr>
<td>Fixed Effects SE Method</td>
</tr>
<tr>
<td>Degrees of Freedom Method</td>
</tr>
</tbody>
</table>

The “Unstructured” covariance structure applies to G here.
Batch is the only classification variable in this analysis, and it has three levels.

The “Dimensions” table indicates that there are three subjects (corresponding to batches). The 24 observations not used correspond to the missing values of \( Y \) in the input data set.

Only one iteration is required for convergence.
The estimated elements of the unstructured $2 \times 2$ matrix comprising the blocks of $G$ are listed in the Estimate column. Note that the random coefficients are negatively correlated.

The null model likelihood ratio test indicates a significant improvement over the null model consisting of no random effects and a homogeneous residual error.

The fixed effects estimates represent the estimated means for the random intercept and slope, respectively.
### The Mixed Procedure

#### Solution for Random Effects

| Effect        | Batch | Estimate | Std Err | Pred | DF  | t Value | Pr > |t| |
|---------------|-------|----------|---------|------|-----|---------|------|---|
| Intercept 1   | 1     | -1.0010  | 0.6842  | 78   | -1.46| 0.1474  |
| Month         | 1     | 0.1287   | 0.1245  | 78   | 1.03 | 0.3047  |
| Intercept 2   | 2     | 0.3934   | 0.6842  | 78   | 0.58 | 0.5669  |
| Month         | 2     | -0.2060  | 0.1245  | 78   | -1.65| 0.1021  |
| Intercept 3   | 3     | 0.6076   | 0.6842  | 78   | 0.89 | 0.3772  |
| Month         | 3     | 0.07731  | 0.1245  | 78   | 0.62 | 0.5365  |

The random effects estimates represent the estimated deviation from the mean intercept and slope for each batch. Therefore, the intercept for the first batch is close to 102.7 - 1 = 101.7, while the intercepts for the other two batches are greater than 102.7. The second batch has a slope less than the mean slope of -0.526, while the other two batches have slopes larger than -0.526.

### The Mixed Procedure

#### Type 3 Tests of Fixed Effects

<table>
<thead>
<tr>
<th>Effect</th>
<th>Num</th>
<th>Den</th>
<th>F Value</th>
<th>Pr &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Month</td>
<td>1</td>
<td>2</td>
<td>19.41</td>
<td>0.0478</td>
</tr>
</tbody>
</table>

The $F$-statistic in the “Type 3 Tests of Fixed Effects” table is the square of the $t$-statistic used in the test of Month in the preceding “Solution for Fixed Effects” table. Both statistics test the null hypothesis that the slope assigned to Month equals 0, and this hypothesis can barely be rejected at the 5% level.

It is also possible to fit a random coefficients model with error terms that follow a nested structure (Fuller and Battese 1973). The following SAS code represents one way of doing this:

```sas
proc mixed data=rc;
  class Batch Monthc;
  model Y = Month / s;
  random Int Month Monthc / sub=Batch s;
run;
```

The variable Monthc is added to the CLASS and RANDOM statements, and it models the nested errors. Note that Month and Monthc are continuous and classification versions of the same variable. Also, the TYPE=UN option is dropped from the RANDOM statement, resulting in the default variance components model instead of correlated random coefficients.

The results from this analysis are shown in Output 46.5.2.
Output 46.5.2. Random Coefficients with Nested Errors Analysis

0 1 367.02768461
1 4 277.51945360
2 1 276.97551718 0.00104208
3 1 276.90304909 0.00003174
4 1 276.90100316 0.00000004
5 1 276.90100092 0.00000000

Convergence criteria met.

Covariance Parameter Estimates

Cov Parm Subject Estimate
Intercept Batch 0
Month Batch 0.01243
Monthc Batch 3.7411
Residual 0.7969
For this analysis, the Newton-Raphson algorithm requires five iterations and nine likelihood evaluations to achieve convergence. The missing value in the Criterion column in iteration 1 indicates that a boundary constraint has been dropped.

The estimate for the Intercept variance component equals 0. This occurs frequently in practice and indicates that the restricted likelihood is maximized by setting this variance component equal to 0. Whenever a zero variance component estimate occurs, the following note appears in the SAS log:

**NOTE: Estimated G matrix is not positive definite.**

The remaining variance component estimates are positive, and the estimate corresponding to the nested errors (MONTHC) is much larger than the other two.

<table>
<thead>
<tr>
<th>The Mixed Procedure</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Fit Statistics</strong></td>
</tr>
<tr>
<td>-2 Res Log Likelihood</td>
</tr>
<tr>
<td>AIC (smaller is better)</td>
</tr>
<tr>
<td>AICC (smaller is better)</td>
</tr>
<tr>
<td>BIC (smaller is better)</td>
</tr>
</tbody>
</table>

A comparison of AIC and BIC for this model with those of the previous model favors the nested error model. Strictly speaking, a likelihood ratio test cannot be carried out between the two models because one is not contained in the other; however, a cautious comparison of likelihoods can be informative.

</table>

The better-fitting covariance model impacts the standard errors of the fixed effects parameter estimates more than the estimates themselves.
Example 46.6. Line-Source Sprinkler Irrigation

The random effects solution provides the empirical best linear unbiased predictions (EBLUPs) for the realizations of the random intercept, slope, and nested errors. You can use these values to compare batches and months.

The test of Month is similar to that from the previous model, although it is no longer significant at the 5% level.

Example 46.6. Line-Source Sprinkler Irrigation

These data appear in Hanks et al. (1980), Johnson, Chaudhuri, and Kanemasu (1983), and Stroup (1989b). Three cultivars (Cult) of winter wheat are randomly assigned to rectangular plots within each of three blocks (Block). The nine plots are located side-by-side, and a line-source sprinkler is placed through the middle. Each plot is subdivided into twelve subplots, six to the north of the line-source, six to the south (Dir). The two plots closest to the line-source represent the maximum irrigation level.
(Irrig=6), the two next-closest plots represent the next-highest level (Irrig=5), and so forth.

This example is a case where both G and R can be modeled. One of Stroup’s models specifies a diagonal G containing the variance components for Block, Block*Dir, and Block*Irrig, and a Toeplitz R with four bands. The SAS code to fit this model and carry out some further analyses follows.

**Caution:** This analysis may require considerable CPU time.

```sas
data line;
  length Cult$ 8;
  input Block Cult$ @;
  row = _n_;
  do Sbplt=1 to 12;
    if Sbplt le 6 then do;
      Irrig = Sbplt;
      Dir = 'North';
    end;
    else do;
      Irrig = 13 - Sbplt;
      Dir = 'South';
    end;
    input Y @; output;
  end;
  datalines;

run;
```
The preceding code uses the bar operator ( | ) and the at sign ( @ ) to specify all two-factor interactions between Cult, Dir, and Irrig as fixed effects.

The RANDOM statement sets up the Z and G matrices corresponding to the random effects Block, Block*Dir, and Block*Irrig.

In the REPEATED statement, the TYPE=TOEP(4) option sets up the blocks of the R matrix to be Toeplitz with four bands below and including the main diagonal. The subject effect is Block(Cult), and it produces nine 12×12 blocks. The R option requests that the first block of R be displayed.

Least-squares means (LSMEANS) are requested for Cult, Irrig, and Cult*Irrig, and a few ESTIMATE statements are specified to illustrate some linear combinations of the fixed effects.

The results from this analysis are shown in Output 46.6.1.

**Output 46.6.1.** Line-Source Sprinkler Irrigation Analysis

<table>

<tr>
<td>Irrig</td>
</tr>
</tbody>
</table>

The levels of each class variable are listed as a single string in the Values column, regardless of whether the levels are numeric or character.
Even though there is a SUBJECT= effect in the REPEATED statement, the analysis considers all of the data to be from one subject because there is no corresponding SUBJECT= effect in the RANDOM statement.

The Newton-Raphson algorithm converges successfully in seven iterations.
The first block of the estimated $R$ matrix has the TOEP(4) structure, and the observations that are three plots apart exhibit a negative correlation.

The preceding table lists the estimated covariance parameters from both $G$ and $R$. The first three are the variance components making up the diagonal $G$, and the final four make up the Toeplitz structure in the blocks of $R$. The Residual row corresponds to the variance of the Toeplitz structure, and it was the parameter profiled out during the optimization process.
The “−2 Res Log Likelihood” value is the same as the final value listed in the “Iteration History” table.

<table>
<thead>

The LS-means are useful in comparing the levels of the various fixed effects. For example, it appears that irrigation levels 5 and 6 have virtually the same effect.

An interesting exercise is to try fitting other variance-covariance models to these data and comparing them to this one using likelihood ratio tests, Akaike’s Information Criterion, or Schwarz’s Bayesian Information Criterion. In particular, some spatial models are worth investigating (Marx and Thompson 1987; Zimmerman and Harville 1991). The following is one example of spatial model code.

```plaintext
proc mixed;
  class Block Cult Dir Irrig;
  model Y = Cult|Dir|Irrig@2;
  repeated / type=sp(pow)(Row Sbplt)
    sub=intercept;
run;
```

The TYPE=SP(POW)(ROW SBPLT) option in the REPEATED statement requests the spatial power structure, with the two defining coordinate variables being Row and Sbplt. The SUB=INTERCEPT option indicates that the entire data set is to be considered as one subject, thereby modeling R as a dense 108×108 covariance matrix. Refer to Wolfinger (1993) for further discussion of this example and additional analyses.
Example 46.7. Influence in Heterogeneous Variance Model
(Experimental)

In this example from Snedecor and Cochran (1976, p. 256) a one-way classification model with heterogeneous variances is fit. The data represent amounts of different types of fat absorbed by batches of doughnuts during cooking, measured in grams.

```
data absorb;
  input FatType Absorbed @@;
  datalines;
  1 164 1 172 1 168 1 177 1 156 1 195
  2 178 2 191 2 197 2 182 2 185 2 177
  3 175 3 193 3 178 3 171 3 163 3 176
  4 155 4 166 4 149 4 164 4 170 4 168
;
```

The statistical model for these data can be written as

\[ Y_{ij} = \mu + \tau_i + \epsilon_{ij} \]
\[ i = 1, \ldots, t = 4 \]
\[ j = 1, \ldots, r = 6 \]
\[ \epsilon_{ij} = (0, \sigma_i^2) \]

where \( Y_{ij} \) is the amount of fat absorbed by the \( j \)th batch of the \( i \)th fat type, and \( \tau_i \) denotes the fat-type effects. A quick glance at the data suggests that observations 6, 9, 14, and 21 might be influential on the analysis, because these are extreme observations for the respective fat types.

The following SAS statements fit this model and request influence diagnostics for the fixed effects and covariance parameters. The experimental ODS GRAPHICS statement requests plots of the influence diagnostics in addition to the tabular output. The ESTIMATE suboption requests plots of “leave-one-out” estimates for the fixed effects and group variances.

```
ods html;
odsc graphics on;
proc mixed data=absorb asycov;
  class FatType;
  model Absorbed = FatType / s
                   influence(iter=10 estimates);
     influence(iter=10 estimates);
  repeated / group=FatType;
  ods output Influence=inf;
run;

ods graphics off;
odsc html close;
```
The “Influence” table is output to the SAS data set inf so that parameter estimates can be printed subsequently. Results from this analysis are shown in Output 46.7.1.

**Output 46.7.1.** Heterogeneous Variance Analysis

</tr>
</tbody>
</table>

The variances in the four groups are shown in the “Covariance Parameter Estimates” table. The estimated variance in the first group is two to three times larger than the variance in the other groups.

The fixed effects solutions correspond to estimates of the following parameters:

- Intercept : \( \mu + \tau_4 \)
- FatType 1 : \( \tau_1 - \tau_4 \)
- FatType 2 : \( \tau_2 - \tau_4 \)
- FatType 3 : \( \tau_3 - \tau_4 \)
- FatType 4 : 0

You can easily verify that these estimates are simple functions of the arithmetic means \( \bar{y}_i \) in the groups. For example, \( \mu + \tau_4 = \bar{y}_4 = 162.0, \tau_1 - \tau_4 = \bar{y}_1 - \bar{y}_4 = 10.0, \)
and so forth. The covariance parameter estimates are the sample variances in the groups and are uncorrelated.

</tbody>
</table>
The estimate of the intercept is affected only when observations from the last group are removed. The estimate of the “FatType 1” effect reacts to removal of observations in the first and last group (Output 46.7.3).

While observations can impact one or more fixed effects solutions in this model, they can only affect one covariance parameter, the variance in their group (Output 46.7.4). Observations 6, 9, 14, and 21, which are extreme in their group, reduce the group variance considerably.

These graphical displays are requested by specifying the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.
Diagnostics related to residuals and predicted values are printed with the following statements.

```sas
proc print data=inf label;
    var observed predicted residual pressres student Rstudent;
run;
```

Observations 6, 9, 14, and 21 have large studentized residuals (Output 46.7.5). That the externally studentized residuals are much larger than the internally studentized residuals for these observations indicates that the variance estimate in the group shrinks when the observation is removed. Also important to note is that comparisons based on raw residuals in models with heterogeneous variance can be misleading. Observation 5, for example, has a larger residual but a smaller studentized residual than observation 21. The variance for the first fat type is much larger than the variance in the fourth group. A “large” residual is more “surprising” in the groups with small variance.

Output 46.7.7. REML Distance and Fixed Effects Diagnostics (Experimental)
Scanning the restricted likelihood distances, observations 6, 9, 14, and 21 clearly displace the REML solution more than any other observations (Output 46.7.6, Output 46.7.7). These observations are also associated with large values for Cook’s D and values of COVRATIO far less than one. The latter indicates that the fixed effects are estimated more precisely when these observations are removed from the analysis.

The same conclusions hold for the covariance parameter estimates.

```plaintext
proc print data=inf label;
  var iter CookDCP CovRatioCP;
run;
```

Observations 6, 9, 14, and 21 change the estimates and their precision considerably (Output 46.7.8, Output 46.7.9). All iterative updates converged within at most four iterations.

Example 46.8. Influence Analysis for Repeated Measures Data (Experimental)

This example revisits the repeated measures data analyzed in Example 46.2. Recall that the data consist of growth measurements at ages 8, 10, 12, and 14 for 11 girls and 16 boys. The model being fit contains fixed effects for Gender, Age and their interaction.

The earlier analysis of these data indicated some unusual observations in this data set. Because of the clustered data structure it is of interest to study the influence of clusters (children) on the analysis rather than the influence of individual observations. A cluster comprises the repeated measurements for each child.

The repeated measures are first modeled with an unstructured within-child variance-covariance matrix. A residual variance is not profiled in this model. A noniterative influence analysis will update the fixed effects only. The statements

```plaintext
proc mixed data=pr method=ml;
   class person gender;
   model y = gender age gender*age /
            influence(effect=person);
   repeated / type=un subject=person;
   ods select influence;
run;
```

request this noniterative maximum likelihood analysis and produce Output 46.8.1. Each observation in the “Influence Diagnostics” table represents the removal of four
observations. The subjects 10, 15, and 24 have the greatest impact on the fixed effects (Cook’s \(D\)), and subject 10 and 21 have large PRESS statistics. The twenty-first child has a large PRESS statistic, and its \(D\) statistic is not that extreme. This is an indication that the model fits rather poorly for this child, whether it is part of the data or not.

</tbody>
</table>

The previous analysis does not take into account the effect on the covariance parameters when a subject is removed from the analysis. If you also update the covariance parameters, the impact of observations on these can amplify or allay their effect on the fixed effects. To assess the overall influence of subjects on the analysis and to compute separate statistics for the fixed effects and covariance parameters, an iterative analysis is obtained by adding the INFLUENCE suboption ITER=.
The number of additional iterations following removal of the observations for a particular subject is limited to five. Graphical displays of influence diagnostics are requested by specifying the experimental ODS GRAPHICS statement. The MIXED procedure produces a plot of influence statistics that pertain to overall influence and the fixed effects (Output 46.8.2) and a second panel that shows the influence on the covariance parameters (Output 46.8.3). For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.

**Output 46.8.2.** Overall and Fixed Effects Diagnostics (Experimental)

As judged by the restricted likelihood distance in **Output 46.8.2**, subjects 20 and 24 clearly have the most influence on the overall analysis. The reference line in this plot is the 75th percentile of a chi-square distribution with degrees of freedom equal to the number of parameters being updated (14). Comparing the $D$ statistics for fixed
effects and covariance parameters, subject 20 has a dramatic effect on the estimates of variances and covariances. This subject also affects the precision of the covariance parameter estimates more than any other subject in Output 46.8.3 (COVRATIO near 0, large COVTRACE, MDFFITS large compared to Cook’s D).

Output 46.8.3. Covariance Parameter Diagnostics (Experimental)

The child who exerts the greatest influence on the fixed effects is subject 24. Maybe surprisingly, this subject impacts the variance-covariance matrix of the fixed effects more than subject 20 (small COVRATIO in Output 46.8.3).

The final model investigated for these data is a random coefficient model as in Stram and Lee (1994) with random effects for the intercept and age effect. The following statements examine the estimates for fixed effects and the entries of the unstructured $2 \times 2$ variance matrix of the random coefficients graphically.

```
ods html;
ods graphics on;
proc mixed data=pr method=ml;
   class person gender;
   model y = gender age gender*age /
       influence(iter=5 effect=person est);
   random intercept age / type=un subject=person;
   ods select InfluenceEstParmPanel1
       InfluenceEstCovPPanel1;
run;
ods graphics off;
ods html close;
```
In Output 46.8.4 the graphs on the left-hand side of the panel represent the intercept and slope estimate for boys; the graphs on the right-hand side represent the difference in intercept and slope between boys and girls. Removing any one of the first eleven children, who are girls, does not alter the intercept or slope in the group of boys. The difference in these parameters between boys and girls is altered by the removal of any child. Subject 24 changes the fixed effects considerably, subject 20 much less so. This is consistent with findings based on the unstructured variance-covariance model (Output 46.8.2).

Output 46.8.4. Fixed Effects Delete Estimates (Experimental)

The covariance parameter estimates in Output 46.8.5 show several important features.

- The panels do not contain information on subject 24. Estimation of the $G$ matrix following removal of that child did not yield a positive definite matrix. As a consequence, covariance parameter diagnostics are not produced for this subject.
- Subject 20 has great impact on the four covariance parameters. Removing this child from the analysis increases the variance of the random intercept and random slope and reduces the residual variance by almost 80%. The repeated measurements of this child exhibit an up-and-down behavior.
- The variance of the random intercept and slope are reduced when child 15 is removed from the analysis. This child’s growth measurements oscillate about 27.0 from age 10 on.
Examining observed and residual values by levels of classification variables is also a useful tool to diagnose the adequacy of the model and unusual observations. Box plots for effects in the model that comprise a single classification variable are requested with the experimental ODS GRAPHICS statement and the experimental BOXPLOT option of the PROC MIXED statement. Since this includes SUBJECT= and GROUP= effects, the statements

```
ods html;
ods graphics on;

proc mixed data=pr method=ml boxplot;
   class person gender;
   model y = gender age gender*age;
   random intercept age / type=un subject=person;
run;

ods graphics off;
ods html close;
```

produce six box plots in the following order: Y by Gender, residual by Gender, Y by Person, residual by Person, and conditional residuals by Gender and Person. The plots for the Person effect are shown in Output 46.8.6 – Output 46.8.8.

Box plots of the observed values show the variation within and between children clearly. The group of girls (subjects 1–11) is distinguishable from the group of boys by somewhat lesser average growth and lesser within-child variation (Output 46.8.6). After adjusting for overall (population-averaged) gender and age effects, the residual within-child variation is reduced but substantial differences in the means remain
If child-specific inferences are desired, a model accounting for only Gender, Age, and Gender*Age effects is not adequate for these data.

Output 46.8.6. Distribution of Observed Values (Experimental)

Output 46.8.7. Distribution of Marginal Residuals (Experimental)
The conditional residuals incorporate the EBLUPs for each child and enable you to examine whether the subject-specific model is adequate (Output 46.8.8). By using each child “as its own control” the residuals are now centered near zero. Subjects 20 and 24 stand out as unusual in all three sets of box plots.

**Output 46.8.8.** Distribution of Conditional Residuals (Experimental)

![Distribution of Conditional Residuals by Person](image)

Example 46.9. Examining Individual Test Components

The LCOMPONENTS option of the MODEL statement enables you to perform single degree of freedom tests for individual rows of the $L$ matrix. Such tests are useful to identify interaction patterns. In a balanced layout, Type 3 components of $L$ associated with $A*B$ interactions correspond to simple contrasts of cell mean differences.

The first example revisits the data from the split-plot design by Stroup (1989a) that was analyzed in Example 46.1 on page 2777. Recall that variables $A$ and $B$ represent the whole-plot and subplot factors, respectively.

```sas
proc mixed data=sp;
  class a b block;
  model y = a b a*b / LComponents e3;
  random block a*block;
run;
```

The MIXED procedure constructs a separate $L$ matrix for each of the three fixed effects components. The matrices are displayed in Output 46.9.1. The test for fixed effects are shown in Output 46.9.2.
Output 46.9.1. Coefficients of Type 3 Estimable Functions

If \( \mu_i \) denotes a whole-plot main effect mean, \( \mu_{.j} \) denotes a subplot main effect mean, and \( \mu_{ij} \) denotes a cell mean, the five components shown in Output 46.9.3 correspond to tests of

- \( H_0 : \mu_1 = \mu_2 \)
- \( H_0 : \mu_2 = \mu_3 \)
- \( H_0 : \mu_{1.} = \mu_{.2} \)
- \( H_0 : \mu_{11} - \mu_{12} = \mu_{31} - \mu_{32} \)
- \( H_0 : \mu_{21} - \mu_{22} = \mu_{31} - \mu_{32} \)

Output 46.9.3. Type 3 LComponents Table

The Mixed Procedure

L Components of Type 3 Tests of Fixed Effects

| Effect | L Index | Standard Error | DF | t Value | Pr > |t| |
|--------|--------|----------------|----|---------|------|---|
| A      | 1      | 3.1672          | 6  | 2.25    | 0.0655 |
| A      | 2      | 3.1672          | 6  | 2.64    | 0.0383 |
| B      | 1      | 1.2491          | 9  | 4.40    | 0.0017 |
| A*B    | 1      | 3.0596          | 9  | 2.53    | 0.0321 |
| A*B    | 2      | 3.0596          | 9  | 2.37    | 0.0419 |

The first three components are comparisons of marginal means. The fourth component compares the effect of factor B at the first whole-plot level against the effect of B at the third whole-plot level. Finally, the last component tests whether the factor B effect changes between the second and third whole-plot level.
The Type 3 component tests can also be produced with corresponding ESTIMATE statements.

```sas
proc mixed data=sp;
   class a b block ;
   model y = a b a*b;
   random block a*block;
   estimate 'a 1' a 1 0 -1;
   estimate 'a 2' a 0 1 -1;
   estimate 'b 1' b 1 -1;
   estimate 'a*b 1' a*b 1 -1 0 0 -1 1;
   estimate 'a*b 2' a*b 0 0 1 -1 -1 1;
   ods select estimates;
run;
```

| Label   | Estimate | Standard Error | DF | t Value | Pr > |t| |
|---------|----------|----------------|----|---------|------|---|
| a 1     | 7.1250   | 3.1672         | 6  | 2.25    | 0.0655 |
| a 2     | 8.3750   | 3.1672         | 6  | 2.64    | 0.0383 |
| b 1     | 5.5000   | 1.2491         | 9  | 4.40    | 0.0017 |
| a*b 1   | 7.7500   | 3.0596         | 9  | 2.53    | 0.0321 |
| a*b 2   | 7.2500   | 3.0596         | 9  | 2.37    | 0.0419 |

A second useful application of the LCOMPONENT option is in polynomial models where Type 1 tests are often used to test the entry of model terms sequentially. The SOLUTION option of the MODEL statement displays the regression coefficients that correspond to a Type 3 analysis, that is,

- the coefficients represent the partial coefficients you would get by adding the regressor variable last in a model containing all other effects
- the tests are identical to those in the “Type 3 Tests of Fixed Effects” table

Consider the following data set and the fit of a third order polynomial regression model.

```sas
data polynomial;
   do x=1 to 20; input y@@; output; end;
datalines;

proc mixed data=polynomial;
   model y = x x*x x*x*x / s lcomponents htype=1;
run;
```
The t-tests displayed in the “Solution for Fixed Effects” table are Type 3 tests, sometimes referred to as partial tests. They measure the contribution of a regressor in the presence of all other regressor variables in the model.

### The Mixed Procedure

**Solution for Fixed Effects**

| Effect     | Estimate | Error  | DF | t Value | Pr > |t| |
|------------|----------|--------|----|---------|------|---|
| Intercept  | 0.7837   | 0.3545 | 16 | 2.21    | 0.0420 |
| x          | 0.3726   | 0.1426 | 16 | 2.61    | 0.0189 |
| x*x        | 0.04756  | 0.01558| 16 | 3.05    | 0.0076 |
| x*x*x      | -0.00306 | 0.000489| 16 | -6.27   | <.0001 |

The Type 3 L components are identical to the tests in the “Solutions for Fixed Effects” table. The Type 1 table yields:

- sequential (Type 1) tests of regression variables which test the significance of a regressor given all other variables preceding it in the model list
- the regression coefficients for sequential submodels

### The Mixed Procedure

**L Components of Type 1 Tests of Fixed Effects**

| Effect | Index | Estimate | Error  | DF | t Value | Pr > |t| |
|--------|-------|----------|--------|----|---------|------|---|
| x      | 1     | 0.1763   | 0.01259| 16 | 14.01   | <.0001 |
| x*x    | 1     | -0.04886 | 0.002449| 16 | -19.95  | <.0001 |
| x*x*x  | 1     | -0.00306 | 0.000489| 16 | -6.27   | <.0001 |

**L Components of Type 3 Tests of Fixed Effects**

| Effect | Index | Estimate | Error  | DF | t Value | Pr > |t| |
|--------|-------|----------|--------|----|---------|------|---|
| x      | 1     | 0.3726   | 0.1426 | 16 | 2.61    | 0.0189 |
| x*x    | 1     | 0.04756  | 0.01558| 16 | 3.05    | 0.0076 |
| x*x*x  | 1     | -0.00306 | 0.000489| 16 | -6.27   | <.0001 |

The estimate of 0.1763 is the regression coefficient in a simple linear regression of \( Y \) on \( X \). The estimate of \(-0.04886\) is the partial coefficient for the quadratic term when it is added to a model containing only a linear component. Similarly, the value \(-0.00306\) is the partial coefficient for the cubic term when it is added to a model containing a linear and quadratic component. The last Type 1 component is always identical to the corresponding Type 3 component.

Chapter 47
The MODECLUS Procedure

Overview

The MODECLUS procedure clusters observations in a SAS data set using any of several algorithms based on nonparametric density estimates. The data can be numeric coordinates or distances. PROC MODECLUS can perform approximate significance tests for the number of clusters and can hierarchically join nonsignificant clusters. The significance tests are empirically validated by simulations with sample sizes ranging from 20 to 2000.

PROC MODECLUS produces output data sets containing density estimates and cluster membership, various cluster statistics including approximate $p$-values, and a summary of the number of clusters generated by various algorithms, smoothing parameters, and significance levels.

Most clustering methods are biased toward finding clusters possessing certain characteristics related to size (number of members), shape, or dispersion. Methods based on the least-squares criterion (Sarle 1982), such as $k$-means and Ward’s minimum variance method, tend to find clusters with roughly the same number of observations in each cluster. Average linkage (see Chapter 23, “The CLUSTER Procedure,”) is somewhat biased toward finding clusters of equal variance. Many clustering methods tend to produce compact, roughly hyperspherical clusters and are incapable of detecting clusters with highly elongated or irregular shapes. The methods with the least bias are those based on nonparametric density estimation (Silverman 1986, pp. 130–146; Scott 1992, pp. 125–190) such as density linkage (see Chapter 23, “The CLUSTER Procedure,”) Wong and Lane 1983, and Wong and Schaack 1982). The biases of many commonly used clustering methods are discussed in Chapter 7, “Introduction to Clustering Procedures.”

PROC MODECLUS implements several clustering methods using nonparametric density estimation. Such clustering methods are referred to hereafter as nonparametric clustering methods. The methods in PROC MODECLUS are related to, but not identical to, methods developed by Gitman (1973), Huizinga (1978), Koontz and Fukunaga (1972a, 1972b), Koontz, Narendra, and Fukunaga (1976), Mizoguchi and Shimura (1980), and Wong and Lane (1983). Details of the algorithms are provided in the section “Clustering Methods” on page 2874.

For nonparametric clustering methods, a cluster is loosely defined as a region surrounding a local maximum of the probability density function (see the section “Significance Tests” on page 2876 for a more rigorous definition). Given a sufficiently large sample, nonparametric clustering methods are capable of detecting clusters of unequal size and dispersion and with highly irregular shapes. Nonparametric methods can also obtain good results for compact clusters of equal size and disper-
For coordinate data, nonparametric clustering methods are less sensitive to changes in scale of the variables or to affine transformations of the variables than are most other commonly used clustering methods. Nevertheless, it is necessary to consider questions of scaling and transformation, since variables with large variances tend to have more effect on the resulting clusters than those with small variances. If two or more variables are not measured in comparable units, some type of standardization or scaling is necessary; otherwise, the distances used by the procedure may be based on inappropriate apples-and-oranges computations. For variables with comparable units of measurement, standardization or scaling may still be desirable if the scale estimates of the variables are not related to their expected importance for defining clusters. If you want two variables to have equal importance in the analysis, they should have roughly equal scale estimates. If you want one variable to have more effect than another, the former should be scaled to have a greater scale estimate than the latter. The STD option in the PROC MODECLUS statement scales all variables to equal variance. However, the variance is not necessarily the most appropriate scale estimate for cluster analysis. In particular, outliers should be removed before using PROC MODECLUS with the STD option. A variety of scale estimators including robust estimators are provided in the STDIZE procedure (for detailed information, see Chapter 66, “The STDIZE Procedure.”). Additionally, the ACECLUS procedure provides another way to transform the variables to try to improve the separation of clusters.

Since clusters are defined in terms of local maxima of the probability density function, nonlinear transformations of the data may change the number of population clusters. The variables should be transformed so that equal differences are of equal practical importance. An interval scale of measurement is required. Ordinal or ranked data are generally inappropriate, since monotone transformations can produce any arbitrary number of modes.

Unlike the methods in the CLUSTER procedure, the methods in the MODECLUS procedure are not inherently hierarchical. However, PROC MODECLUS can do approximate nonparametric significance tests for the number of clusters by obtaining an approximate $p$-value for each cluster, and it can hierarchically join nonsignificant clusters.

Another important difference between the MODECLUS procedure and many other clustering methods is that you do not tell PROC MODECLUS how many clusters you want. Instead, you specify a smoothing parameter (see the section “Density Estimation” on page 2870) and, optionally, a significance level, and PROC MODECLUS determines the number of clusters. You can specify a list of smoothing parameters, and PROC MODECLUS performs a separate cluster analysis for each value in the list.
This section illustrates how PROC MODECLUS can be used to examine the clusters of data in the following artificial data set.

```sas
data example;
  input x y @@;
datalines;
18 18 20 22 21 20 12 23 17 12 23 25 25 20 16 27
20 13 28 22 80 20 75 19 77 23 81 26 55 21 64 24
72 26 70 35 75 30 78 42 18 52 27 57 41 61 48 64
59 72 69 72 80 80 31 53 51 69 72 81
;
```

It is a good practice to plot the data to check for obvious clusters or pathologies prior to the analysis. The interactive graphics of the SAS/INSIGHT product are effective for visualizing clusters. In this example, with only two variables and a small sample size, the GPLOT procedure is adequate. The following statements produce Figure 47.1:

```sas
axis1 label=(angle=90 rotate=0) minor=none
  order=(0 to 80 by 20);
axis2 minor=none;
proc gplot;
  plot y*x /frame cframe=ligr vaxis=axis1 haxis=axis2;
run;
```

The plot suggests three clusters. Of these clusters, the one in the lower left corner is the most compact, while the lower right cluster is more dispersed.

The upper cluster is elongated and would be difficult for most clustering algorithms to identify as a single cluster. The plot also suggests that a Euclidean distance of 10 or 20 is a good initial guess for the neighborhood size in density estimation and clustering.
To obtain a cluster analysis, you must specify the METHOD= option; for most purposes, METHOD=1 is recommended. The cluster analysis can be performed with a list of radii (R=10 15 35), as illustrated in the following PROC MODECLUS step. An output data set containing the cluster membership is created with the OUT= option and then used by PROC GPLOT to display the membership. The following statements produce Figure 47.2 through Figure 47.5:

```plaintext
proc modeclus data=example method=1 r=10 15 35 out=out;
run;
```

For each cluster solution, PROC MODECLUS produces a table of cluster statistics including the cluster number, the number of observations in the cluster, the maximum estimated density within the cluster, the number of observations in the cluster having a neighbor that belongs to a different cluster, and the estimated saddle density of the cluster. The results are displayed in Figure 47.2, Figure 47.3, and Figure 47.4 for three different radii. A smaller radius (R=10) yields a larger number of clusters (6), as displayed in Figure 47.1; a larger radius (R=35) includes all observations in a single cluster, as displayed in Figure 47.5. Note that all clusters in these three figures are “isolated” since their corresponding boundary frequencies are all 0s. Therefore, all the estimated saddle densities are missing.

Syntax

The following statements invoke the MODECLUS procedure:

```
PROC MODECLUS < options > ;
    BY variables ;
    FREQ | FREQUENCY variable ;
    ID variable ;
    VAR | VARIABLES variables ;
```

The PROC MODECLUS statement is required. All other statements are optional.

**PROC MODECLUS Statement**

```
PROC MODECLUS < options > ;
```

The PROC MODECLUS statement invokes the procedure.

Options available in the PROC MODECLUS statement are classified by function in Table 47.1. The corresponding default value for each option, if applicable, is also listed in this table.

You can specify at least one of the following options for smoothing parameters for density estimation: DK=, K=, DR=, or R=. To obtain a cluster analysis, you can specify the METHOD= option and at least one of the following smoothing parameters for clustering: CK=, K=, CR=, or R=. If you want significance tests for the number of clusters, you should specify either the DR= or R= option. If none of the smoothing parameters is specified, the MODECLUS procedure provides a default value for the R= option. See the section “Density Estimation” on page 2870 for the formula of a reasonable first guess for R= and a discussion of smoothing parameters.

You can specify lists of values for the DK=, CK=, K=, DR=, CR=, and R= options. Numbers in the lists can be separated by blanks or commas. You can include in the lists one or more items of the form start TO stop BY increment. Each list can contain either one value or the same number of values as in every other list that contains more than one value. If a list has only one value, that value is used in combination with all the values in longer lists. If two or more lists have more than one value, then one analysis is done using the first value in each list, another analysis is done using the second value in each list, and so on.

You can specify the following options in the PROC MODECLUS statement.
ALL
produces all optional output.

AM
specifies arithmetic means for cascading density estimates. See the description of the CASCADE= option.

BOUNDARY
displays the density and cluster membership of observations with neighbors belonging to a different cluster.

CASCADE=n
CASC=n
specifies the number of times the density estimates are to be cascaded (see the section “Density Estimation” on page 2870). The default value 0 performs no cascading.

You can specify a list of values for the CASCADE= option. Each value in the list is combined with each combination of smoothing parameters to produce a separate analysis.

CK=n
specifies the number of neighbors to use for clustering. The number of neighbors should be at least 2 but less than the number of observations. See the section “Density Estimation” on page 2870.

CLUSTER=name
provides a name for the variable in the OUT= and OUTCLUS= data sets identifying clusters. The default name is CLUSTER.

CORE
keeps the neighbor lists for each observation in the computer memory to make small problems run faster.

CR=n
specifies the radius of the neighborhood for clustering. See the section “Density Estimation” on page 2870.

CROSS
computes the likelihood cross-validation criterion (Silverman 1986, pp. 52–55). This option appears to be of limited usefulness (see the section “Density Estimation” on page 2870).

CROSSLIST
displays the cross-validated log density of each observation.

DATA=SAS-data-set
specifies the input data set containing observations to be clustered. If you omit the DATA= option, the most recently created SAS data set is used.

If the data set is TYPE=DISTANCE, the data are interpreted as a distance matrix. The number of variables must equal the number of observations in the data set or in each BY group. The distances are assumed to be Euclidean, but the procedure accepts other types of distances or dissimilarities. Unlike the CLUSTER procedure,
PROC MODECLUS uses the entire distance matrix, not just the lower triangle; the distances are not required to be symmetric. The neighbors of a given observation are determined solely from the distances in that observation. Missing values are considered infinite. Various distance measures can be computed from coordinate data using the DISTANCE procedure (for detailed information, see Chapter 26, “The DISTANCE Procedure,”).

If the data set is not TYPE=DISTANCE, the data are interpreted as coordinates in a Euclidean space, and Euclidean distances are computed. The variables can be discrete or continuous and should be at the interval level of measurement.

**DENSITY=name**

provides a name for the variable in the OUT= data set containing density estimates. The default name is DENSITY.

**DIMENSION=n**

**DIM=n**
specifies the dimensionality to be used when computing density estimates. The default is the number of variables if the data are coordinates; the default is 1 if the data are distances.

**DK=n**
specifies the number of neighbors to use for $k$th-nearest-neighbor density estimation. The number of neighbors should be at least 2 but less than the number of observations. See the section “Density Estimation” on page 2870.

**DOCK=n**
dissolves clusters with $n$ or fewer members by making the members unassigned.

**DR=n**
specifies the radius of the sphere of support for uniform-kernel density estimation. See the section “Density Estimation” on page 2870.

**EARLY**

stops the cluster analysis after obtaining either a solution with no cluster or a solution with one cluster to which all observations are assigned. The smoothing parameters should be specified in increasing order. This can reduce the computer time required for the analysis but may occasionally miss some multiple-cluster solutions.

**HM**

uses harmonic means for cascading density estimates. See the description of the CASCADE= option.

**JOIN=<p>**

requests that nonsignificant clusters be hierarchically joined. The JOIN option implies the TEST option. After each solution is obtained, the cluster with the largest approximate $p$-value is either joined to a neighboring cluster or, if there is no neighboring cluster, dissolved by making all of its members unassigned. After two clusters are joined, an analysis of the remaining clusters is displayed.

If you do not specify a $p$-value with the JOIN= option, joining continues until only one cluster remains, and the results are written to the output data sets after each
analysis. If you specify a $p$-value with the JOIN= option, joining continues until the greatest approximate $p$-value is less than the value given in the JOIN= option, and only if there is more than one cluster are the results for that analysis written to the output data sets.

Any value of $p$ less than $1E^{-8}$ is set to $1E^{-8}$.

$K=n$

specifies the number of neighbors to use for $k$th-nearest-neighbor density estimation and clustering. The number of neighbors should be at least 2 but less than the number of observations. Specifying $K=n$ is equivalent to specifying both $DK=n$ and $CK=n$. See the section “Density Estimation” on page 2870.

**LIST**

displays the estimated density and cluster membership of each observation.

**LOCAL**

**MAXCLUSTERS=n**

**MAXC=n**

specifies the maximum number of clusters to be obtained with the METHOD=6 option. By default, there is no fixed limit.

**METHOD=n**

**MET=n**

**M=n**

specifies what clustering method to use. Since these methods do not have widely recognized names, the methods are indicated by numbers from 0 to 6. The methods are described in the section “Clustering Methods” on page 2874. For most purposes, METHOD=1 is recommended, although METHOD=6 may occasionally produce better results in return for considerably greater computer time and space requirements. METHOD=1 is not good for discrete coordinate data with only a few equally spaced values. In this case, METHOD=6 or METHOD=3 works better. METHOD=4 or METHOD=5 is less desirable than other methods when there are ties, since a general characteristic of agglomerative hierarchical clustering methods is that the results are indeterminate in the presence of ties.

You must specify the METHOD= option to obtain a cluster analysis.

You can specify a list of values for the METHOD= option. Each value in the list is combined with each combination of smoothing and cascading parameters to produce a separate cluster analysis.

**MODE=n**

specifies that when two clusters are joined using the METHOD=5 option (no other methods are affected by the MODE= option), each must have at least $n$ members for either cluster to be designated a modal cluster. In any case, each cluster must also have a maximum density greater than the fusion density for either cluster to be designated a modal cluster. If you specify the $K$= option, the default value of the MODE= option is the same as the value of the $K$= option because the use of $k$th-nearest-neighbor density estimation limits the resolution that can be obtained for
clusters with fewer than \( k \) members. If you do not specify the K= option, the default is \( \text{MODE}=2 \). If you specify \( \text{MODE}=0 \), the default value is used instead of 0. If you specify a FREQ statement, the \( \text{MODE}= \) value is compared to the number of observations in each cluster, not to the sum of the frequencies.

### NEIGHBOR

Displays the neighbors of each observation in a table called “Nearest Neighbor List.”

### NOPRINT

Suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

### NOSUMMARY

Suppresses the display of the summary of the number of clusters, number of unassigned observations, and maximum \( p \)-value for each analysis.

### OUT= SAS-data-set

Specifies the output data set containing the input data plus density estimates, cluster membership, and variables identifying the type of solution. There is an output observation corresponding to each input observation for each solution. Therefore, the OUT= data set can be very large.

### OUTCLUS= SAS-data-set

Specifies the output data set containing an observation corresponding to each cluster in each solution. The variables identify the solution and contain statistics describing the clusters.

### OUTSUM= SAS-data-set

Specifies the output data set containing an observation corresponding to each cluster solution giving the number of clusters and the number of unclassified observations for that solution.

### OUTLENGTH= n

OUTL= n

Specifies the length of those output variables that are not copied from the input data set but are created by PROC MODECLUS.

The OUTLENGTH= option applies only to the following variables that appear in all of the output data sets: \(_K_\), \(_DK_\), \(_CK_\), \(_R_\), \(_DR_\), \(_C_\), \(_CASCAD_\), \(_\text{METHOD}_\), \(_NJOIN_\), and \(_\text{LOCAL}_\).

The minimum value is 2 or 3, depending on the operating system. The maximum value is 8. The default value is 8.

### POWER= n

POW= n

Specifies the power of the density used with the METHOD=6 option. The default value is 2.
BY Statement

BY variables;

You can specify a BY statement with PROC MODECLUS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
• Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MODECLUS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

• Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

**FREQ Statement**

    FREQ | FREQUENCY  variable ;

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable’s name in a FREQ statement. PROC MODECLUS then treats the data set as if each observation appeared \( n \) times, where \( n \) is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value.

**ID Statement**

    ID  variable ;

The values of the ID variable identify observations in the displayed results and in the OUT= data set. If you omit the ID statement, each observation is identified by its observation number, and a variable called `_OBS_` is written to the OUT= data set containing the original observation numbers.

**VAR Statement**

    VAR | VARIABLES  variables ;

The VAR statement specifies numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not specified in other statements are used.

**Details**

**Density Estimation**

Refer to Silverman (1986) or Scott (1992) for an introduction to nonparametric density estimation.

PROC MODECLUS uses (hyper)spherical uniform kernels of fixed or variable radius. The density estimate at a point is computed by dividing the number of observations within a sphere centered at the point by the product of the sample size and the volume of the sphere. The size of the sphere is determined by the smoothing parameters that you are required to specify.
For fixed-radius kernels, specify the radius as a Euclidean distance with either the DR= or R= option. For variable-radius kernels, specify the number of neighbors desired within the sphere with either the DK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations including the observation at which the density is being estimated. If you specify both the DR= or R= option and the DK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers.

It is convenient to refer to the sphere of support of the kernel at observation \( x_i \) as the neighborhood of \( x_i \). The observations within the neighborhood of \( x_i \) are the neighbors of \( x_i \). In some contexts, \( x_i \) is considered a neighbor of itself, but in other contexts it is not. The following notation is used in this chapter.

\[
\begin{align*}
    x_i & \quad \text{the } i\text{th observation} \\
    d(x,y) & \quad \text{the distance between points } x \text{ and } y \\
    n & \quad \text{the total number of observations in the sample} \\
    n_i & \quad \text{the number of observations within the neighborhood of } x_i \text{ including } x_i \text{ itself} \\
    n_i^- & \quad \text{the number of observations within the neighborhood of } x_i \text{ not including } x_i \text{ itself} \\
    N_i & \quad \text{the set of indices of neighbors of } x_i \text{ including } i \\
    N_i^- & \quad \text{the set of indices of neighbors of } x_i \text{ not including } i \\
    v_i & \quad \text{the volume of the neighborhood of } x_i \\
    \hat{f}_i & \quad \text{the estimated density at } x_i \\
    \hat{f}_i^- & \quad \text{the cross-validated density estimate at } x_i \\
    C_k & \quad \text{the set of indices of observations assigned to cluster } k \\
    v & \quad \text{the number of variables or the dimensionality} \\
    s_l & \quad \text{standard deviation of the } l\text{th variable}
\end{align*}
\]

The estimated density at \( x_i \) is

\[
\hat{f}_i = \frac{n_i}{nv_i}
\]

that is, the number of neighbors of \( x_i \) divided by the product of the sample size and the volume of the neighborhood at \( x_i \).

The density estimates provided by uniform kernels are not quite as good as those provided by some other types of kernels, but they are quite satisfactory for clustering. The significance tests for the number of clusters require the use of fixed-size uniform kernels.

There is no simple answer to the question of which smoothing parameter to use (Silverman 1986, pp. 43–61, 84–88, 98–99). It is usually necessary to try several different smoothing parameters. A reasonable first guess for the K= option is in the
range of 0.1 to 1 times $n^{4/(v+4)}$, smaller values being suitable for higher dimensions. A reasonable first guess for the R= option in many coordinate data sets is given by

$$\left[ \frac{2^{v+2}(v+2)\Gamma(0.5v+1)}{nv^2} \right]^{1/(v+4)} \sqrt{\frac{\sum s_l^2}{nv}}$$

which can be computed in a DATA step using the GAMMA function for $\Gamma$. The MODECLUS procedure also provides this first guess as a default smoothing parameter if none of the options (DR=, CR=, R=, DK=, CK=, and K= ) is specified. This formula is derived under the assumption that the data are sampled from a multivariate normal distribution and, therefore, tend to be too large (oversmooth) if the true distribution is multimodal. Robust estimates of the standard deviations may be preferable if there are outliers. If the data are distances, the factor $\sqrt{\sum s_l^2}$ can be replaced by an average root-mean-square Euclidean distance divided by $\sqrt{2}$. To prevent outliers from appearing as separate clusters, you can also specify K=2 or CK=2 or, more generally, K=m or CK=m, $m \geq 2$, which in most cases forces clusters to have at least $m$ members.

If the variables all have unit variance (for example, if you specify the STD option), you can use Table 47.2 to obtain an initial guess for the R= option.

**Table 47.2.** Reasonable First Guess for R= for Standardized Data

</table>

One data-based method for choosing the smoothing parameter is likelihood cross validation (Silverman 1986, pp. 52–55). The cross-validated density estimate at an observation is obtained by omitting the observation from the computations.

$$\hat{f}_i^- = \frac{n_i^-}{nv_i}$$
The (log) likelihood cross-validation criterion is then computed as

$$\sum_{i=1}^{n} \log \hat{f}_i$$

The suggested smoothing parameter is the one that maximizes this criterion. With fixed-radius kernels, likelihood cross validation oversmooths long-tailed distributions; for purposes of clustering, it tends to undersmooth short-tailed distributions. With $k$-nearest-neighbor density estimation, likelihood cross validation is useless because it almost always indicates $k=2$.

Cascaded density estimates are obtained by computing initial kernel density estimates and then, at each observation, taking the arithmetic mean, harmonic mean, or sum of the initial density estimates of the observations within the neighborhood. The cascaded density estimates can, in turn, be cascaded, and so on. Let $k\hat{f}_i$ be the density estimate at $x_i$ cascaded $k$ times. For all types of cascading, $0\hat{f}_i = \hat{f}_i$. If the cascading is done by arithmetic means, then, for $k \geq 0$,

$$k+1\hat{f}_i = \sum_{j \in N_i} k\hat{f}_j / n_i$$

For harmonic means,

$$k+1\hat{f}_i = \left( \sum_{j \in N_i} k\hat{f}_j^{-1} / n_i \right)^{-1}$$

and for sums,

$$k+1\hat{f}_i = \left( \sum_{j \in N_i} k\hat{f}_j^{k+1} / n_i \right)^{1/(k+2)}$$

To avoid cluttering formulas, the symbol $\hat{f}_i$ is used from now on to denote the density estimate at $x_i$ whether cascaded or not, since the clustering methods and significance tests do not depend on the degree of cascading.

Cascading increases the smoothness of the estimates with less computation than would be required by increasing the smoothing parameters to yield a comparable degree of smoothness. For population densities with bounded support and discontinuities at the boundaries, cascading improves estimates near the boundaries. Cascaded estimates, especially using sums, may be more sensitive to the local covariance structure of the distribution than are the uncascaded kernel estimates. Cascading seems to be useful for detecting very nonspherical clusters. Cascading was suggested by Tukey and Tukey (1981, p. 237). Additional research into the properties of cascaded density estimates is needed.
Clustering Methods

The number of clusters is a function of the smoothing parameters. The number of clusters tends to decrease as the smoothing parameters increase, but the relationship is not strictly monotonic. Generally, you should specify several different values of the smoothing parameters to see how the number of clusters varies.

The clustering methods used by PROC MODECLUS use spherical clustering neighborhoods of fixed or variable radius that are similar to the spherical kernels used for density estimation. For fixed-radius neighborhoods, specify the radius as a Euclidean distance with either the CR= or R= option. For variable-radius neighborhoods, specify the number of neighbors desired within the sphere with either the CK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations including the observation for which the neighborhood is being determined. However, in the following descriptions of clustering methods, an observation is not considered to be one of its own neighbors. If you specify both the CR= or R= option and the CK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers. In this section, the symbols $N_i$, $N_i^-$, $n_i$, and $n_i^-$ refer to clustering neighborhoods, not density estimation neighborhoods.

$METHOD=0$

Begin with each observation in a separate cluster. For each observation and each of its neighbors, join the cluster to which the observation belongs with the cluster to which the neighbor belongs. This method does not use density estimates. With a fixed clustering radius, the clusters are those obtained by cutting the single linkage tree at the specified radius (see Chapter 23, “The CLUSTER Procedure,”).

$METHOD=1$

Begin with each observation in a separate cluster. For each observation, find the nearest neighbor with a greater estimated density. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Next, consider each observation with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor. Join the cluster containing the observation with (1) each cluster containing a neighbor of the observation such that the maximum density estimate in the cluster equals the density estimate at the observation and (2) the cluster containing the nearest neighbor of the observation such that the maximum density estimate in the cluster exceeds the density estimate at the observation.

This method is similar to the classification or assignment stage of algorithms described by Gitman (1973) and Huizinga (1978).
**METHOD=2**

Begin with each observation in a separate cluster. For each observation, find the neighbor with the greatest estimated density exceeding the estimated density of the observation. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1.

This method is similar to the first stage of an algorithm proposed by Mizoguchi and Shimura (1980).

**METHOD=3**

Begin with each observation in a separate cluster. For each observation, find the neighbor with greater estimated density such that the slope of the line connecting the point on the estimated density surface at the observation with the point on the estimated density surface at the neighbor is a maximum. That is, for observation \( x_i \), find a neighbor \( x_j \) such that \( (\hat{f}_j - \hat{f}_i) / d(x_j, x_i) \) is a maximum. If this slope is positive, join the cluster to which observation \( x_i \) belongs with the cluster to which the specified neighbor \( x_j \) belongs. This method was invented by Koontz, Narendra, and Fukunaga (1976).

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1. The algorithm suggested for this situation by Koontz, Narendra, and Fukunaga (1976) may fail for flat areas in the estimated density that contain four or more observations.

**METHOD=4**

This method is equivalent to the first stage of two-stage density linkage (see Chapter 23, “The CLUSTER Procedure,”) without the use of the MODE=option.

**METHOD=5**

This method is equivalent to the first stage of two-stage density linkage (see Chapter 23, “The CLUSTER Procedure,”) with the use of the MODE=option.

**METHOD=6**

Begin with all observations unassigned.

**Step 1:** Form a list of seeds, each seed being a single observation such that the estimated density of the observation is not less than the estimated density of any of its neighbors. If you specify the MAXCLUSTERS=\( n \) option, retain only the \( n \) seeds with the greatest estimated densities.

**Step 2:** Consider each seed in decreasing order of estimated density.
1. If the current seed has already been assigned, proceed to the next seed. Otherwise, form a new cluster consisting of the current seed.

2. Add to the cluster any unassigned seed that is a neighbor of a member of the cluster or that shares a neighbor with a member of the cluster; repeat until no unassigned seed satisfies these conditions.

3. Add to the cluster all neighbors of seeds that belong to the cluster.

4. Consider each unassigned observation. Compute the ratio of the sum of the $p-1$ powers of the estimated density of the neighbors that belong to the current cluster to the sum of the $p-1$ powers of the estimated density of all of its neighbors, where $p$ is specified by the POWER= option and is 2 by default. Let $x_i$ be the current observation, and let $k$ be the index of the current cluster. Then this ratio is

$$r_{ik} = \frac{\sum_{j \in N_i \cap C_k} \hat{f}_j^{p-1}}{\sum_{j \in N_i} \hat{f}_j^{p-1}}$$

(The sum of the $p-1$ powers of the estimated density of the neighbors of an observation is an estimate of the integral of the $p$th power of the density over the neighborhood.) If $r_{ik}$ exceeds the maximum of 0.5 and the value of the THRESHOLD= option, add the observation $x_i$ to the current cluster $k$. Repeat until no more observations can be added to the current cluster.

**Step 3:** (This step is performed only if the value of the THRESHOLD= option is less than 0.5.) Form a list of unassigned observations in decreasing order of estimated density. Repeat the following actions until the list is empty.

1. Remove the first observation from the list, for example, observation $x_i$.

2. For each cluster $k$, compute $r_{ik}$.

3. If the maximum over clusters of $r_{ik}$ exceeds the value of the THRESHOLD= option, assign observation $x_i$ to the corresponding cluster and insert all observations of which the current observation is a neighbor into the list, keeping the list in decreasing order of estimated density.

METHOD=6 is related to a method invented by Koontz and Fukunaga (1972a) and discussed by Koontz and Fukunaga (1972b).

### Significance Tests

Significance tests require that a fixed-radius kernel be specified for density estimation via the DR= or R= option. You can also specify the DK= or K= option, but only the fixed radius is used for the significance tests.

The purpose of the significance tests is as follows: given a simple random sample of objects from a population, obtain an estimate of the number of clusters in the population such that the probability in repeated sampling that the estimate exceeds
the true number of clusters is not much greater than \( \alpha \), \( 1\% \leq \alpha \leq 10\% \). In other words, a sequence of null hypotheses of the form

\[ H_0^{(i)}: \text{The number of population clusters is } i \text{ or less} \]

where \( i = 1, 2, \ldots, n \), is tested against the alternatives such as

\[ H_a^{(i)}: \text{The number of population clusters exceeds } i \]

with a maximum experimentwise error rate of approximately \( \alpha \). The tests protect you from overestimating the number of population clusters. It is impossible to protect against underestimating the number of population clusters without introducing much stronger assumptions than are used here, since the number of population clusters could conceivably exceed the sample size.

The method for conducting significance tests is as follows:

1. Estimate densities using fixed-radius uniform kernels.
2. Obtain preliminary clusters by a “valley-seeking” method. Other clustering methods could be used but would yield less power.
3. Compute an approximate \( p \)-value for each cluster by comparing the estimated maximum density in the cluster with the estimated maximum density on the cluster boundary.
4. Repeatedly join the least significant cluster with a neighboring cluster until all remaining clusters are significant.
5. Estimate the number of population clusters as the number of significant sample clusters.
6. The preceding steps can be repeated for any number of different radii, and the estimate of the number of population clusters can be taken to be the maximum number of significant sample clusters for any radius.

This method has the following useful features:

- No distributional assumptions are required.
- The choice of smoothing parameter is not critical since you can try any number of different values.
- The data can be coordinates or distances.
- Time and space requirements for the significance tests are no worse than those for obtaining the clusters.
- The power is high enough to be useful for practical purposes.
The method for computing the $p$-values is based on a series of plausible approximations. There are as yet no rigorous proofs that the method is infallible. Neither are there any asymptotic results. However, simulations for sample sizes ranging from 20 to 2000 indicate that the $p$-values are almost always conservative. The only case discovered so far in which the $p$-values are liberal is a uniform distribution in one dimension for which the simulated error rates exceed the nominal significance level only slightly for a limited range of sample sizes.

To make inferences regarding population clusters, it is first necessary to define what is meant by a cluster. For clustering methods using nonparametric density estimation, a cluster is usually loosely defined as a region surrounding a local maximum of the probability density function or a maximal connected set of local maxima. This definition may not be satisfactory for very rough densities with many local maxima. It is not applicable at all to discrete distributions for which the density does not exist. As another example in which this definition is not intuitively reasonable, consider a uniform distribution in two dimensions with support in the shape of a figure eight (including the interior). This density might be considered to contain two clusters even though it does not have two distinct modes.

These difficulties can be avoided by defining clusters in terms of the local maxima of a smoothed probability density or mass function. For example, define the neighborhood distribution function (NDF) with radius $r$ at a point $x$ as the probability that a randomly selected point will lie within a radius $r$ of $x$, that is, the probability integral over a hypersphere of radius $r$ centered at $x$:

$$s(x) = P(d(x, X) <= r)$$

where $X$ is the random variable being sampled, $r$ is a user-specified radius, and $d(x,y)$ is the distance between points $x$ and $y$.

The NDF exists for all probability distributions. You can select the radius according to the degree of resolution required. The minimum-variance unbiased estimate of the NDF at a point $x$ is proportional to the uniform-kernel density estimate with corresponding support.

You can define a modal region as a maximal connected set of local maxima of the NDF. A cluster is a connected set containing exactly one modal region. This definition seems to give intuitively reasonable results in most cases. An exception is a uniform density on the perimeter of a square. The NDF has four local maxima. There are eight local maxima along the perimeter, but running PROC MODECLUS with the R= option would yield four clusters since the two local maxima at each corner are separated by a distance equal to the radius. While this density does indeed have four distinctive features (the corners), it is not obvious that each corner should be considered a cluster.

The number of population clusters depends on the radius of the NDF. The significance tests in PROC MODECLUS protect against overestimating the number of clusters at any specified radius. It is often useful to look at the clustering results across a range of radii. A plot of the number of sample clusters as a function of the radius is a useful descriptive display, especially for high-dimensional data (Wong and Schaack 1982).
If a population has two clusters, it must have two modal regions. If there are two modal regions, there must be a “valley” between them. It seems intuitively desirable that the boundary between the two clusters should follow the bottom of this valley. All the clustering methods in PROC MODECLUS are designed to locate the estimated cluster boundaries in this way, although methods 1 and 6 seem to be much more successful at this than the others. Regardless of the precise location of the cluster boundary, it is clear that the maximum of the NDF along the boundary between two clusters must be strictly less than the value of the NDF in either modal region; otherwise, there would be only a single modal region; according to Hartigan and Hartigan (1985), there must be a “dip” between the two modes. PROC MODECLUS assesses the significance of a sample cluster by comparing the NDF in the modal region with the maximum of the NDF along the cluster boundary. If the NDF has second-order derivatives in the region of interest and if the boundary between the two clusters is indeed at the bottom of the valley, then the maximum value of the NDF along the boundary occurs at a saddle point. Hence, this test is called a saddle test. This term is intended to describe any test for clusters that compares modal densities with saddle densities, not just the test currently implemented in the MODECLUS procedure.

The obvious estimate of the maximum NDF in a sample cluster is the maximum estimated NDF at an observation in the cluster. Let $m(k)$ be the index of the observation for which the maximum is attained in cluster $k$.

Estimating the maximum NDF on the cluster boundary is more complicated. One approach is to take the maximum NDF estimate at an observation in the cluster that has a neighbor belonging to another cluster. This method yields excessively large estimates when the neighborhood is large. Another approach is to try to choose an object closer to the boundary by taking the observation with the maximum sum of estimated densities of neighbors belonging to a different cluster. After some experimentation, it is found that a combination of these two methods works well. Let $B_k$ be the set of indices of observations in cluster $k$ that have neighbors belonging to a different cluster, and compute

$$\max_{i \in B_k} \left( 0.2 \tilde{f}_i n_i + \sum_{j \in N_i - C_k} \tilde{f}_j \right)$$

Let $s(k)$ be the index of the observation for which the maximum is attained.

Using the notation $\#(S)$ for the cardinality of set $S$, let

\[
\begin{align*}
n_{ij} &= \#(N_i^- \cap N_j^-) \\
c_m(k) &= n_m^- - n_{m(k)s(k)}^- \\
c_s(k) &= n_{s(k)}^- - n_{m(k)s(k)}^- \quad \text{if } B_k \neq \emptyset, \\
&= 0 \quad \text{otherwise} \\
q_k &= 1/2 \quad \text{if } B_k \neq \emptyset, \\
&= 2/3 \quad \text{otherwise} \\
z_k &= \frac{c_m(k) - q_k(c_m(k) + c_s(k)) - 1/2}{\sqrt{q_k(1 - q_k)(c_m(k) + c_s(k))}}
\end{align*}
\]
Chapter 47. The MODECLUS Procedure

\[
u = \left\lceil \left(0.2 + 0.05\sqrt{n} \right) \sum_{i: n_i > 1} \frac{1}{n_i + 1} \right\rceil
\]

Let \( R(u) \) be a random variable distributed as the range of a random sample of \( u \) observations from a standard normal distribution. Then the approximate \( p \)-value \( p_k \) for cluster \( k \) is

\[p_k = Pr(z_k > R(u)/\sqrt{2})\]

If points \( m(k) \) and \( s(k) \) are fixed a priori, \( z_k \) would be the usual approximately normal test statistic for comparing two binomial random variables. In fact, \( m(k) \) and \( s(k) \) are selected in such a way that \( c_m(k) \) tends to be large and \( c_s(k) \) tends to be small. For this reason, and because there may be a large number of clusters, each with its own \( z_k \) to be tested, each \( z_k \) is referred to the distribution of \( R(u) \) instead of a standard normal distribution. If the tests are conducted for only one radius and if \( u \) is chosen equal to \( n \), then the \( p \)-values are very conservative because (1) you are not making all possible pairwise comparisons of observations in the sample and (2) \( n_i^- \) and \( n_j^- \) are positively correlated if the neighborhoods overlap. In the formula for \( u \), the summation overcorrects somewhat for the conservativeness due to correlated \( n_i^- \)’s. The factor \( 0.2 + 0.05\sqrt{n} \) is empirically estimated from simulation results to adjust for the use of more than one radius.

If the JOIN option is specified, the least significant cluster (the cluster with the smallest \( z_k \)) is either dissolved or joined with a neighboring cluster. If no members of the cluster have neighbors belonging to a different cluster, all members of the cluster are unassigned. Otherwise, the cluster is joined to the neighboring cluster such that the sum of density estimates of neighbors of the estimated saddle point belonging to it is a maximum. Joining clusters increases the power of the saddle test. For example, consider a population with two well-separated clusters. Suppose that, for a certain radius, each population cluster is divided into two sample clusters. None of the four sample clusters is likely to be significant, but after the two sample clusters corresponding to each population cluster are joined, the remaining two clusters may be highly significant.

The saddle test implemented in PROC MODECLUS has been evaluated by simulation from known distributions. Some results are given in the following three tables. In Table 47.3, samples of 20 to 2000 observations are generated from a one-dimensional uniform distribution. For sample sizes of 1000 or less, 2000 samples are generated and analyzed by PROC MODECLUS. For a sample size of 2000, only 1000 samples are generated. The analysis is done with at least 20 different values of the R= option spread across the range of radii most likely to yield significant results. The six central columns of the table give the observed error rates at the nominal error rates \( \alpha \) at the head of each column. The standard errors of the observed error rates are given at the bottom of the table. The observed error rates are conservative for \( \alpha \leq 5\% \), but they increase with \( \alpha \) and become slightly liberal for sample sizes in the middle of the range tested.
Table 47.3. Observed Error Rates (%) for Uniform Distribution

All unimodal distributions other than the uniform that have been tested, including normal, Cauchy, and exponential distributions and uniform mixtures, have produced much more conservative results. Table 47.4 displays results from a unimodal mixture of two normal distributions with equal variances and equal sampling probabilities and with means separated by two standard deviations. Any greater separation would produce a bimodal distribution. The observed error rates are quite conservative.

Table 47.4. Observed Error Rates (%) for Normal Mixture with $2\sigma$ Separation

</tbody>
</table>

All distributions in two or more dimensions that have been tested yield extremely conservative results. For example, a uniform distribution on a circle yields observed error rates that are never more than one-tenth of the nominal error rates for sample sizes up to 1000. This conservatism is due to the fact that, as the dimensionality increases, more and more of the probability lies in the tails of the distribution (Silverman 1986, p. 92), and the saddle test used by PROC MODECLUS is more conservative for distributions with pronounced tails. This applies even to a uniform distribution on a hypersphere because, although the density has no tails, the NDF does.

Since the formulas for the significance tests do not involve the dimensionality, no problems are created when the data are linearly dependent. Simulations of data in nonlinear subspaces (the circumference of a circle or surface of a sphere) have also yielded conservative results.

Table 47.5 displays results in terms of power for identifying two clusters in samples from a bimodal mixture of two normal distributions with equal variances and equal sampling probabilities separated by four standard deviations. In this simulation, PROC MODECLUS never indicated more than two significant clusters.

The saddle test is not as efficient as excess-mass tests for multimodality (Müller and Sawitzki 1991, Polonik 1993). However, there is not yet a general approximation for the distribution of excess-mass statistics to circumvent the need for simulations to do significance tests. Refer to Minnotte (1992) for a review of tests for multimodality.

**Computational Resources**

The MODECLUS procedure stores coordinate data in memory if there is enough space. For distance data, only one observation at a time is in memory.

PROC MODECLUS constructs lists of the neighbors of each observation. The total space required is $12 \sum n_i$ bytes, where $n_i$ is based on the largest neighborhood required by any analysis. The lists are stored in a SAS utility data set unless you specify the CORE option. You may get an error message from the SAS System or from the operating system if there is not enough disk space for the utility data set. Clustering method 6 requires a second list that is always stored in memory.

For coordinate data, the time required to construct the neighbor lists is roughly proportional to $v(\log n)(\sum n_i) \log(\sum n_i/n)$. For distance data, the time is roughly proportional to $n^2 \log(\sum n_i/n)$.

The time required for density estimation is proportional to $\sum n_i$ and is usually small compared to the time required for constructing the neighbor lists.

Clustering methods 0 through 3 are quite efficient, requiring time proportional to $\sum n_i$. Methods 4 and 5 are slower, requiring time roughly proportional to $(\sum n_i) \log(\sum n_i)$. Method 6 can also be slow, but the time requirements depend very much on the data and the particular options specified. Methods 4, 5, and 6 also require more memory than the other methods.

The time required for significance tests is roughly proportional to $g \sum n_i$, where $g$ is the number of clusters.

PROC MODECLUS can process data sets of several thousand observations if you specify reasonable smoothing parameters. Very small smoothing values produce many clusters, whereas very large values produce many neighbors; either case can require excessive time or space.
Missing Values

If the data are coordinates, observations with missing values are excluded from the analysis.

If the data are distances, missing values are treated as infinite. The neighbors of each observation are determined solely by the distances in that observation. The distances are not required to be symmetric, and there is no check for symmetry; the neighbors of each observation are determined only from the distances in that observation. This treatment of missing values is quite different from that of the CLUSTER procedure, which ignores the upper triangle of the distance matrix.

Output Data Sets

The OUT= data set contains one complete copy of the input data set for each cluster solution. There are additional variables identifying each solution and giving information about individual observations. Solutions with only one remaining cluster when JOIN=p is specified are omitted from the OUT= data set (see the description of the JOIN= option on page 2866). The OUT= data set can be extremely large, so it may be advisable to specify the DROP= data set option to exclude unnecessary variables.

The OUTCLUS= or OUTC= data set contains one observation for each cluster in each cluster solution. The variables identify the solution and provide statistics describing the cluster.

The OUTSUM= or OUTS= data set contains one observation for each cluster solution. The variables identify the solution and provide information about the solution as a whole.

The following variables can appear in all of the output data sets:

- _K_, which is the value of the K= option for the current solution. This variable appears only if you specify the K= option.
- _DK_, which is the value of the DK= option for the current solution. This variable appears only if you specify the DK= option.
- _CK_, which is the value of the CK= option for the current solution. This variable appears only if you specify the CK= option.
- _R_, which is the value of the R= option for the current solution. This variable appears only if you specify the R= option.
- _DR_, which is the value of the DR= option for the current solution. This variable appears only if you specify the DR= option.
- _CR_, which is the value of the CR= option for the current solution. This variable appears only if you specify the CR= option.
- _CASCAD_, which is the number of times the density estimates have been cascaded for the current solution. This variable appears only if you specify the CASCADE= option.
- _METHOD_, which is the value of the METHOD= option for the current solution. This variable appears only if you specify the METHOD= option.
The OUT= data set contains the following variables:

- the variables from the input data set
- _OBS_, which is the observation number from the input data set. This variable appears only if you omit the ID statement.
- DENSITY, which is the estimated density at the observation. This variable can be renamed by the DENSITY= option.
- CLUSTER, which is the number of the cluster to which the observation is assigned. This variable can be renamed by the CLUSTER= option.

The OUTC= data set contains the following variables:

- the BY variables, if any
- _NCLUS_, which is the number of clusters in the solution
- CLUSTER, which is the number of the current cluster
- _FREQ_, which is the number of observations in the cluster
- _MODE_, which is the maximum estimated density in the cluster
- _BFREQ_, which is the number of observations in the cluster with neighbors belonging to a different cluster
- _SADDLE_, which is the estimated saddle density for the cluster
- _MC_, which is the number of observations within the fixed-radius density-estimation neighborhood of the modal observation. This variable appears only if you specify the TEST or JOIN option.
- _SC_, which is the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation. This variable appears only if you specify the TEST or JOIN option.
- _OC_, which is the number of observations within the overlap of the two previous neighborhoods. This variable appears only if you specify the TEST or JOIN option.
- _Z_, which is the approximate z statistic for the cluster. This variable appears only if you specify the TEST or JOIN option.
- _P_, which is the approximate p-value for the cluster. This variable appears only if you specify the TEST or JOIN option.
The OUTS= data set contains the following variables:

- the BY variables, if any
- _NCLUS_, which is the number of clusters in the solution
- _UNCL_, which is the number of unclassified observations
- _CROSS_, which is the likelihood cross-validation criterion if you specify the CROSS or CROSSLIST option

**Displayed Output**

If you specify the SIMPLE option and the data are coordinates, PROC MODECLUS displays the following simple descriptive statistics for each variable:

- the MEAN
- the standard deviation, STD DEV
- the SKEWNESS
- the KURTOSIS
- a coefficient of BIMODALITY (see Chapter 23, “The CLUSTER Procedure,”)

If you specify the NEIGHBOR option, PROC MODECLUS displays a list of the neighbors of each observation. The table contains

- the observation number or ID value of the observation
- the observation number or ID value of each of its neighbors
- the distance to each neighbor

If you specify the CROSSLIST option, PROC MODECLUS produces a table of information regarding cross validation of the density estimates. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the radius of the neighborhood
- the number of neighbors
- the estimated log density
- the estimated cross-validated log density

If you specify the LOCAL option, PROC MODECLUS produces a table of information regarding estimates of local dimensionality. Each table has a row for each observation. For each observation, the following are displayed:
• the observation number or ID value of the observation
• the radius of the neighborhood
• the estimated local dimensionality

If you specify the LIST option, PROC MODECLUS produces a table listing the observations within each cluster. The table can include

• the cluster number
• the observation number or ID value of the observation
• the estimated density
• the sum of the density estimates of observations within the neighborhood that belong to the same cluster
• the sum of the density estimates of observations within the neighborhood that belong to a different cluster
• the sum of the density estimates of all the observations within the neighborhood
• the ratio of the sum of the density estimates for the same cluster to the sum of all the density estimates in the neighborhood

If you specify the LIST option and there are unassigned objects, PROC MODECLUS produces a table listing those observations. The table includes

• the observation number or ID value of the observation
• the estimated density
• the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you specify the BOUNDARY option, PROC MODECLUS produces a table listing the observations in each cluster that have a neighbor belonging to a different cluster. The table includes

• the observation number or ID value of the observation
• the estimated density
• the cluster number
• the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you do not specify the SHORT option, PROC MODECLUS produces a table of cluster statistics including

• the cluster number
• the cluster frequency (the number of observations in the cluster)
• the maximum estimated density within the cluster
• the number of observations in the cluster having a neighbor that belongs to a different cluster
• the estimated saddle density of the cluster

If you specify the TEST or JOIN option, the table of cluster statistics includes the following items pertaining to the saddle test:

• the number of observations within the fixed-radius density-estimation neighborhood of the modal observation
• the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation
• the number of observations within the overlap of the two preceding neighborhoods
• the $z$ statistic for comparing the preceding counts
• the approximate $p$-value

If you do not specify the NOSUMMARY option, PROC MODECLUS produces a table summarizing each cluster solution containing the following items:

• the smoothing parameters and cascade value
• the number of clusters
• the frequency of unclassified objects
• the likelihood cross-validation criterion if you specify the CROSS or CROSSLIST option

If you specify the JOIN option, the summary table also includes

• the number of clusters joined
• the maximum $p$-value of any cluster in the solution

If you specify the TRACE option, PROC MODECLUS produces a table for each cluster solution that lists each observation along with its cluster membership as it is reassigned from the “Old” cluster to the “New” cluster. This reassignment is described in **Step 1** through **Step 3** of the section “METHOD=6” on page 2875. Each table has a row for each observation. For each observation, the following are displayed:

• the observation number or ID value of the observation
• the estimated density
• the “Old” cluster membership. 0 represents an unassigned observation and -1 represents a seed.
• the “New” cluster membership
• “Ratio,” which is documented in the section “METHOD=6” on page 2875. The following character values can also be displayed:
  “M” means the observation is a mode
  “S” means the observation is a seed
  “N” means the neighbor of a mode or seed, for which the ratio is not computed

**ODS Table Names**

PROC MODECLUS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Example 47.1. Cluster Analysis of Samples from Univariate Distributions

This example uses pseudo-random samples from a uniform distribution, an exponential distribution, and a bimodal mixture of two normal distributions. Results are presented in Output 47.1.1 through Output 47.1.3 as plots displaying both the true density and the estimated density, as well as cluster membership.

The following statements produce Output 47.1.1:

```plaintext

**Example 47.3. Cluster Analysis with Significance Tests**

This example uses artificial data containing two clusters. One cluster is from a circular bivariate normal distribution. The other is a ring-shaped cluster that completely surrounds the first cluster. Without significance tests, the ring is divided into several sample clusters for any degree of smoothing that yields reasonable density estimates. The JOIN= option puts the ring back together. **Output 47.3.1** displays a short summary generated from the first PROC MODECLUS statement. **Output 47.3.2** contains a series of tables produced from the second PROC MODECLUS statement. The lack of p-value in the JOIN= option makes joining continue until only one cluster remains (see the description of the JOIN= option on page 2866). The cluster memberships are then plotted as displayed in **Output 47.3.3**.

Example 47.4. Cluster Analysis: Hertzsprung-Russell Plot

This example uses computer-generated data to mimic a Hertzsprung-Russell plot (Struve and Zebergs 1962, p. 259) of the temperature and luminosity of stars. The data are plotted and displayed in Output 47.4.1; see “Example 4 from Proc Modeclus” in the SAS/STAT Sample Program Library for the complete data set. It appears that there are two main groups of stars and a collection of isolated stars. The long straggling group of points appearing diagonally across the figure represents the main group of stars; the more compact group in the top right-hand corner contains giant stars. The JOIN= option is specified at a 0.05 significance level with various smoothing parameters. The CK=5 option is specified in order to prevent the numerous outliers from forming separate clusters. The results from PROC MODECLUS is displayed in Output 47.4.2. The cluster memberships are then plotted by PROC GPLOT, as displayed in Output 47.4.3.

Notice in Output 47.4.3 that the graphic output from PROC GPLOT when _R_ = 2.5 is not available because only one cluster remains after joining at a 5% significance level, and the results are not written to the OUT= data set. See the description of the JOIN= option on page 2866 for more information.

Example 47.5. Using the TRACE Option when METHOD=6

To illustrate how the TRACE option can help you to understand the clustering process when METHOD=6 is specified, the following data set is created with 12 observations.

```sas
/*-- METHOD=6 with TRACE and THRESHOLD=0.5 (default) --*/
proc modeclus method=6 r=2.5 trace short out=out;
  var x;
run;
```

```sas
data markobs;
  drop _r_ _method_ _obs_ density cluster;
  length function style $8 text $ 2;
run;
```

The first five observations seem to be close to each other, and the last five observations seem to be close to each other. Observation 6 is separated from the first five observations with a (Euclidean) distance of 2.5, and the same distance separates observation 7 from the last five observations. Observations 6 and 7 differ by 1.5.

Suppose METHOD=6 with a radius=2.5 is chosen for the cluster analysis. You can specify the TRACE option to understand how each observation is assigned.

The following statements produce Output 47.5.1 and Output 47.5.2:
retain xsys '2' ysys '2' hsys '1' when 'a';
set out;
/* create the text for obs */
function='label'; size=4;
style='swiss';
text=left(put(_obs_,2.));
position='3';
x=x; y=density;
output;
run;
legend1 frame cframe=ligr cborder=black
   position=center value=(justify=center);
axis1 label=(angle=90 rotate=0) minor=none;
axis2 minor=none;
title 'Plot of DENSITY*X=CLUSTER';
proc gplot data=out;
   plot density*x=cluster/ annotate=markobs
      frame cframe=ligr
      legend=legend1
      vaxis=axis1 haxis=axis2;
run;

Output 47.5.1. Partial Output of METHOD=6 with TRACE and Default THRESHOLD=

</tr>
</tbody>
</table>
Notice that in Output 47.5.1, observation 7 is originally a seed (indicated by a value of -1 in the “Old” column) and then assigned to cluster 1. This is because the ratio of observation 7 to cluster 1 is 0.5 and is not less than the default value of THRESHOLD= (0.5).

If the value of the THRESHOLD= option is increased to 0.55, observation 7 should be excluded from cluster 1 and the cluster membership of observation 7 is changed.

The following statements produce Output 47.5.3 and Output 47.5.4:

```plaintext
/*-- METHOD=6 with TRACE and THRESHOLD=0.55 --*/
proc modeclus method=6 r=2.5 trace threshold=0.55 short
   out=out;
   var x;
   run;

... (the Data Step and the PROC GPLOT statement are omitted because they are the same as the previous job)```
Output 47.5.3.  Partial Output of METHOD=6 with TRACE and THRESHOLD=.55

Chapter 48. The MULTTEST Procedure
Chapter 48
The MULTTEST Procedure

Overview

The MULTTEST procedure addresses the multiple testing problem. This problem arises when you perform many hypothesis tests on the same data set. Carrying out multiple tests is often reasonable because of the cost of obtaining data, the discovery of new aspects of the data, and the many alternative statistical methods. However, a negative feature of multiple testing is the greatly increased probability of declaring false significances.

For example, suppose you carry out 10 hypothesis tests at the 5% level, and you assume that the distributions of the $p$-values from these tests are uniform and independent. Then, the probability of declaring a particular test significant under its null hypothesis is 0.05, but the probability of declaring at least 1 of the 10 tests significant is 0.401. If you perform 20 hypothesis tests, the latter probability increases to 0.642. These high chances illustrate the danger in multiple testing.

PROC MULTTEST approaches the multiple testing problem by adjusting the $p$-values from a family of hypothesis tests. An adjusted $p$-value is defined as the smallest significance level for which the given hypothesis would be rejected, when the entire family of tests is considered. The decision rule is to reject the null hypothesis when the adjusted $p$-value is less then $\alpha$; in most cases, this procedure controls the familywise error rate at or below the $\alpha$ level. PROC MULTTEST offers the following $p$-value adjustments:

- Bonferroni
- Sidak
- Stepdown methods
- Hochberg
- Hommel
- Fisher Combination
- False Discovery Rate
- Bootstrap
- Permutation

The Bonferroni and Sidak adjustments are simple functions of the raw $p$-values. They are computationally quick, but they can be too conservative. Stepdown methods remove some conservativeness, as do the step-up methods of Hochberg (1988). The bootstrap and permutation adjustments resample the data with and without replacement, respectively, to approximate the distribution of the minimum $p$-value of all
tests. This distribution is then used to adjust the individual raw \( p \)-values. The bootstrap and permutation methods are computationally intensive but appealing in that, unlike the other methods, correlations and distributional characteristics are incorporated into the adjustments (Westfall and Young 1989, 1993; Westfall et al. 1999).

PROC MULTTEST handles data arising from a multivariate one-way ANOVA model, possibly stratified, with continuous and discrete response variables; it can also accept raw \( p \)-values as input data. You can perform a \( t \)-test for the mean for continuous data and the following statistical tests for discrete data:

- Cochran-Armitage (CA) linear trend test
- Freeman-Tukey (FT) double arcsine test
- Peto (PETO) mortality-prevalence (log-rank) test
- Fisher (FISHER) exact test

The CA and PETO tests have exact versions that use permutation distributions and asymptotic versions that use an optional continuity correction. Also, with the exception of the FISHER test, you can use a stratification variable to construct Mantel-Haenszel type tests. All of the previously mentioned tests can be one- or two-sided.

As in the GLM procedure, you can specify linear contrasts that compare means or proportions of the treated groups. The output contains summary statistics and regular and multiplicity-adjusted \( p \)-values. You can create output data sets containing raw and adjusted \( p \)-values, test statistics and other intermediate calculations, permutation distributions, and resampling information.

## Getting Started

### Drug Example

Suppose you conduct a small study to test the effect of a drug on 15 subjects. You randomly divide the subjects into three balanced groups receiving 0 mg, 1 mg, and 2 mg of the drug, respectively. You carry out the experiment and record the presence or absence of 10 side effects for each subject. Your data set is as follows:

```sas
data Drug;
  input Dose$ SideEff1-SideEff10;
datalines;
0MG 0 0 1 0 0 1 0 0 0 0
0MG 0 0 0 0 0 0 0 0 0 1
0MG 0 0 0 0 0 0 0 0 1 0
0MG 0 0 0 0 0 0 0 0 0 0
0MG 0 1 0 0 0 0 0 0 0 0
1MG 1 0 0 1 0 1 0 0 1 0
1MG 0 0 0 1 1 0 0 1 0 1
1MG 0 1 0 0 0 0 1 0 0 0
1MG 0 0 1 0 0 0 0 0 0 1
1MG 1 0 1 0 0 0 0 1 0 0
```

```sas
```
The increasing incidence of 1s for higher dosages in the preceding data set provides an initial visual indication that the drug has an effect. To explore this statistically, you decide to perform an analysis in which the possibility of side effects increases linearly with drug level. You can analyze the data for each side effect separately, but you are concerned that, with so many tests, there may be a high probability of incorrectly declaring some drug effects significant. You want to correct for this multiplicity problem in a way that accounts for the discreteness of the data and for the correlations between observations on the same unit.

PROC MULTTEST addresses these concerns by processing all of the data simultaneously and adjusting the \( p \)-values. The following statements perform a typical analysis:

```scm
proc multtest bootstrap nsample=20000 seed=41287 notables pvals;
   class Dose;
   test ca(SideEff1-SideEff10);
   contrast 'Trend' 0 1 2;
run;
```

This analysis uses the BOOTSTRAP option to adjust the \( p \)-values. The NSAMPLE= option requests 20,000 samples for the bootstrap analysis, and the starting seed for the random number generator is 41287. The NOTABLES option suppresses the display of summary statistics for each side effect and drug level combination.

The CLASS statement is used to specify the grouping variable, Dose. The CA(SIDEEFF1-SIDEEFF10) specification in the TEST statement requests a Cochran-Armitage linear trend test for all 10 characteristics. The CONTRAST statement gives the coefficients for the linear trend test.

The results from this analysis are as follows.

```

**Figure 48.3.** Summary of p-values for the MULTTEST Procedure

Figure 48.3 lists the $p$-values for the drug example. The Raw column lists the $p$-values for the Cochran-Armitage test on the original data, and the Bootstrap column provides the bootstrap adjustment of the raw $p$-values.

Note that the raw $p$-values lead you to reject the null hypothesis of no linear trend for 3 of the 10 characteristics at the 5% level and for 7 of the 10 characteristics at the 10% level. The bootstrap $p$-values, however, lead to this conclusion for 0 of the 10 characteristics at the 5% level and only 2 of the 10 characteristics at the 10% level. The bootstrap adjustment gives the probability of observing a $p$-value as extreme as each given $p$-value, considering all ten tests simultaneously. This adjustment incorporates the correlation of the raw $p$-values, the discreteness of the data, and the multiple testing problem. Failure to account for these issues can certainly lead to misleading inferences for these data.
Syntax

The following statements are available in PROC MULTTEST.

```latex
PROC MULTTEST < options > ;
   BY variables ;
   CLASS variable ;
   CONTRAST 'label' values ;
   FREQ variable ;
   STRATA variable ;
   TEST name (variables < / options > ) ;
```

Items within angle brackets (< >) are optional, and statements following the PROC MULTTEST statement can appear in any order. The CLASS and TEST statements are required. The syntax of each statement is described in the following section in alphabetical order after the description of the PROC MULTTEST statement.

PROC MULTTEST Statement

```latex
PROC MULTTEST < options > ;
```

You can specify the following options in the PROC MULTTEST statement.

**BONFERRONI**

**BON**
specifies that the Bonferroni adjustments (number of tests \( \times \) \( p \)-value) be computed for each test. These adjustments can be extremely conservative and should be viewed with caution. When exact tests are specified via the PERMUTATION= option in the TEST statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997).

**BOOTSTRAP**

**BOOT**
specifies that the \( p \)-values be adjusted using the bootstrap method to resample vectors (Westfall and Young 1993). Resampling is performed with replacement and independently within levels of the STRATA variable. Continuous variables are mean-centered by default prior to resampling. The BOOTSTRAP option is not allowed with the PETO test for theoretical reasons.

If the PERMUTATION= suboption is used with the CA test on the TEST statement, the exact permutation distribution is recomputed for each bootstrap sample. **Caution:** This can be very time-consuming. It is preferable to use permutation resampling when permutation base tests are used.

**CENTER**

requests that continuous variables be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.
DATA=SAS-data-set
names the input SAS data set to be used by PROC MULTTEST. The default is to use the most recently created data set. The DATA= and PDATA= options cannot both be specified.

FDR
requests adjusted $p$-values using the method of Benjamini and Hochberg (1995). These $p$-values do not control the familywise error rate, but they do control the false discovery rate in some cases.

FISHER_C
requests adjusted $p$-values using Fisher’s combination method.

HOC
requests adjusted $p$-values using Hochberg’s (1988) step-up Bonferroni method.

HOMMEL
requests adjusted $p$-values using Hommel’s (1988) method.

HOML
is an alias for the STEPBON adjustment.

NOCENTER
requests that continuous variables not be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.

NOPRINT
suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “The Output Delivery System,” for more information.

NOTABLES
suppresses display of the “Discrete Variable Tabulations” and “Continuous Variable Tabulations” tables.

NOZEROS
suppresses display of tables having zero occurrences for all CLASS levels.

NSAMPLE= number
N= number
specifies the number of resamples for use with the BOOTSTRAP and PERMUTATION options; it is assumed to be 20,000 by default. Large values of number (20,000 or more) are usually recommended for accuracy, but long execution times may result, particularly with large data sets.

ORDER=DATA | FORMATTED | FREQ | INTERNAL
specifies the sorting order for the levels of the CLASS variable. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use CONTRAST statements.
When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values. In order to revert to the previous method, you can specify this format explicitly for the CLASS variable. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and required you to use an explicit format or to specify ORDER=INTERNAL to get the more natural ordering.

The following table shows how PROC MULTTEST interprets values of the ORDER= option.

<table>
<thead>
<tr>
<th>Value of ORDER=</th>
<th>Levels Sorted By</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATA</td>
<td>order of appearance in the input data set</td>
</tr>
<tr>
<td>FORMATTED</td>
<td>external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value</td>
</tr>
<tr>
<td>FREQ</td>
<td>descending frequency count; levels with the most observations come first in the order</td>
</tr>
<tr>
<td>INTERNAL</td>
<td>unformatted value</td>
</tr>
</tbody>
</table>

For more information on sorting order, see the chapter on the SORT procedure in the SAS Procedures Guide and the discussion of BY-group processing in SAS Language Reference: Concepts.

**OUT=SAS-data-set**
names the output SAS data set containing variable names, contrast names, intermediate calculations, and all associated p-values.

**OUTPERM=SAS-data-set**
names the output SAS data set containing entire permutation distributions (upper-tail probabilities) for all tests when the PERMUTATION= option is used. **Caution:** This data set can be very large.

**OUTSAMP=SAS-data-set**
names the output SAS data set containing information from the resampled data sets when resampling is performed. **Caution:** This data set can be very large.

**PDATA=SAS-data-set**
names an input SAS data set containing the variable **raw_p** with observations that consist of raw p-values. The MULTTEST procedure adjusts the collection of raw p-values for multiplicity. Resampling-based adjustments are not permitted with this type of data input. The PDATA= and DATA= options cannot both be specified.
PERMUTATION
PERM specifies adjusted p-values in identical fashion as the BOOTSTRAP option, with the exception that PROC MULTTEST resamples without replacement rather than with replacement. Resampling is performed independently within levels of the STRATA variable. Continuous variables are not mean-centered prior to resampling. The PERMUTATION option is not allowed with the PETO test for theoretical reasons.

PVALS
requests that a summary table of raw and adjusted p-values be included.

SEED= number  
S= number
specifies the initial seed for the random number generator used for resampling. The value for number must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC MULTTEST uses the time of day from the computer’s clock to generate an initial seed. For more details about seed values, refer to SAS Language Reference: Concepts.

SIDAK
SID specifies that the Sidak adjustments be computed for each test. These adjustments take the form

\[ 1 - (1 - p)^n \]

where \( p \) is the raw p-value and \( n \) is the number of tests. These are slightly less conservative than the Bonferroni adjustments, but they still should be viewed with caution. When exact tests are specified via the PERMUTATION= option in the TEST statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997).

STEPBON
requests adjusted p-values using the stepdown Bonferroni method of Holm (1979).

STEPBOOT
requests that adjusted p-values be computed using bootstrap resampling as described under the BOOTSTRAP option, but in stepdown fashion.

STEPPERM
requests that adjusted p-values be computed using permutation resampling as described under the PERMUTATION option, but in stepdown fashion.

STEPSID
requests adjusted p-values using the Sidak method as described in the SIDAK option, but in stepdown fashion.
BY Statement

BY variables;

You can specify a BY statement with PROC MULTTEST to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The variables are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MIXED procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

Since sorting the data changes the order in which PROC MULTTEST reads observations, this can affect the sorting order for the levels of the CLASS variable if you have specified ORDER=DATA in the PROC MULTTEST statement. This, in turn, affects specifications in the CONTRAST statements.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

CLASS Statement

CLASS variable;

The CLASS statement is required. It declares a single variable (character or numeric) used to identify the groups for the analysis. For example, if the variable Treatment defines different levels of a treatment, then the statement is

    class Treatment;

The CLASS variable can be either character or numeric. By default, its levels are determined from entire formatted values. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option in the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the SAS Procedures Guide and to the discussions of the FORMAT statement and SAS
formats in *SAS Language Reference: Dictionary*. You can adjust the order of CLASS variable levels with the `ORDER=` option in the PROC MULTTEST statement. You need to be aware of the order when using the CONTRAST statement, and you should check the “Contrast Coefficients” table to verify that it is suitable.

You can specify the following option in the CLASS statement after a slash(/):

- **TRUNCATE** specifies that class levels should be determined using only no more than the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

The order of the CLASS levels used by PROC MULTTEST correspond to their formatted values; this order can be changed with the `ORDER=` option in the PROC MULTTEST statement.

### CONTRAST Statement

```plaintext
CONTRAST 'label' values;
```

This statement is used to identify tests between the levels of the CLASS variable; in particular, it is used to specify the coefficients for the trend tests. The *label* is a string naming the contrast; it contains a maximum of 21 characters. The *values* are scoring coefficients across the CLASS variable levels.

You can specify multiple CONTRAST statements, thereby specifying multiple contrasts for each variable. Multiplicity adjustments are computed for all contrasts and all variables simultaneously. The coefficients are applied in the order of the CLASS variables; this order can be changed with the `ORDER=` option in the PROC MULTTEST statement. For example, consider a four-group experiment with CLASS variable levels A1, A2, B1, and B2 denoting two levels of two treatments. The following statements produce three linear trend tests for each variable identified in the TEST statement. PROC MULTTEST computes the multiplicity adjustments over the entire collection of tests, which is three times the number of variables.

```plaintext
contrast 'a vs b' -1 -1 1 1;
contrast 'a linear' -1 1 0 0;
contrast 'b linear' 0 0 -1 1;
```

As another example, consider an animal carcinogenicity experiment with dose levels 0, 4, 8, 16, and 50. You might consider trend tests defined using the following statement:

```plaintext
contrast 'arithmetic trend' 0 4 8 16 50;
```

This statement produces a trend test using the indicated scoring coefficients. Multiplicity-adjusted *p*-values are then computed over the collection of variables identified in the TEST statement. Refer to Lagakos and Louis (1985) for guidelines on the selection of contrast-scoring values.
When a Fisher test is specified in the TEST statement, the CONTRAST statement coefficients are used to group the CLASS variable’s levels. Groups with a \(-1\) contrast coefficient are combined and compared with groups with a 1 contrast coefficient for each test, and groups with a 0 coefficient are not included in the contrast. For example, the statements

```plaintext
contrast 'c vs all' 1 -1 -1 -1;
contrast 'c vs t1' 1 -1 0 0;
contrast 'c vs t3' 1 0 0 -1;
```

compute Fisher exact tests for (a) control versus the combined treatment groups, (b) control versus the first treatment group, and (c) control versus the third treatment group. Multiplicity adjustments are then computed over the entire collection of tests and variables. Only \(-1, 1,\) and \(0\) are acceptable CONTRAST coefficients when the Fisher test is specified; PROC MULTTEST ignores the CONTRAST statement if any other coefficients appear.

If you specify the FISHER test and no CONTRAST statements, then all contrasts of control versus treatment are automatically generated, with the first level of the CLASS variable deemed to be the control. In this case, the control level is assigned the value 1 in each contrast and the other treatment levels are assigned \(-1\). You should therefore use the LOWERTAILED option to test for higher success rates in the treatment groups.

For tests other than FISHER, CONTRAST values are 0,1,2,\,... by default. For \(t\)-tests for the mean using continuous data (and for the FT tests), the contrast coefficients are centered to have mean 0. The resulting centered scoring coefficients are then applied to the sample means (or to the double-arcsine-transformed proportions in the case of the FT tests).

---

**FREQ Statement**

```plaintext
FREQ variable ;
```

The FREQ statement names a variable that provides frequencies for each observation in the DATA= data set. Specifically, if \(n\) is the value of the FREQ variable for a given observation, then that observation is used \(n\) times.

If the value of the FREQ variable is missing or is less than 1, the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

---

**STRATA Statement**

```plaintext
STRATA variable ;
```

The STRATA statement identifies a single variable to use as a stratification variable in the analysis. This yields tests similar to those discussed in Mantel and Haenszel (1959) and Hoel and Walburg (1972) for binary data and pooled-means tests for continuous data. For example, when you test for prevalence in a carcinogenicity study, it is common to stratify on intervals of the time at death; the first level of the stratification variable may represent weeks 0–52, the second weeks 53–80, and so on.
multicenter clinical studies, each level of the stratification variable may represent a particular center.

The following option is available in the STRATA statement after a slash (/):

**WEIGHT=**

specifies the type of strata weighting to use when computing the Freeman-Tukey and $t$-tests for the mean. Valid values are SAMPLESIZE, HARMONIC, and EQUAL. SAMPLESIZE requests weights proportional to the within-stratum sample sizes, and is the default method. HARMONIC sets up weights equal to the harmonic mean of the non-missing within-stratum CLASS sizes, and is similar to a Type 2 analysis in PROC GLM. EQUAL specifies equal weights, and is similar to a Type 3 analysis in PROC GLM.

---

### TEST Statement

**TEST**  

*name* ( *variables* < / *options* > ) ;

The TEST statement is required. It identifies statistical tests to be performed and the discrete and continuous variables to be tested. The following tests are permitted as *name* in the TEST statement.

- **CA** requests the Cochran-Armitage linear trend tests for group comparisons. The test variables should take the value 0 for a failure and 1 for a success. The PERMUTATION= option can be used to request an exact permutation test; otherwise, a Z-score approximation is used. The CONTINUITY= option can be used to specify a continuity correction for the Z-score approximation.

- **FISHER** requests Fisher exact tests for comparing two treatment groups. The test variables should take the value 0 for a failure and 1 for a success.

- **FT** requests Z-score CA tests based upon the Freeman-Tukey double arcsine transformation of the frequencies. The test variables should take the value 0 for a failure and 1 for a success.

- **MEAN** requests the $t$-test for the mean. The test variables can take on any numeric values.

- **PETO** requests the Peto mortality-prevalence test. The test variables should take the value 0 for a nonoccurrence, 1 for an incidental occurrence, and 2 for a fatal occurrence. The TIME= option should be used with the PETO test to specify a variable giving the age at death. The CONTINUITY= option can be used to specify a continuity correction for the test.

If the value of a TEST variable is invalid, the observation is not used in the analysis. You can specify two tests only if one of them is MEAN. For example, the following statement is valid

```
test ca(d1-d2) mean(c1-c2);
```
but the statement

    test ca(d1-d2) ft(d1-d2);

is invalid.

You can specify the following options in the TEST statement (some apply to only one test).

**BINOMIAL**

specifies that the binomial variance estimate be used for CA and PETO tests in their asymptotic normal approximations. The default is to use the hypergeometric variance.

**CONTINUITY= number**
**C= number**

specifies *number* as a particular continuity correction for the *Z*-score approximation in the CA and PETO tests. The default is 0.

**LOWERTAILED**
**LOWER**

is used to make all tests lower-tailed. All tests are two-tailed by default.

**PERMUTATION= number**
**PERM= number**

specifies that *p*-values for the CA and PETO tests be computed using exact permutation distributions when marginal success or failure totals within a stratum are *number* or less. For values greater than *number* (or when the PERMUTATION= option is omitted), PROC MULTTEST uses standard normal approximations with a continuity correction chosen to approximate the permutation distribution. PROC MULTTEST computes the appropriate convolution distributions when you use the STRATA statement along with the PERMUTATION= option.

**TIME= variable**

identifies the PETO test variable containing the age at death, which is assumed to be integer valued. If the TIME= option is omitted, all ages are assumed to equal 1.

**UPPERTAILED**
**UPPER**

is used to make all tests upper-tailed. All tests are two-tailed by default.
Details

Statistical Tests

The following section discusses the statistical tests performed in the MULTTEST procedure. For continuous data, a \( t \)-test for the mean is available. For discrete variables, available tests are the Cochran-Armitage (CA) linear trend test, the Freeman-Tukey (FT) double arcsine test, the Peto mortality-prevalence test, and the Fisher exact test.

Throughout this section, the discrete and continuous variables are denoted by \( S_{vgsr} \) and \( X_{vgsr} \), respectively, where \( v \) is the variable, \( g \) is the treatment group, \( s \) is the stratum, and \( r \) is the replication. A plus sign (+) subscript denotes summation over an index. Note that the tests are invariant to the location and scale of the contrast coefficients \( t_g \).

Cochran-Armitage Linear Trend Test

The Cochran-Armitage linear trend test (Cochran 1954; Armitage 1955; Agresti 1990) is implemented using a \( Z \)-score approximation, an exact permutation distribution, or a combination of both.

Z-Score Approximation

Let \( m_{vgs} \) denote the sample size for a binary variable \( v \) within group \( g \) and stratum \( s \). The pooled probability estimate for variable \( v \) and stratum \( s \) is

\[
p_{vs} = \frac{S_{v+s+}}{m_{v+s}}
\]

The expected value (under constant within-stratum treatment probabilities) for variable \( v \), group \( g \), and stratum \( s \) is

\[
E_{vgs} = m_{vgs} p_{vs}
\]

The test statistic for variable \( v \) has numerator

\[
N_v = \sum_s \sum_g t_g (S_{vgs+} - E_{vgs})
\]

where \( t_g \) denotes the contrast trend coefficients specified by the CONTRAST statement. The binomial variance estimate for this statistic is

\[
V_v = \sum_s p_{vs} (1 - p_{vs}) \sum_g m_{vgs} (t_g - \bar{t}_{vs})^2
\]

where

\[
\bar{t}_{vs} = \frac{\sum_g m_{vgs} t_g}{m_{v+s}}
\]
The hypergeometric variance estimate (the default) is
\[ V_v = \sum_s \{ m_{v+s}/(m_{v+s} - 1)\} p_{vs} (1 - p_{vs}) \sum_g m_{vgs} (t_g - \bar{t}_{vs})^2 \]

For any strata \( s \) with \( m_{v+s} \leq 1 \), the contribution to the variance is taken to be zero.

PROC MULTTEST computes the Z-score statistic
\[ Z_v = \frac{N_v}{\sqrt{V_v}} \]

The \( p \)-value for this statistic comes from the standard normal distribution. Whenever a 0 is computed for the denominator, the \( p \)-value is set to 1. This \( p \)-value approximates the probability obtained from the exact permutation distribution, discussed in the following text.

The Z-score statistic can be continuity-corrected to better approximate the permutation distribution. With continuity correction \( c \), the upper-tailed \( p \)-value is computed from
\[ Z_v = \frac{N_v - c}{\sqrt{V_v}} \]

For two-tailed, noncontinuity-corrected tests, PROC MULTTEST reports the \( p \)-value as \( 2 \min(p, 1 - p) \), where \( p \) is the upper-tailed \( p \)-value. The same formula holds for the continuity-corrected test, with the exception that when the noncontinuity-corrected \( Z \) and the continuity-corrected \( Z \) have opposite signs, the two-tailed \( p \)-value is 1.

When the PERMUTATION= option is specified and no STRATA variable is specified, PROC MULTTEST uses a continuity correction selected to optimally approximate the upper-tail probability of permutation distributions with smaller marginal totals (Westfall and Lin 1988). Otherwise, the continuity correction is specified using the CONTINUITY= option in the TEST statement.

The CA Z-score statistic is the Hoel-Walburg (Mantel-Haenszel) statistic reported by Dinse (1985).

**Exact Permutation Test**

When you use the PERMUTATION= option for CA in the TEST statement, PROC MULTTEST computes the exact permutation distribution of the trend score
\[ T_v = \sum_s \sum_g t_g S_{vgs} \]

and then compares the observed value of this trend with the permutation distribution to obtain the \( p \)-value
\[ p_v = \Pr(X \geq \text{observed } T_v) \]
where $X$ is a random variable from the permutation distribution and where upper-tailed tests are requested. This probability can be viewed as a binomial probability, where the within-stratum probabilities are constant and where the probability is conditional with respect to the marginal totals $S_{v+s}$ and $S_{v+s}$, It also can be considered a rerandomization probability.

Because the computations can be quite time-consuming with large data sets, specifying the PERMUTATION=number option in the TEST statement limits the situations where PROC MULTTEST computes the exact permutation distribution. When marginal total success or total failure frequencies exceed number for a particular stratum, the permutation distribution is approximated using a continuity-corrected normal distribution. You should be cautious in using the PERMUTATION= option in conjunction with bootstrap resampling because the permutation distribution is recomputed for each bootstrap sample. This recomputation is not necessary with permutation resampling.

The permutation distribution is computed in two steps:

1. The permutation distributions of the trend scores are computed within each stratum.
2. The distributions are convolved to obtain the distribution of the total trend.

As long as the total success or failure frequency does not exceed number for any stratum, the computed distributions are exact. In other words, if $S_{v+s} \leq \text{number}$ or $(m_{v+s} - S_{v+s}) \leq \text{number}$ for all $s$, then the permutation trend distribution for variable $v$ is computed exactly.

In step 1, the distribution of the within-stratum trend

$$\sum_g t_g S_{vgs}$$

is computed using the multivariate hypergeometric distribution of the $S_{vgs}$, provided number is not exceeded. This distribution can be written as

$$\Pr(S_{v1s+}, S_{v2s+}, \ldots, S_{vGs+}) = \prod_{g=1}^{G} \left( \frac{m_{vgs}}{S_{vgs+}} \right) \left( \frac{m_{v+s}}{S_{v+s}} \right)$$

The distribution of the within-stratum trend is then computed by summing these probabilities over appropriate configurations. For further information on this technique, refer to Bickis and Kreuski (1986) and Westfall and Lin (1988). In step 2, the exact convolution distribution is obtained for the trend statistic summed over all strata having totals that meet the threshold criterion. This distribution is obtained by applying the fast Fourier transform to the exact within-stratum distributions. A description of this general method can be found in Pagano and Tritchler (1983) and Good (1987).
The convolution distribution of the overall trend is then computed by convolving the exact distribution with the distribution of the continuity-corrected standard normal approximation. To be more specific, let $S_1$ denote the subset of stratum indices that satisfy the threshold criterion, and let $S_2$ denote the subset of indices that do not satisfy the criterion. Let $T_{v1}$ denote the combined trend statistic from the set $S_1$, which has an exact distribution obtained using Fourier analysis as previously outlined, and let $T_{v2}$ denote the combined trend statistic from the set $S_2$. Then the distribution of the overall trend $T_v = T_{v1} + T_{v2}$ is obtained by convolving the analytic distribution of $T_{v1}$ with the continuity-corrected normal approximation for $T_{v2}$. Using the notation from the “Z-Score Approximation” section on page 2948, this convolution can be written as

$$\Pr(T_{v1} + T_{v2} \geq u) = \sum_{u1} \Pr(T_{v1} + T_{v2} \geq u \mid T_{v1} = u1) \Pr(T_{v1} = u1) \approx \sum_{u1} \Pr(Z \geq z) \Pr(T_{v1} = u1)$$

where $Z$ is a standard normal random variable, and

$$z = \frac{1}{\sqrt{V_v}} \left( u - u1 - \sum_{s2} p_{gs} \sum_{g} t_g m_{vgs} - c \right)$$

In this expression, the summation of $s$ in $V_v$ is over $S_2$, and $c$ is the continuity correction discussed under the Z-score approximation.

When a two-tailed test is requested, the expected trend

$$E_v = \sum_{s} \sum_{g} t_g E_{vgs}$$

is computed, and the two-tailed $p$-value is reported as the permutation tail probability for the observed trend $T_v$ plus the permutation tail probability for $2E_v - T_v$, the reflected trend.

**Freeman-Tukey Double Arcsine Test**

For this test, the contrast trend coefficients $t_1, \ldots, t_G$ are centered to the values $c_1, \ldots, c_G$, where $c_g = t_g - \bar{t}, \bar{t} = \sum_{g} t_g / G$, and $G$ is the number of groups. The numerator of this test statistic is

$$N_v = \sum_{s} w_{vgs} \sum_{g} c_g f(S_{vgs+}, m_{vgs})$$

where the weights $w_{vgs}$ take on three different types of values depending upon your specification of the WEIGHT= option in the STRATA statement. The default value
is the within-strata sample size $m_{v+s}$, ensuring comparability with the ordinary CA trend statistic. WEIGHT=HARMONIC sets $w_{v_s}$ equal to the harmonic mean

$$\left[\left(\sum_g \frac{1}{m_{vg}}\right)/G^*\right]^{-1}$$

where $G^*$ is the number of non-missing groups and the summation is over only the non-missing elements. The harmonic means analysis places more weight on the smaller sample sizes than does the default sample size method, and is similar to a Type 2 analysis in PROC GLM. WEIGHT=EQUAL sets $w_{v_s} = 1$ for all $v$ and $s$, and is similar to a Type 3 analysis in PROC GLM.

The function $f(r, n)$ is the double arcsine transformation:

$$f(r, n) = \arcsin\left(\sqrt{\frac{r}{n+1}}\right) + \arcsin\left(\sqrt{\frac{r+1}{n+1}}\right)$$

The variance estimate is

$$V_v = \sum_s w_{v_s}^2 \sum_g c_g^2 \frac{1}{m_{vg} + \frac{1}{2}}$$

and the test statistic is

$$Z_v = \frac{N_v}{\sqrt{V_v}}$$

The Freeman-Tukey transformation and its variance are described by Freeman and Tukey (1950) and Miller (1978). Since its variance is not weighted by the pooled probabilities, as is the CA test, the FT test can be more useful than the CA test for tests involving only a subset of the groups.

**Peto Mortality-Prevalence Trend Test**

The Peto test is a modified Cochran-Armitage procedure incorporating mortality and prevalence information. It represents a special case in PROC MULTTEST because the data structure requirements are different, and the resampling methods used for adjusting $p$-values are not valid. The TIME= option variable is required to specify “death” times or, more generally, time of occurrence. In addition, the test variables must assume one of the following three values.

- 0 = no occurrence
- 1 = incidental occurrence
- 2 = fatal occurrence
Use the TIME= option variable to define the mortality strata, and use the STRATA statement variable to define the prevalence strata.

The Peto test is computed like two Cochran-Armitage $Z$-score approximations, one for prevalence and one for mortality.

In the following notation, the subscript $v$ represents the variable, $g$ represents the treatment group, $s$ represents the stratum, and $t$ represents the time. Recall that a plus sign (+) in a subscript location denotes summation over that subscript.

Let $S_{vgs}^P$ be the number of incidental occurrences, and let $m_{vgs}^P$ be the total sample size for variable $v$ in group $g$, stratum $s$, excluding fatal tumors.

Let $S_{vgt}^F$ be the number of fatal occurrences in time period $t$, and let $m_{vgt}^F$ be the number alive at the end of time $t-1$.

The pooled probability estimates are

\[
P_{vs}^P = \frac{S_{v+}^P}{m_{v+}^P}
\]

\[
P_{vt}^F = \frac{S_{v+t}^F}{m_{v+t}^F}
\]

The expected values are

\[
E_{vgs}^P = m_{vgs}^P p_{vs}^P
\]

\[
E_{vgt}^F = m_{vgt}^F p_{vt}^F
\]

Define the numerator terms:

\[
N_{v}^P = \sum_s \sum_g t_g \left( S_{vgs}^P - E_{vgs}^P \right)
\]

\[
N_{v}^F = \sum_t \sum_g t_g \left( S_{vgt}^F - E_{vgt}^F \right)
\]

where $t_g$ denotes a contrast trend coefficient. Define the denominator variance terms (using the binomial variance):

\[
V_{v}^P = \sum_s p_{vs}^P (1 - p_{vs}^P) \left[ \left( \sum_g m_{vgs}^P t_g \right)^2 - \frac{1}{m_{v+}^P} \left( \sum_g m_{vgs}^P t_g \right)^2 \right]
\]

\[
V_{v}^F = \sum_s p_{vt}^F (1 - p_{vt}^F) \left[ \left( \sum_g m_{vgt}^F t_g \right)^2 - \frac{1}{m_{v+t}^F} \left( \sum_g m_{vgt}^F t_g \right)^2 \right]
\]
The hypergeometric variances (the default) are calculated by weighting the within-strata variances as discussed in the “Z-Score Approximation” section on page 2948.

The Peto statistic is computed as

\[ Z_v = \frac{N_v^P + N_v^F - c}{\sqrt{V_v^P + V_v^F}} \]

where \( c \) is a continuity correction. The \( p \)-value is determined from the standard normal distribution unless the PERMUTATION=number option is used. When you use the PERMUTATION= option for PETO in the TEST statement, PROC MULTTEST computes the “discrete approximation” permutation distribution described by Mantel (1980) and Soper and Tonkonoh (1993). Specifically, the permutation distribution of

\[ \sum_s \sum_g t_{gSvgs} + \sum_t \sum_g t_{gSvgt} \]

is computed, assuming that \( \{\sum_g t_{gSvgs}\} \) and \( \{\sum_g t_{gSvgt}\} \) are independent over all \( s \) and \( t \). The \( p \)-values are exact under this independence assumption. However, the independence assumption is valid only asymptotically, which is why these \( p \)-values are called “approximate.”

An exact permutation distribution is available only under the assumption of equal risk of censoring in all treatment groups; even then, computing this distribution can be cumbersome. Soper and Tonkonoh (1993) describe situations where the discrete approximation distribution closely fits the exact permutation distribution.

**Fisher Exact Test**

The CONTRAST statement in PROC MULTTEST enables you to compute Fisher exact tests for two-group comparisons. No stratification variable is allowed for this test. Note, however, that the FISHER exact test is a special case of the exact permutation tests performed by PROC MULTTEST and that these permutation tests allow a stratification variable. Recall that contrast coefficients can be \(-1, 0,\) or \(1\) for the Fisher test. The frequencies and sample sizes of the groups scored as \(-1\) are combined, as are the frequencies and sample sizes of the groups scored as \(1\). Groups scored as \(0\) are excluded. The \(-1\) group is then compared with the \(1\) group using the Fisher exact test.

Letting \(x\) and \(m\) denote the frequency and sample size of the \(1\) group, and \(y\) and \(n\) denote those of the \(-1\) group, the \(p\)-value is calculated as

\[ \Pr(X \geq x \mid X + Y = x + y) = \sum_{i=x}^{m} \frac{\binom{m}{i} \binom{n}{x+y-i}}{\binom{m+n}{x+y}} \]

where \(X\) and \(Y\) are independent binomially distributed random variables with sample sizes \(m\) and \(n\) and common probability parameters. The hypergeometric distribution is used to determine the stated probability; Yates (1984) discusses this technique.
PROC MULTTEST computes the two-tailed $p$-values by adding probabilities from both tails of the hypergeometric distribution. The first tail is from the observed $x$ and $y$, and the other tail is chosen so that the resulting probability is as large as possible without exceeding the probability from the first tail.

**t-Test for the Mean**

For continuous variables, PROC MULTTEST automatically centers the contrast trend coefficients, as in the Freeman-Tukey test. These centered coefficients $c_g$ are then used to form a $t$-statistic contrasting the within-group means. Let $n_{vgs}$ denote the sample size within group $g$ and stratum $s$; it depends on variable $v$ only when there are missing values. Define

$$X_{vgs+} = \frac{1}{n_{vgs}} \sum_r X_{vgsr}$$

as the sample mean within a group-and-stratum combination, and define

$$s^2_v = \frac{\sum_s \sum_g \sum_r (X_{vgsr} - \bar{X}_{vgs+})^2}{\sum_s \sum_g (n_{vgs} - 1)}$$

as the pooled sample variance. Assume constant variance for all group-and-stratum combinations. Then the $t$-statistic for the mean is

$$M_v = \frac{\sum_s w_{vs} \sum_g c_g \bar{X}_{vgs+}}{\sqrt{s^2_v \left( \sum_s w_{vs}^2 \sum_g \frac{c^2_g}{n_{vgs}} \right)}}$$

where the weights $w_{vs}$ are determined as in the Freeman-Tukey test with $n_{vgs}$ replacing $m_{vgs}$.

Let $\mu_{vgs}$ denote the treatment means. Then under the null hypothesis that

$$\sum_s w_{vs} \sum_g c_g \mu_{vgs} = 0$$

and assuming normality, independence, and homoscedasticity, $M_v$ follows a $t$-distribution with $\sum_s \sum_g (n_{vgs} - 1)$ degrees of freedom.

Whenever a denominator of 0 is computed, the $p$-value is set to 1. When missing data force $n_{vgs} = 0$, then the contribution to the denominator of the pooled variance is 0 and not $-1$. This is also true for degrees of freedom.
**p-Value Adjustments**

PROC MULTTEST offers p-value adjustments using Bonferroni, Sidak, Bootstrap resampling, and Permutation resampling, all with single-step or stepdown versions. In addition, Hochberg’s (1988) and Benjamini and Hochberg’s (1995) step-up methods are offered, as are Hommel’s (1988) and Fisher’s combination method. The Bonferroni and Sidak methods are calculated from the permutation distributions when exact permutation tests are used with CA or PETO tests.

All methods but the resampling methods are calculated using simple functions of the raw p-values or marginal permutation distributions; the permutation and bootstrap adjustments require the raw data. Because the resampling techniques incorporate distributional and correlational structures, they tend to be less conservative than the other methods.

When a resampling (bootstrap or permutation) method is used with only one test, the adjusted p-value is the bootstrap or permutation p-value for that test, with no adjustment for multiplicity, as described by Westfall and Soper (1994).

**Bonferroni**

Suppose that PROC MULTTEST performs R statistical tests, yielding p-values $p_1, \ldots, p_R$. Then the Bonferroni p-value for test $r$ is simply $R p_r$. If the adjusted p-value exceeds 1, it is set to 1.

If the unadjusted p-values are computed using exact permutation distributions, then the Bonferroni adjustment for $p_r$ is $p_1^* + \cdots + p_R^*$, where $p_j^*$ is the largest p-value from the permutation distribution of test $j$ satisfying $p_j^* \leq p_r$, or 0 if all permutational p-values of test $j$ are greater than $p_r$. These adjustments are much less conservative than the ordinary Bonferroni adjustments because they incorporate the discrete distributional characteristics. However, they remain conservative in that they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).

**Sidak**

A technique slightly less conservative than Bonferroni is the Sidak p-value (Sidak 1967), which is $1 - (1 - p_r)^R$. It is exact when all of the p-values are uniformly distributed and independent, and it is conservative when the test statistics satisfy the positive orthant dependence condition (Holland and Copenhaver 1987).

If the unadjusted p-values are computed using exact permutation distributions, then the Sidak adjustment for $p_r$ is $1 - (1 - p_1^*) \cdots (1 - p_R^*)$, where the $p_j^*$ are as described previously. These adjustments are less conservative than the corresponding Bonferroni adjustments, but they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).
**Bootstrap**

The bootstrap method creates pseudo-data sets by sampling observations with replacement from each within-stratum pool of observations. An entire data set is thus created, and $p$-values for all tests are computed on this pseudo-data set. A counter records whether the minimum $p$-value from the pseudo-data set is less than or equal to the actual $p$-value for each base test. (If there are $R$ tests, then there are $R$ such counters.) This process is repeated a large number of times, and the proportion of resampled data sets where the minimum pseudo-$p$-value is less than or equal to an actual $p$-value is the adjusted $p$-value reported by PROC MULTTEST. The algorithms are described by Westfall and Young (1993).

In the case of continuous data, the pooling of the groups is not likely to recreate the shape of the null hypothesis distribution, since the pooled data are likely to be multimodal. For this reason, PROC MULTTEST automatically mean-centers all continuous variables prior to resampling. Such mean-centering is akin to resampling residuals in a regression analysis, as discussed by Freedman (1981). You can specify the NOCENTER option if you do not want to center the data. (In most situations, it does not seem to make much difference whether or not you center the data.)

The bootstrap method explicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted $p$-values incorporate all correlations and distributional characteristics.

**Permutation**

The permutation-style adjusted $p$-values are computed in identical fashion as the bootstrap adjusted $p$-values, with the exception that the within-stratum resampling is performed without replacement instead of with replacement. This produces a rerandomization analysis such as in Brown and Fears (1981) and Heyse and Rom (1988). In the spirit of rerandomization analyses, the continuous variables are not centered prior to resampling. This default can be overridden by using the CENTER option.

The permutation method explicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted $p$-values incorporate all correlations and distributional characteristics.

**Stepdown Methods**

Stepdown testing is available for the Bonferroni, Sidak, bootstrap, and permutation methods. The benefit of using stepdown methods is that the tests are made more powerful (smaller adjusted $p$-values) while, in most cases, maintaining strong control of the familywise error rate. The stepdown method was pioneered by Holm (1979) and further developed by Shaffer (1986), Holland and Copenhaver (1987), and Hochberg and Tamhane (1987).
Suppose the base test p-values are ordered as $p_1 < p_2 < \cdots < p_R$. The Bonferroni stepdown p-values $s_1, \ldots, s_R$ are obtained from

\[
\begin{align*}
    s_1 &= Rp_1 \\
    s_2 &= \max(s_1, (R-1)p_2) \\
    s_3 &= \max(s_2, (R-2)p_3) \\
    &\vdots
\end{align*}
\]

As always, if any adjusted p-value exceeds 1, it is set to 1. The Sidak stepdown p-values are determined similarly:

\[
\begin{align*}
    s_1 &= 1 - (1 - p_1)^R \\
    s_2 &= \max(s_1, 1 - (1 - p_2)^{R-1}) \\
    s_3 &= \max(s_2, 1 - (1 - p_3)^{R-2}) \\
    &\vdots
\end{align*}
\]

Stepdown Bonferroni adjustments using exact tests are defined as

\[
\begin{align*}
    s_1 &= p_1^* + \cdots + p_R^* \\
    s_2 &= \max(s_1, p_2^* + \cdots + p_R^*) \\
    s_3 &= \max(s_2, p_3^* + \cdots + p_R^*) \\
    &\vdots
\end{align*}
\]

where the $p_j^*$ are defined as before. Note that $p_j^*$ is taken from the permutation distribution corresponding to the $j$th smallest unadjusted p-value. Also, any $s_j$ greater than 1.0 is truncated to 1.0.

Stepdown Sidak adjustments for exact tests are defined analogously by substituting $1 - (1 - p_j^*) \cdots (1 - p_R^*)$ for $p_j^* + \cdots + p_R^*$.

The resampling-style stepdown method is analogous to the preceding stepdown methods; the most extreme p-value is adjusted according to all $R$ tests, the second-most extreme p-value is adjusted according to $(R-1)$ tests, and so on. The difference is that all correlational and distributional characteristics are incorporated when you use resampling methods. More specifically, assuming the same ordering of p-values as discussed previously, the resampling-style stepdown adjusted p-value for test $r$ is the probability that the minimum pseudo-p-value of tests $r, \ldots, R$ is less than or equal to $p_r$.

This probability is evaluated using Monte Carlo, as are the previously described resampling-style adjusted p-values. In fact, the computations for stepdown adjusted p-values are essentially no more time-consuming than the computations for the non-stepdown adjusted p-values. After Monte Carlo, the stepdown adjusted p-values are corrected to ensure monotonicity; this correction leaves the first adjusted p-values
alone, then corrects the remaining ones as needed. The stepdown method approximately controls the familywise error rate, and it is described in more detail by Westfall and Young (1993), Westfall et al. (1999), and Westfall and Wolfinger (2000).

**Hochberg**

Assuming \( p \)-values are independent and uniformly distributed under their respective null hypotheses, Hochberg (1988) demonstrated that Holm’s stepdown adjustments control the familywise error rate even when calculated in *step-up* fashion. Since the adjusted \( p \)-values are uniformly smaller for Hochberg’s method than for Holm’s method, the Hochberg method is more powerful. However, this improved power comes at the cost of having to make the assumption of independence.

The Hochberg adjusted \( p \)-values are defined in reverse order as the stepdown Bonferroni:

\[
\begin{align*}
    s_R &= p_R \\
    s_{(R-1)} &= \min \left( s_R, 2p_{(R-1)} \right) \\
    s_{(R-2)} &= \min \left( s_{(R-1)}, 3p_{(R-2)} \right) \\
    &\vdots
\end{align*}
\]

**Hommel**

Hommel’s (1988) method is a closed testing procedure based on Simes’ (1986) test. The Simes \( p \)-value for a joint test of any set of \( S \) hypotheses with \( p \)-values \( p_1 \leq p_2 \leq \ldots \leq p_S \) is \( \min((S/1)p_1, (S/2)p_2, \ldots, (S/S)p_S) \). The Hommel adjusted \( p \)-value for test \( j \) is the maximum of all such Simes \( p \)-values, taken over all joint tests that include \( j \) as one of their components.

Hochberg adjusted \( p \)-values are always as large or larger than Hommel adjusted \( p \)-values. Sarker and Chang (1997) showed that Simes’ method is valid under independent or positively dependent \( p \)-values, so Hommel’s and Hochberg’s methods also are valid in such cases by the closure principle.

**Fisher Combination**

The FISHER_C option requests adjusted \( p \)-values using closed tests, based on the idea of Fisher’s combination test. The Fisher combination test for a joint test of any set of \( S \) hypotheses with \( p \)-values uses the chi-square statistic \( \chi^2 = -2 \sum \log(p_i) \), with \( 2S \) degrees of freedom. The FISHER_C adjusted \( p \)-value for test \( j \) is the maximum of all \( p \)-values for the combination tests, taken over all joint tests that include \( j \) as one of their components. Independence of \( p \)-values is required for the validity of this method.

**False Discovery Rate**

The FDR option requests \( p \)-values that control the “false discovery rate,” described by Benjamini and Hochberg (1995). These adjustments are potentially much less conservative than the Hochberg adjustments; however, they do not necessarily control the familywise error rate. Furthermore, they are guaranteed to control the false
discovery rate only with independent \( p \)-values that are uniformly distributed under their respective null hypotheses.

The FDR adjusted \( p \)-values are defined in step-up fashion, like the Hochberg adjustments, but with less conservative multipliers:

\[
\begin{align*}
    s_R &= p_R \\
    s_{(R-1)} &= \min\left(s_R, \frac{R}{R-1}p_{(R-1)}\right) \\
    s_{(R-2)} &= \min\left(s_{(R-1)}, \frac{R}{R-2}p_{(R-2)}\right) \\
    &\ldots
\end{align*}
\]

**Missing Values**

If a CLASS or STRATA variable has a missing value, then PROC MULTTEST removes that observation from the analysis.

When there are missing values for test variables, the within group-and-stratum sample sizes may differ from variable to variable. In most cases this is not a problem; however, it is possible for all data to be missing for a particular group within a particular stratum. For continuous variables and Freeman-Tukey tests, PROC MULTTEST recenters the contrast trend coefficients within strata where all data for a particular group are missing. The Cochran-Armitage and Peto tests are unaffected by this situation.

PROC MULTTEST uses missing values for resampling if they exist in the original data set. If all variables have missing values for any observation, then PROC MULTTEST removes it prior to resampling. Otherwise, PROC MULTTEST treats all missing values as ordinary observations in the resampling. This means that different resampled data sets can have different group sizes. In some cases it means that a resampled data set can have all missing values for a particular variable in a particular group/stratum combination, even when values exist for that combination in the original data. For this reason, PROC MULTTEST recomputes all quantities within each pseudo-data set, including such items as centered scoring coefficients and degrees of freedom for \( p \)-values.

While PROC MULTTEST does provide analyses in missing value cases, you should not feel that it completely solves the missing value problem. If you are concerned about the adverse effects of missing data on a particular analysis, you should consider using imputation and sensitivity analyses to assess the effects of the missing data.

**Computational Resources**

PROC MULTTEST keeps all of the data in memory to expedite resampling. A large portion of the memory requirement is thus 8*NOBS*NVAR bytes, where NOBS is the number of observations in the data set, and NVAR is the number of variables analyzed, including CLASS, FREQ, and STRATA variables.
If you specify PERMUTATION=number (for exact permutation distributions), then
PROC MULTTEST requires additional memory. This requirement is approximately
4*NTTEST*NSTRATA*CMAX*number*(number+1) bytes, where NTTEST is
the number of contrasts, NSTRATA is the number of STRATA levels, and CMAX is
the maximum contrast coefficient.

The execution time is linear in the number of resamples; that is, 10,000 resamples
will take 10 times longer than 1,000 resamples.

## Output Data Sets

### OUT= Data Set

The OUT= data set contains contrast names (_test_), variable names (_var_), the
contrast label (_contrast_), raw p-values (raw_p), and all requested adjusted p-
values (bon_p, sid_p, stpbon_p, stpsid_p, boot_p, perm_p, stpbootp, stppermp, hoc_p, or fdr_p).

If a resampling-based adjusted p-value is requested, then the simulation standard error
is included as either sim_se or stpsimse, depending upon whether single-step or
stepdown adjustments are requested. The simulation standard errors are used to
bound the true resampling-based adjusted p-value. For example, if the resampling-
based estimate is 0.0312 and the simulation standard error is 0.00123, then a 95%
confidence interval for the true adjusted p-value is 0.0312 ± 1.96(0.00123), or 0.0288
to 0.0336.

Intermediate statistics used to calculate the p-values are also written to the OUT= data set. The statistics are separated by the _strat_ level. When _strat_ is reported
as missing, then the statistics refer to the pooled analysis over all _strat_ levels.
The p-values are provided only for the pooled analyses and are therefore reported as
missing for the strata-specific statistics.

For the PETO test, an additional variable, _tstrat_, is included to indicate whether
the stratum is an incidental occurrence stratum (_tstrat_=0) or a fatal occurrence
stratum (_tstrat_=1).

The statistic _value_ is the per-strata contribution to the numerator of the overall
test statistic. In the case of the MEAN test, this is the contrast function of the sample
means multiplied by the total number of observations within the stratum. For the FT
test, _value_ is the contrast function of the double-arcsine transformed proportions,
again multiplied by the total number of observations within the stratum. For the
CA and PETO tests, _value_ is the observed value of the trend statistic within that
stratum.

When either PETO or CA is requested, the variable _exp_ is included; this variable
contains the expected value of the trend statistic for the given stratum.

The statistic _se_ is the square root of the variance of the per-strata _value_ value
for any of the tests.

For MEAN tests, the variable _nval_ is included. When reported with an individual stratum level (that is, when the _strat_ value is nonmissing), the value _nval_
refers to the within-stratum sample size. For the combined analysis (that is, the value of the _strat_ is missing), the value _nval_ contains degrees of freedom of the \( t \)-distribution used to compute the unadjusted \( p \)-value.

When the FISHER test is requested, the OUT= data set contains variables _xval_, _nval_, _yval_, and _nval_, which define observations and sample sizes in the two groups defined by the CONTRAST statement.

For example, the OUT= data set from the drug example in the “Getting Started” section on page 2936 is displayed in Figure 48.4.

**Figure 48.4.** Output Data for the MULTTEST Procedure

**OUTPERM= Data Set**

The OUTPERM= data set contains contrast names (_contrast_), variable names (_var_), and the associated permutation distributions (_value_ and upper_p). PROC MULTTEST computes the permutation distributions when you use the PERMUTATION= option with the CA or Peto tests. The _value_ variable represents the support of the distributions, and upper_p represents their cumulative upper-tail probabilities. The size of this data set depends on the number of variables and the support of their permutation distributions. For information on how this distribution is computed, see the “Exact Permutation Test” section on page 2949. For an illustration, see Example 48.1 on page 2964.

**OUTSAMP= Data Set**

The OUTSAMP= data set contains the data sets used in the resampling analysis, if such an analysis is requested. The variable _sample_ indicates the number of the resampled data set. This variable ranges from 1 to NSAMPLE. For each value of the _sample_ variable, an entire resampled data set is included, with _strat_, _class_, and all other variables in the original data set. The values of the original variables are mean-centered for the mean test, if requested. The variable _obs_ indicates the observation’s position in the original data set.

Each new data set is randomly drawn from the original data set, either with (bootstrap) or without (permutation) replacement. The size of this data set is, thus, the number of observations in the original data set times the number of samples.
Displayed Output

The output produced by PROC MULTTEST is divided into several tables:

- The “Model Information” table provides a list of the options and settings used for that particular invocation of the procedure. Included in this list are the following items:
  - statistical tests
  - support of the exact permutation distribution for the CA and PETO tests
  - continuity corrections used for the CA test
  - test tails
  - strata adjustment
  - \( p \)-value adjustments
  - centering of continuous variables
  - number of samples and seed

- The “Contrast Coefficients” table lists the coefficients used in constructing the statistical tests. These coefficients are either specified in CONTRAST statements or generated by default. The coefficients apply to the levels of the CLASS statement variable.

- The “Variable Tabulations” tables provide summary statistics for each variable listed in the TEST statement. Included for discrete variables are the count, sample size, and percentage of occurrences. For continuous variables, the mean, sample standard deviation, and sample size are displayed. All of the previously mentioned statistics are computed for distinct combinations of the CLASS and STRATA statement variables.

- The “p-Values” table is a collection of the raw and adjusted \( p \)-values from this run of PROC MULTTEST. The \( p \)-values are listed by variable and test.

ODS Table Names

PROC MULTTEST assigns a name to each table it creates, and you must use this name to reference the table when using the Table Delivery System (ODS). These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Examples

Example 48.1. Cochran-Armitage Test with Permutation Resampling

This example, from Keith Soper at Merck, illustrates the exact permutation Cochran-Armitage test carried out on permutation resamples. In the following data set, each observation represents an animal. The binary variables S1 and S2 indicate two tumor types, with 0s indicating no tumor (failure) and 1 indicating a tumor (success); note that they have perfect negative association. The grouping variable is Dose.

1 0 3 1 0 3 1 0 3
0 1 3 0 1 3 1 0 3
;
proc multtest data=a permutation nsample=10000 seed=36607 outperm=pmt pvals;
   test ca(S1 S2 / permutation=10 uppertailed);
   class Dose;
   contrast 'CA Linear Trend' 0 1 2;
run;
proc print data=pmt;
run;

The PROC MULTTEST statement requests 10,000 permutation resamples. The OUTPERM=PMT option creates an output SAS data set for the exact permutation distribution computed for the CA test.

The TEST statement specifies an upper-tailed Cochran-Armitage linear trend test for S1 and S2. The cutoff for exact permutation calculations is 10, as specified with the PERMUTATION= option in the TEST statement. Since S1 and S2 have ten and eight successes, respectively, PROC MULTTEST uses exact permutation distributions to compute the p-values for both variables.

The groups for the CA test are the levels of Dose from the CLASS statement. The trend coefficients applied to these groups are 0, 1, and 2, respectively, as specified in the CONTRAST statement.

Finally, PROC PRINT displays the SAS data set containing the permutation distributions.

The results from this analysis are listed in Output 48.1.1 through Output 48.1.5.
Output 48.1.1. Cochran-Armitage Test with Permutation Resampling

The Multtest Procedure

Model Information

- Test for discrete variables: Cochran-Armitage
- Exact permutation distribution used: Everywhere
- Tails for discrete tests: Upper-tailed
- Strata weights: None
- P-value adjustment: Permutation
- Number of resamples: 10000
- Seed: 36607

You should check the preceding table to verify that the analysis specifications are correct.

Output 48.1.2. Contrast Coefficients

The Multtest Procedure

Contrast Coefficients

<table>
<thead>
<tr>
<th>Dose</th>
<th>Contrast 1</th>
<th>Contrast 2</th>
<th>Contrast 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>CA Linear Trend</td>
<td>0</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

The preceding table lists the label and coefficients from the CONTRAST statement.

Output 48.1.3. Summary Statistics

The Multtest Procedure

Discrete Variable Tabulations

<table>
<thead>
<tr>
<th>Variable</th>
<th>Dose</th>
<th>Count</th>
<th>NumObs</th>
<th>Percent</th>
</tr>
</thead>
<tbody>
<tr>
<td>S1</td>
<td>1</td>
<td>2</td>
<td>6</td>
<td>33.33</td>
</tr>
<tr>
<td>S1</td>
<td>2</td>
<td>4</td>
<td>6</td>
<td>66.67</td>
</tr>
<tr>
<td>S1</td>
<td>3</td>
<td>4</td>
<td>6</td>
<td>66.67</td>
</tr>
<tr>
<td>S2</td>
<td>1</td>
<td>4</td>
<td>6</td>
<td>66.67</td>

<td>6</td>
<td>33.33</td>
</tr>
<tr>
<td>S2</td>
<td>3</td>
<td>2</td>
<td>6</td>
<td>33.33</td>
</tr>
</tbody>
</table>

The preceding table contains summary statistics for the two test variables, S1 and S2. The Count column lists the number of successes for each level of the class variable, Dose. The NumObs column is the sample size, and the Percent column is the percentage of successes in the sample.
Output 48.1.4. Resulting p-Values

<table>
<thead>
<tr>
<th>Variable</th>
<th>Contrast</th>
<th>Raw</th>
<th>Permutation</th>
</tr>
</thead>
<tbody>
<tr>
<td>S1</td>
<td>CA Linear Trend</td>
<td>0.1993</td>
<td>0.4058</td>
</tr>
<tr>
<td>S2</td>
<td>CA Linear Trend</td>
<td>0.9220</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

The Raw column in the preceding “p-Values” table contains the $p$-values from the CA test, and the Permutation column contains the permutation-adjusted $p$-values.

This table shows that, for S1, the adjusted $p$-value is almost twice the raw $p$-value. In fact, from theoretical considerations, the permutation-adjusted $p$-value for S1 should be $2 \times 0.1993 = 0.3986$; the difference is due to resampling error. For S2, the raw $p$-value is 0.9220, and the adjusted $p$-value equals 1, as you would expect from theoretical considerations. The permutation $p$-values for S1 and S2 also happen to be the Bonferroni-adjusted $p$-values for this example.
Output 48.1.5. Exact Permutation Distribution

</tbody>
</table>

The preceding table lists the OUTPERM= data set, which contains the exact permutation distributions for S1 and S2 in terms of cumulative probabilities.
Example 48.2. Freeman-Tukey and t-Tests with Bootstrap Resampling

The data for the following example are the same as for Example 48.1, except that a continuous variable T, which indicates the time of death of the animal, has been added.

```plaintext
data a;
  input S1 S2 T Dose @@;
  datalines;
  0  1  104  1  0  80  1  0  104  1
  0  1  104  1  0  100  1  1  0  104  1
  1  0  85  2  1  60  2  0  1  89  2
  1  0  96  2  0  96  2  1  0  99  2
  1  0  60  3  1  50  3  1  0  80  3
  0  1  98  3  0  99  3  1  0  50  3
;
proc multtest data=a bootstrap nsample=10000 pvals seed=37081 outsamp=res;
  test ft(S1 S2 / lowertailed) mean(T / lowertailed);
  class Dose;
  contrast 'Linear Trend' 0 1 2;
run;
proc print data=res(obs=36);
run;
```

The BOOTSTRAP option in the PROC MULTTEST statement requests bootstrap resampling, and NSAMPLE=10000 requests 10,000 bootstrap samples. The seed for the random number generation is 37081. The OUTSAMP=RES option creates an output SAS data set containing the 10,000 bootstrap samples.

The TEST statement specifies the Freeman-Tukey test for S1 and S2 and specifies the t-test for T. Both tests are lower-tailed. The grouping variable in the CLASS statement is Dose, and the coefficients across the levels of Dose are 0, 1, and 2, as specified in the CONTRAST statement. PROC PRINT displays the first 36 observations of the Res data set containing the bootstrap samples.

The results from this analysis are listed in Output 48.2.1 through Output 48.2.5.
Output 48.2.1. FT and t-tests with Bootstrap Resampling

The Multtest Procedure

</tr>
<tr>
<td>T</td>
<td>3</td>
<td>6</td>
<td>72.8333</td>
<td>22.7017</td>
</tr>
</tbody>
</table>

The summary statistics in the preceding table for S1 and S2 are the same as those from Example 48.1. The variables S1 and S2 are discrete, and T is a continuous variable. The mean, standard deviation, and sample size for each level of Dose is listed in the table for T. The p-values for S1 and S2 are from the Freeman-Tukey test, and the p-values for T are from the t-test.

Output 48.2.4. p-Values

The Multtest Procedure

p-Values

<table>
<thead>
<tr>
<th>Variable</th>
<th>Contrast</th>
<th>Raw</th>
<th>Bootstrap</th>
</tr>
</thead>
<tbody>
<tr>
<td>S1</td>
<td>Linear Trend</td>
<td>0.8547</td>
<td>1.0000</td>
</tr>
<tr>
<td>S2</td>
<td>Linear Trend</td>
<td>0.1453</td>
<td>0.4471</td>
</tr>
<tr>
<td>T</td>
<td>Linear Trend</td>
<td>0.0070</td>
<td>0.0253</td>
</tr>
</tbody>
</table>

The p-values are listed in the preceding table. The Raw column contains the results from the tests on the original data, and the Bootstrap column contains the bootstrap resampled adjustment to raw p. Note that the adjusted p-values are larger than the raw p-values for all three variables. The adjusted p-values more accurately reflect the correlation of the raw p-values, the small size of the data, and the multiple testing.
The preceding table lists the first 36 observations of the SAS data set resulting from the OUTSAMP=RES option in the PROC MULTTEST statement. The entire data set has 180,000 observations, which is 10,000 times the number of observations in the data set. The _sample_ variable is the sample indicator and _class_ indicates the resampling group, that is, the level of the CLASS variable Dose assigned to the new observation. The number of the observation in the original data set is represented by _obs_. Also listed are the values of the original test variables, S1 and S2, and the mean-centered values of T.
Example 48.3. Peto Mortality-Prevalence Test

This example illustrates the use of the Peto mortality-prevalence test. The test is a combination of analyses about the prevalence of incidental tumors in the population and mortality due to fatal tumors.

In the data set, each observation represents an animal. The variables S1–S3 are three tumor types, with a value of 0 indicating no tumor, 1 indicating an incidental (nonlethal) tumor, and 2 indicating a lethal tumor. The time variable T indicates the time of death of the animal, a strata variable B is constructed from T, and the grouping variable Dose is drug dosage.

```sas
data a;
  input S1-S3 T Dose @@;
  if T<=90 then B=1; else B=2;
datalines;
0 0 0 104 0 2 0 1 80 0 0 0 104 0
0 0 0 104 0 0 2 0 100 0 1 0 104 0
2 0 1 85 1 2 1 0 60 1 0 1 0 89 1
2 0 1 96 1 0 0 0 96 1 2 0 1 99 1
2 1 1 69 2 2 0 0 50 2 2 0 1 80 2
0 0 2 98 2 0 0 1 99 2 2 1 1 50 2
;
proc multtest data=a notables out=p stepsid;
  test peto(S1-S3 / permutation=20 time=T uppertailed);
  class Dose;
  strata B;
  contrast 'mort-prev' 0 1 2;
run;
proc print data=p;
run;
```

The NOTABLES option in the PROC MULTTEST statement suppresses the display of the summary statistics for each variable. The OUT=P option creates an output SAS data set containing all p-values and intermediate statistics. The STEPSID option is used to adjust the p-values.

The TEST statement specifies an upper-tailed Peto test for S1–S3. The mortality strata are defined by TIME=T, the death times. The CLASS statement contains the grouping variable Dose. The prevalence strata are defined by the STRATA statement as the blocking variable B. The CONTRAST statement lists the default linear trend coefficients. PROC PRINT displays the requested p-value data set.

The results from this analysis are listed in Output 48.3.1 through Output 48.3.4.
Output 48.3.1. Peto Test

The Multtest Procedure

Model Information

<table>
<thead>
<tr>
<th>Test for discrete variables</th>
<th>Peto</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exact permutation distribution used</td>
<td>Everywhere</td>
</tr>
<tr>
<td>Tails for discrete tests</td>
<td>Upper-tailed</td>
</tr>
<tr>
<td>Strata weights</td>
<td>Sample size</td>
</tr>
<tr>
<td>P-value adjustment</td>
<td>Stepdown Sidak</td>
</tr>
</tbody>
</table>

The preceding information corresponds to the PROC MULTTEST invocation. In this case the totals for all prevalence and fatality strata are less than 20, so exact permutation tests are used everywhere, and the STEPSID adjustments are computed from these permutation distributions.

Output 48.3.2. Contrast Coefficients

The Multtest Procedure

Contrast Coefficients

<table>
<thead>
<tr>
<th>Dose</th>
<th>Contrast 0</th>
<th>1</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>mort-prev</td>
<td>0</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

The contrast trend coefficients are listed in the preceding table. They happen to be the same as the levels of the Dose variable.

Output 48.3.3. p-Values

The Multtest Procedure

p-Values

<table>
<thead>
<tr>
<th>Variable</th>
<th>Contrast</th>
<th>Raw</th>
<th>Stepdown Sidak</th>
</tr>
</thead>
<tbody>
<tr>
<td>S1</td>
<td>mort-prev</td>
<td>0.0681</td>
<td>0.0814</td>
</tr>
<tr>
<td>S2</td>
<td>mort-prev</td>
<td>0.5000</td>
<td>0.5000</td>
</tr>
<tr>
<td>S3</td>
<td>mort-prev</td>
<td>0.0363</td>
<td>0.0781</td>
</tr>
</tbody>
</table>

In the preceding “p-Values” table, the p-values for the Peto tests are listed in the Raw column, and the stepdown Sidak adjusted p-values are in the Stepdown Sidak column. Significant p-values support the claim that higher dosage levels promote higher mortality and prevalence. The raw Peto test is significant at the 5% level for S3, but the adjusted S3 test is no longer significant at 5%. The raw and adjusted p-values for S2 are the same because of the stepdown technique.
### Output 48.3.4. OUT= Data Set

```
<table>

```

The preceding table lists the OUT= data set. The first 30 observations correspond to intermediate statistics used to compute the Peto $p$-values. The _test_ variable lists the name of the test, the _var_ variable lists the name of the TEST variables, and the _contrast_ variable lists the CONTRAST label. The _strat_ variable lists the level of the STRATA variable, and the _tstrat_ variable indicates whether or not the stratum corresponds to values of the TIME= variable. The _value_ variable is the observed contrast for a stratum and the _exp_ variable is its expected value. The variable _se_ contains the square root of the variance terms summed to form the denominator of the Peto statistics.

The final three observations correspond to the three Peto tests, with their $p$-values listed under the _raw_p variable. The _stpsid_p variable contains the stepdown Sidak adjusted $p$-values.
Example 48.4. Fisher Test with Permutation Resampling

These data, from Brown and Fears (1981), are the results from an 80-week carcinogenesis bioassay with female mice. Six tissue sites are examined at necropsy; 1 indicates the presence of a tumor and 0 the absence. A frequency variable $\text{Freq}$ is included. A control and four different doses of a drug (in parts per milliliter) make up the levels of the grouping variable $\text{Dose}$.

  test fisher(Liver Lung Lymph Cardio Pitui Ovary /
    lowertailed);
  class Dose;
  freq Freq;
run;
proc print data=p;
run;
```

In the PROC MULTTEST statement, the ORDER=DATA option is required to keep the levels of $\text{Dose}$ in the order in which they appear in the data set. Without this option, the levels are sorted by their formatted value, resulting in an alphabetic ordering. The NOTABLES option suppresses the display of summary statistics, and the OUT=P option requests an output data set containing $p$-values. The PERMUTATION option specifies permutation resampling, NSAMPLE=1000 requests 1000 samples, and SEED=764511 provides a starting value for the random number generator. You should specify a seed if you need to duplicate resampling results.
To test for higher rates of tumor occurrence in the treatment groups compared to the control group, the LOWERTAILED option is specified in the TEST statement to produce a lower-tailed Fisher exact test for the six tissue sites. The Fisher test is appropriate for comparing a treatment and a control, but multiple testing can be a problem. Brown and Fears (1981) use a multivariate permutation to evaluate the entire collection of tests. PROC MULTTEST adjusts the $p$-values by simulation.

The treatments make up the levels of the grouping variable Dose, listed in the CLASS statement. Since no CONTRAST statement is specified, PROC MULTTEST uses the default pairwise contrasts with the first level of Dose. The FREQ statement is used since this is summary data containing frequency counts of occurrences.

The results from this analysis are listed in Output 48.4.1 through Output 48.4.4.

The preceding “p-Values” table lists p-values for the Fisher exact tests and their permutation-based adjustments. As noted by Brown and Fears, only one of the twenty-four tests is significant at the 5% level (Lymph, CTRL vs. 16PPM). Brown and Fears report a 12% chance of observing at least one significant raw p-value for 16PPM and a 9% chance of observing at least one significant raw p-value for Lymph (both at the 5% level). Adjusted p-values exhibit much lower chances of false significances. For this example, none of the adjusted p-values are close to significant.
The preceding table lists the OUT= data set. The _test_, _var_, and _contrast_ variables provide the TEST name, TEST variable, and CONTRAST label, respectively. The _xval_, _mval_, _yval_, and _nval_ variables contain the components used to compute the Fisher exact tests from the hypergeometric distribution. The raw_p variable contains the p-values from the Fisher exact tests, and the perm_p variable contains their permutation-based adjustments. The variable sim_se is the simulation standard error from the permutation resampling.

**Example 48.5. Inputting Raw p-Values**

This example illustrates how to use PROC MULTTEST to multiplicity-adjust a collection of raw p-values obtained from some other source. This is a valuable option for those cases where PROC MULTTEST cannot compute the raw p-values directly.

```sas
data a;
  input Test$ Raw_P;
datelines;
test1 .09108
  test2 .69122
  test3 .00177
  test4 .57181
  test5 .03121
  test6 .01413;
proc multtest pdata=a holm hoc fdr;
run;
```

Note that there are no statements other than the PROC MULTTEST statement using the p-value input mode. In this example, the raw p-values are adjusted using the
Holm, Hochberg, and Benjamini and Hocherg (FDR) methods.
The output from this analysis is listed in Output 48.5.1.

**Output 48.5.1.** Inputting Raw $p$-Values

<table>
<thead>
<tr>

</tr>
<tr>
<td>6</td>
<td>0.0141</td>
<td>0.0707</td>
<td>0.0707</td>
<td>0.0424</td>
<td></td>
</tr>
</tbody>
</table>

Note that the adjusted $p$-values for the Hochberg method (hoc$_p$) are less than or equal to those for the Holm method (stpbon$_p$). In turn, the adjusted $p$-values for the Benjamini and Hochberg method (fdr$_p$) are less than or equal to those for the Hochberg method. These comparisons hold generally for all $p$-value configurations. The FDR method controls the false discovery rate and not the familywise error rate. The Hochberg method controls the familywise error rate under independence. The Holm method controls the familywise error rate without assuming independence.

  Example 49.1. Variability of Calcium Concentration in Turnip Greens 2994

REFERENCES ........................................................... 2995
The NESTED procedure performs random effects analysis of variance for data from an experiment with a nested (hierarchical) structure. A random effects model for data from a completely nested design with two factors has the following form:

\[ y_{ijr} = \mu + \alpha_i + \beta_{ij} + \epsilon_{ijr} \]

where

- \( y_{ijr} \) is the value of the dependent variable observed at the \( r \)th replication with the first factor at its \( i \)th level and the second factor at its \( j \)th level.
- \( \mu \) is the overall (fixed) mean of the sampling population.
- \( \alpha_i, \beta_{ij}, \epsilon_{ijr} \) are mutually uncorrelated random effects with zero means and respective variances \( \sigma^2_\alpha, \sigma^2_\beta, \) and \( \sigma^2_\epsilon \) (the variance components).

This model is appropriate for an experiment with a multi-stage nested sampling design. An example of this is given in Example 49.1 on page 2994, where four turnip plants are randomly chosen (the first factor), then three leaves are randomly chosen from each plant (the second factor nested within the first), and then two samples are taken from each leaf (the different replications at fixed levels of the two factors).

Note that PROC NESTED is appropriate for models with only classification effects; it does not handle models that contain continuous covariates. For random effects models with covariates, use either the GLM or MIXED procedure.

Contrasted with Other SAS Procedures

The NESTED procedure performs a computationally efficient analysis of variance for data with a nested design, estimating the different components of variance and also testing for their significance if the design is balanced (see the “Unbalanced Data” section on page 2990). Although other procedures (such as GLM and MIXED) provide similar analyses, PROC NESTED is both easier to use and computationally more efficient for this special type of design. This is especially true when the design involves a large number of factors, levels, or observations.

For example, to specify a four-factor completely nested design in the GLM procedure, you use the form

*PROC NESTED is modeled after the General Purpose Nested Analysis of Variance program of the Dairy Cattle Research Branch of the United States Department of Agriculture. That program was originally written by M.R. Swanson, Statistical Reporting Service, United States Department of Agriculture.*
### Chapter 49. The NESTED Procedure

```sas
class a b c d;
model y=a b(a) c(a b) d(a b c);
```

However, to specify the same design in PROC NESTED, you simply use the form

```sas
class a b c d;
var y;
```

In addition, other procedures require TEST statements to perform appropriate tests, whereas the NESTED procedure produces the appropriate tests automatically. However, PROC NESTED makes one assumption about the input data that the other procedures do not: PROC NESTED assumes that the input data set is sorted by the classification (CLASS) variables defining the effects. If you use PROC NESTED on data that is not sorted by the CLASS variables, then the results may not be valid.

---

## Getting Started

### Reliability of Automobile Models

A study is performed to compare the reliability of several models of automobiles. Three different automobile models (Model) from each of four domestic automobile manufacturers (Make) are tested. Three different cars of each make and model are subjected to a reliability test and given a score between 1 and 100 (Score), where higher scores indicate greater reliability.

The following statements create the SAS data set auto.

```sas
title 'Reliability of Automobile Models';
data auto;
  input Make $ Model Score @@;
datelines;
a 1 62 a 2 77 a 3 59
a 1 67 a 2 73 a 3 64
a 1 60 a 2 79 a 3 60
b 1 72 b 2 58 b 3 80
b 1 75 b 2 63 b 3 84
b 1 69 b 2 57 b 3 89
с 1 94 с 2 76 с 3 81
c 1 90 c 2 75 c 3 85
c 1 88 c 2 78 c 3 85
d 1 69 d 2 73 d 3 90
d 1 72 d 2 88 d 3 87
d 1 76 d 2 87 d 3 92
;
```

The Make variable contains the make of the automobile, represented here by ‘a’, ‘b’, ‘c’, or ‘d’, while the Model variable represents the automobile model with a ‘1’, ‘2’, or ‘3’. The Score variable contains the reliability scores given to the three sampled
cars from each Make-Model group. Since the automobile models are nested within their makes, the NESTED procedure is used to analyze this data. The NESTED procedure requires the data to be sorted by Make and, within Make, by Model, so the following statements execute a PROC SORT before completing the analysis.

```plaintext
proc sort;
   by Make Model;
proc nested;
   class Make Model;
   var Score;
run;
```

The Model variable appears after the Make variable in the CLASS statement because it is nested within Make. The VAR statement specifies the response variable. The output is displayed in Figure 49.1.

### Figure 49.1. Output from PROC NESTED

Figure 49.1 first displays the coefficients of the variance components that make up each of the expected mean squares, then the ANOVA table is displayed. The results do not indicate significant variation between the different automobile makes ($F = 2.15, p = 0.1719$). However, they do suggest that there is significant variation between the different models within the makes ($F = 18.16, p < 0.0001$). This is evident in the fact that the make of car accounts for only 25.7% of the total variation in the data, while the car model accounts for 63.3% (as shown in the Percent of Total column). The estimated variance components are shown in the Variance Component column.
Syntax

The following statements are available in PROC NESTED.

```
PROC NESTED < options > ;
   CLASS variables < / option > ;
   VAR variables ;
   BY variables ;
```

The PROC NESTED and CLASS statements are required. The BY, CLASS, and VAR statements are described after the PROC NESTED statement.

PROC NESTED Statement

```
PROC NESTED < options > ;
```

The PROC NESTED statement has the following options:

- **AOV**
  displays only the analysis of variance statistics when there is more than one dependent variable. The “analysis of covariation” statistics are suppressed (see the “Analysis of Covariation” section on page 2990).

- **DATA=SAS-data-set**
  names the SAS data set to be used by PROC NESTED. By default, the procedure uses the most recently created SAS data set.

BY Statement

```
BY variables ;
```

You can specify a BY statement with PROC NESTED to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

Note: When you use the NESTED procedure, your data must be sorted first by the BY variables and, within the BY variables, by the CLASS variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NESTED procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).
For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**CLASS Statement**

```
CLASS variables < / option > ;
```

You must include a CLASS statement with PROC NESTED specifying the classification variables for the analysis.

Values of a variable in the CLASS statement denote the levels of an effect. The name of that variable is also the name of the corresponding effect. The second effect is assumed to be nested within the first effect, the third effect is assumed to be nested within the second effect, and so on.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 8 characters of the formatted values, except for numeric variables with no explicit format, for which class levels were determined from the raw numeric values. If you wish to revert to this previous behavior you can use the TRUNCATE option on the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide*, and the discussions for the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*.

*Note:* The data set must be sorted by the classification variables in the order that they are given in the CLASS statement. Use PROC SORT to sort the data if they are not already sorted.

You can specify the following option in the CLASS statement after a slash (/):

**TRUNCATE**

specifies that class levels should be determined using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

**VAR Statement**

```
VAR variables ;
```

The VAR statement lists the dependent variables for the analysis. The dependent variables must be numeric variables. If you do not specify a VAR statement, PROC NESTED performs an analysis of variance for all numeric variables in the data set, except those already specified in the CLASS statement.
Details

Missing Values

An observation with missing values for any of the variables used by PROC NESTED is omitted from the analysis. Blank values of CLASS character variables are treated as missing values.

Unbalanced Data

A completely nested design is defined to be unbalanced if the groups corresponding to the levels of some classification variable are not all of the same size. The NESTED procedure can compute unbiased estimates for the variance components in an unbalanced design, but because the sums of squares on which these estimates are based no longer have \( \chi^2 \) distributions under a Gaussian model for the data, \( F \) tests for the significance of the variance components cannot be computed. PROC NESTED checks to see that the design is balanced. If it is not, a warning to that effect is placed on the log, and the columns corresponding to the \( F \) tests in the analysis of variance are left blank.

General Random Effects Model

A random effects model for data from a completely nested design with \( n \) factors has the general form

\[
y_{i_1i_2\ldots i_nr} = \mu + \alpha_{i_1} + \beta_{i_1i_2} + \cdots + \epsilon_{i_1i_2\ldots i_nr}
\]

where

- \( y_{i_1i_2\ldots i_nr} \) is the value of the dependent variable observed at the \( r \)th replication with factor \( j \) at level \( i_j \), for \( j = 1, \ldots, n \).
- \( \mu \) is the overall (fixed) mean of the sampled population.
- \( \alpha_{i_1}, \beta_{i_1i_2}, \ldots, \epsilon_{i_1i_2\ldots i_nr} \) are mutually uncorrelated random effects with zero means and respective variances \( \sigma^2_\alpha, \sigma^2_\beta, \ldots, \sigma^2_\epsilon \).

Analysis of Covariation

When you specify more than one dependent variable, the NESTED procedure produces a descriptive analysis of the covariance between each pair of dependent variables in addition to a separate analysis of variance for each variable. The analysis of covariation is computed under the basic random effects model for each pair of dependent variables:

\[
y_{i_1i_2\ldots i_nr} = \mu + \alpha_{i_1} + \beta_{i_1i_2} + \cdots + \epsilon_{i_1i_2\ldots i_nr}
\]

\[
y'_{i_1i_2\ldots i_nr} = \mu' + \alpha'_{i_1} + \beta'_{i_1i_2} + \cdots + \epsilon'_{i_1i_2\ldots i_nr}
\]
where the notation is the same as that used in the preceding general random effects model.

There is an additional assumption that all the random effects in the two models are mutually uncorrelated except for corresponding effects, for which

\[
\text{Corr}(\alpha_{i1}, \alpha'_{i1}) = \rho_\alpha \\
\text{Corr}(\beta_{i1i2}, \beta'_{i1i2}) = \rho_\beta \\
\vdots \\
\text{Corr}(\epsilon_{i1i2\ldots i_r}, \epsilon'_{i1i2\ldots i_r}) = \rho_\epsilon
\]

### Error Terms in F Tests

Random effects ANOVAs are distinguished from fixed effects ANOVAs by which error mean squares are used as the denominator for $F$ tests. Under a fixed effects model, there is only one true error term in the model, and the corresponding mean square is used as the denominator for all tests. This is how the usual analysis is computed in PROC ANOVA, for example. However, in a random effects model for a nested experiment, mean squares are compared sequentially. The correct denominator in the test for the first factor is the mean square due to the second factor; the correct denominator in the test for the second factor is the mean square due to the third factor; and so on. Only the mean square due to the last factor, the one at the bottom of the nesting order, should be compared to the error mean square.

### Computational Method

The building blocks of the analysis are the sums of squares for the dependent variables for each classification variable within the factors that precede it in the model, corrected for the factors that follow it. For example, for a two-factor nested design, PROC NESTED computes the following sums of squares:

\[
\text{Total SS} = \sum_{ijr} (y_{ijr} - \ldots)^2 \\
\text{SS for Factor 1} = \sum_i n_i \left( \frac{y_{i.} - \ldots}{n_i} - \ldots \right)^2 \\
\text{SS for Factor 2 within Factor 1} = \sum_{ij} n_{ij} \left( \frac{y_{ij.} - y_{i..}}{n_{ij}} - \ldots \right)^2 \\
\text{Error SS} = \sum_{ijr} \left( \frac{y_{ijr} - y_{ij.}}{n_{ij}} \right)^2
\]
where \( y_{ijr} \) is the \( r \)th replication, \( n_{ij} \) is the number of replications at level \( i \) of the first factor and level \( j \) of the second, and a dot as a subscript indicates summation over the corresponding index. If there is more than one dependent variable, PROC NESTED also computes the corresponding sums of crossproducts for each pair. The expected value of the sum of squares for a given classification factor is a linear combination of the variance components corresponding to this factor and to the factors that are nested within it. For each factor, the coefficients of this linear combination are computed.

(The efficiency of PROC NESTED is partly due to the fact that these various sums can be accumulated with just one pass through the data, assuming that the data have been sorted by the classification variables.) Finally, estimates of the variance components are derived as the solution to the set of linear equations that arise from equating the mean squares to their expected values.

**Displayed Output**

PROC NESTED displays the following items for each dependent variable:

- Coefficients of Expected Mean Squares, which are the coefficients of the \( n + 1 \) variance components making up the expected mean square. Denoting the element in the \( i \)th row and \( j \)th column of this matrix by \( C_{ij} \), the expected value of the mean square due to the \( i \)th classification factor is

\[
C_{i1}\sigma_1^2 + \cdots + C_{in}\sigma_n^2 + C_{i,n+1}\sigma_\epsilon^2.
\]

\( C_{ij} \) is always zero for \( i > j \), and if the design is balanced, \( C_{ij} \) is equal to the common size of all classification groups of the \( j \)th factor for \( i \leq j \). Finally, the mean square for error is always an unbiased estimate of \( \sigma_\epsilon^2 \). In other words, \( C_{n+1,n+1} = 1 \).

For every dependent variable, PROC NESTED displays an analysis of variance table. Each table contains the following:

- each Variance Source in the model (the different components of variance) and the total variance
- degrees of freedom (DF) for the corresponding sum of squares
- Sum of Squares for each classification factor. The sum of squares for a given classification factor is the sum of squares in the dependent variable within the factors that precede it in the model, corrected for the factors that follow it. (See the “Computational Method” section on page 2991.)
- \( F \) Value for a factor, which is the ratio of its mean square to the appropriate error mean square. The next column, labeled PR > F, gives the significance levels that result from testing the hypothesis that each variance component equals zero.
- the appropriate Error Term for an \( F \) test, which is the mean square due to the next classification factor in the nesting order. (See the “Error Terms in F Tests” section on page 2991.)
• Mean Square due to a factor, which is the corresponding sum of squares divided by the degrees of freedom

• estimates of the Variance Components. These are computed by equating the mean squares to their expected values and solving for the variance terms. (See the “Computational Method” section on page 2991.)

• Percent of Total, the proportion of variance due to each source. For the $i$th factor, the value is

$$100 \times \frac{\text{source variance component}}{\text{total variance component}}$$

• Mean, the overall average of the dependent variable. This gives an unbiased estimate of the mean of the population. Its variance is estimated by a certain linear combination of the estimated variance components, which is identical to the mean square due to the first factor in the model divided by the total number of observations when the design is balanced.

If there is more than one dependent variable, then the NESTED procedure displays an “analysis of covariation” table for each pair of dependent variables (unless the AOV option is specified in the PROC NESTED statement). See the “Analysis of Covariation” section on page 2990 for details. For each source of variation, this table includes the following:

• Degrees of Freedom
• Sum of Products
• Mean Products
• Covariance Component, the estimate of the covariance component

Items in the analysis of covariation table are computed analogously to their counterparts in the analysis of variance table. The analysis of covariation table also includes the following:

• Variance Component Correlation for a given factor. This is an estimate of the correlation between corresponding effects due to this factor. This correlation is the ratio of the covariance component for this factor to the square root of the product of the variance components for the factor for the two different dependent variables. (See the “Analysis of Covariation” section on page 2990.)

• Mean Square Correlation for a given classification factor. This is the ratio of the Mean Products for this factor to the square root of the product of the Mean Squares for the factor for the two different dependent variables.
ODS Table Names

PROC NESTED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Example

Example 49.1. Variability of Calcium Concentration in Turnip Greens

In the following example from Snedecor and Cochran (1976), an experiment is conducted to study the variability of calcium concentration in turnip greens. Four plants are selected at random; then three leaves are randomly selected from each plant. Two 100-mg samples are taken from each leaf. The amount of calcium is determined by microchemical methods.

Because the data are read in sorted order, it is not necessary to use PROC SORT on the CLASS variables. Leaf is nested in Plant; Sample is nested in Leaf and is left for the residual term. All the effects are random effects. The following statements read the data and invoke PROC NESTED. These statements produce Output 49.1.1:

```plaintext

Chapter 50
The NLIN Procedure

Overview

The NLIN procedure produces least squares or weighted least squares estimates of the parameters of a nonlinear model. Nonlinear models are more difficult to specify and estimate than linear models. Instead of simply listing regressor variables, you must write the regression expression, declare parameter names, and supply initial parameter values. Some models are difficult to fit, and there is no guarantee that the procedure can fit the model successfully.

For each nonlinear model to be analyzed, you must specify the model (using a single dependent variable) and the names and starting values of the parameters to be estimated.

Using PROC NLIN, you can also

- confine the estimation procedure to a certain range of values of the parameters by imposing bounds on the estimates
- produce new SAS data sets containing predicted values, residuals, parameter estimates and SSE at each iteration, the covariance matrix of parameter estimates, and other statistics
- define your own objective function to be minimized

Estimation of a nonlinear model is an iterative process. To begin this process the NLIN procedure first examines the starting value specifications of the parameters. If a grid of values is specified, PROC NLIN evaluates the residual sum of squares at each combination of parameter values to determine the set of parameter values producing the lowest residual sum of squares. These parameter values are used for the initial step of the iteration.

Then PROC NLIN uses one of these five iterative methods:

- steepest-descent or gradient method
- Newton method
- modified Gauss-Newton method
- Marquardt method

These methods use derivatives or approximations to derivatives of the SSE with respect to the parameters to guide the search for the parameters producing the smallest SSE.
You can use the NLIN procedure for segmented models (see Example 50.1) or robust regression (see Example 50.2). You can also use it to compute maximum-likelihood estimates for certain models (refer to Jennrich and Moore 1975; Charnes, Frome, and Yu 1976).

**Getting Started**

The NLIN procedure performs univariate nonlinear regression using the least squares method. Nonlinear regression analysis is indicated when you have information specifying that the functional relationship between the predictor and response variables is nonlinear in the parameters. Such information might come from direct knowledge of the true model, theoretical developments, or previous studies. _Nonlinear_, in this sense, means that the mathematical relationship between the variables and parameters is not required to have a linear form. For example, consider the following two models:

\[ Y = aX^2 + b \]

\[ Y = \frac{1}{a}X + b \]

where \(a\) and \(b\) are parameters and \(X\) and \(Y\) are random variables. The first model is linear in the parameters; the second model is nonlinear.

**Estimating the Nonlinear Model**

As an example of a nonlinear regression analysis, consider the following theoretical model of enzyme kinetics. The model relates the initial velocity of an enzymatic reaction to the substrate concentration.

\[ f(x, \theta) = \frac{\theta_1 x_i}{\theta_2 + x_i}, \text{ for } i = 1, 2, \ldots, n \]

where \(x_i\) represents the amount of substrate for \(n\) trials and \(f(x, \theta)\) is the velocity of the reaction. The vector \(\theta\) contains the rate parameters.

Suppose that you want to study the relationship between concentration and velocity for a particular enzyme/substrate pair. You record the reaction rate (velocity) observed at different substrate concentrations. Your data set is as follows:

```
data Enzyme;
   input Concentration Velocity @@;
datalines;
  0.26 124.7  0.30 126.9  0.48 135.9  0.50 137.6
  0.54 139.6  0.68 141.1  0.82 142.8  1.14 147.6
  1.28 149.8  1.38 149.4  1.80 153.9  2.30 152.5
  2.44 154.5  2.48 154.7
;```
The SAS data set Enzyme contains the two variables Concentration (substrate concentration) and Velocity (reaction rate). The double trailing unsigned (@@) in the INPUT statement specifies that observations are input from each line until all of the values are read.

The following statements request a nonlinear regression analysis:

```sas
proc nlin data=Enzyme method=marquardt hougaard;
   parms theta1=155
       theta2=0 to 0.07 by 0.01;
   model Velocity = theta1*Concentration / (theta2 + Concentration);
run;
```

The DATA= option specifies that the SAS data set Enzyme be used in the analysis. The METHOD= option directs PROC NLIN to use the MARQUARDT iterative method. The HOUGAARD option requests that a skewness measure be calculated for the parameters.

The MODEL statement specifies the enzymatic reaction model

\[ V = \frac{\theta_1 C}{\theta_2 + C} \]

where \( V \) represents the velocity or reaction rate and \( C \) represents the substrate concentration.

The PARMS statement declares the parameters and specifies their initial values. In this example, the initial estimates in the PARMS statement are obtained as follows. Since the model is a monotonic increasing function in \( C \), and

\[ \lim_{C \to \infty} \left( \frac{\theta_1 C}{\theta_2 + C} \right) = \theta_1 \]

take the largest observed value of the variable Velocity (154.7) as the initial value for the parameter Theta1. Thus, the PARMS statement specifies 155 as the initial value for Theta1, which is approximately equal to the maximum observed velocity.

To obtain an initial value for the parameter \( \theta_2 \), first rearrange the model equation to solve for \( \theta_2 \):

\[ \theta_2 = \frac{\theta_1 C}{V} - C \]

By substituting the initial value of Theta1 for \( \theta_1 \) and taking each pair of observed values of Concentration and Velocity for \( C \) and \( V \), respectively, you obtain a set of possible starting values for Theta2 ranging from about 0.01 to 0.07.

You can choose any value within this range as a starting value for Theta2, or you can direct PROC NLIN to perform a preliminary search for the best initial Theta2 value.
within that range of values. The PARMS statement specifies a range of values for Theta2, which results in a search over the grid points from 0 to 0.07 in increments of 0.01. The output from this PROC NLIN invocation are displayed in the following figures.

PROC NLIN evaluates the model at each point on the specified grid for the Theta2 parameter. Figure 50.1 displays the calculations resulting from the grid search.

Figure 50.1. Nonlinear Least Squares Grid Search from the NLIN Procedure

The parameter Theta1 is held constant at its specified initial value of 155, the grid is traversed, and the residual sums of squares are computed at each point. The “best” starting value is the point that corresponds to the smallest value of the residual sum of squares. Figure 50.1 shows that the best starting value for Theta2 is 0.06. PROC NLIN uses this point as the initial value for Theta2 in the following iterative phase.

PROC NLIN determines convergence using the relative offset measure of Bates and Watts (1981). When this measure is less than $10^{-5}$, convergence is declared. Figure 50.1 displays the iteration history.

Figure 50.2. Estimation Summary from the NLIN Procedure

Figure 50.2 displays a summary of the estimation including several convergence measures R, PPC, RPC, and Object.

The R measure is the relative offset convergence measure of Bates and Watts. A PPC value of 8.569E-7 indicates that the parameter Theta2 (which has the largest PPC value of all the parameters) would change by that relative amount were PROC NLIN to take an additional iteration step. The RPC value indicates that Theta2 changed by 0.000078, relative to its value in the last iteration. These changes are measured before steplength adjustments are made. The Object measure indicates that the objective function value changed 2.902E-7 in relative value from the last iteration.

The NLIN Procedure

NOTE: An intercept was not specified for this model.

Figure 50.3. Nonlinear Least Squares Summary from the NLIN Procedure

Figure 50.3 displays the least squares summary statistics for the model. The degrees of freedom, sums of squares, and mean squares are listed.
Figure 50.4. Parameter Estimates from the NLIN Procedure

Figure 50.4 displays the estimates for each parameter, the associated asymptotic standard error, and the upper and lower values for the asymptotic 95% confidence interval. PROC NLIN also displays the asymptotic correlations between the estimated parameters (not shown).

The skewness measures of 0.0152 and 0.0362 indicate that the parameters are nearly linear and that their standard errors and confidence intervals can be safely used for inferences.

Thus, the estimated nonlinear model relating reaction velocity and substrate concentration can be written as

\[
\hat{V} = \frac{158.105C}{0.0741 + C}
\]

where \(V\) represents the velocity or rate of the reaction, and \(C\) represents the substrate concentration.

Syntax

```
PROC NLIN < options > ;
   MODEL dependent=expression ;
   PARAMETERS parameter=values < . . . , parameter=values> ;
   other program statements
   BOUNDS inequality < , . . . , inequality > ;
   BY variables ;
   DER.parameter=expression ;
   DER.parameter.parameter=expression ;
   ID variables ;
   OUTPUT OUT=SAS-data-set keyword=names < . . . , keyword=names > ;
   CONTROL variable <=values> < . . . , variable <=values> > ;
```

A vertical bar (|) denotes a choice between two specifications. The other program statements are valid SAS expressions that can appear in the DATA step. PROC NLIN enables you to create new variables within the procedure and use them in the nonlinear analysis. The NLIN procedure automatically creates several variables that are also available for use in the analysis. See the section “Special Variables” beginning
The statements used in PROC NLIN, in addition to the PROC statement, are as follows:

- **BOUNDS**: constrains the parameter estimates within specified bounds
- **BY**: specifies variables to define subgroups for the analysis
- **DER**: specifies the first or second partial derivatives
- **ID**: specifies additional variables to add to the output data set
- **MODEL**: defines the relationship between the dependent and independent variables
- **OUTPUT**: creates an output data set containing statistics for each observation
- **PARMS**: identifies parameters to be estimated and the starting values for each parameter
- **other program statements**: includes assignment statements, ARRAY statements, DO loops, and program control statements
requests that PROC NLIN display the residual sums of squares only for the best \( n \) combinations of possible starting values from the grid. If you do not specify the \( \text{BEST=} \) option, PROC NLIN displays the residual sum of squares for every combination of possible parameter starting values.

\( \text{CONVERGE=}c \) specifies the convergence criteria for PROC NLIN. For all iterative methods the relative offset convergence measure of Bates and Watts is used by default to determine convergence. This measure is labeled "R" in the Estimation Summary table. The
iterations are said to have converged for CONVERGE=c if

\[ \sqrt{\frac{r'X(X'X)^{-1}X'r}{\text{LOSS}_i}} < c \]

where \( r \) is the residual vector and \( X \) is the Jacobian matrix. The default LOSS function is the sum of squared errors (SSE). By default, CONVERGE=10^{-5}. The R convergence measure cannot be computed accurately in the special case of a perfect fit (residuals close to zero). When the SSE is less than the value of the SINGULAR= option, convergence is assumed.

CONVERGEOBJ=c uses the change in the LOSS function as the convergence criterion. For more details on the LOSS function, see the section “Special Variable Used to Determine Convergence Criteria” on page 3021. The iterations are said to have converged for CONVERGEOBJ=c if

\[ \frac{\text{LOSS}_{i-1} - \text{LOSS}_i}{\text{LOSS}_i + 10^{-6}} < c \]

where \( \text{LOSS}_i \) is the LOSS for the \( i \)th iteration. The default LOSS function is the sum of squared errors (SSE). The constant \( c \) should be a small positive number. See the “Computational Methods” section beginning on page 3024 for more details. If specified, the CONVERGEOBJ= option overrides the default CONVERGE= convergence criterion so that NLIN performs as it did in version 6 releases of the procedure.

CONVERGEPARM=c uses the maximum change among parameter estimates as the convergence criterion. The iterations are said to have converged for CONVERGEPARM=c if

\[ \max_j \left( \frac{|\beta_j^{i-1} - \beta_j^i|}{|\beta_j^{i-1}|} \right) < c \]

where \( \beta_j^i \) is the value of the \( j \)th parameter at the \( i \)th iteration.

The default convergence criterion is CONVERGE. If you specify CONVERGEPARM=c, the maximum change in parameters is used as the convergence criterion. If you specify both the CONVERGEOBJ= and CONVERGEPARM= options, PROC NLIN continues to iterate until the decrease in LOSS is sufficiently small (as determined by the CONVERGEOBJ= option) and the maximum change among the parameters is sufficiently small (as determined by the CONVERGEPARM= option).

DATA=SAS-data-set specifies the SAS data set containing the data to be analyzed by PROC NLIN. If you omit the DATA= option, the most recently created SAS data set is used.
Chapter 50. The NLIN Procedure

FLOW

displays a message for each statement in the model program as it is executed. This debugging option is rarely needed, and it produces large amounts of output.

G4

uses a Moore-Penrose \((g_4)\) inverse in parameter estimation. Refer to Kennedy and Gentle (1980) for details.

HOUGAARD

adds Hougaard’s measure of skewness to the parameter estimation table. Computation of the measure requires derivatives (see the section “Hougaard’s Measure of Skewness” on page 3019).

LIST

displays the model program and variable lists, including the statements added by macros. Note that the expressions displayed by the LIST option do not necessarily represent the way the expression is actually calculated, since intermediate results for common subexpressions can be reused but are shown in expanded form by the LIST option. To see how the expression is actually evaluated, see the description for the LISTCODE option, which follows.

LISTALL

selects the LIST, LISTDEP, LISTDER, and LISTCODE options.

LISTCODE

displays the derivative tables and compiled model program code. The LISTCODE option is a debugging feature and is not normally needed.

LISTDEP

produces a report that lists, for each variable in the model program, the variables that depend on it and on which it depends.

LISTDER

displays a table of derivatives. The derivatives table lists each nonzero derivative computed for the problem. The derivative listed can be a constant, a variable in the model program, or a special derivative variable created to hold the result of the derivative expression.

MAXITER=\(i\)

limits the number of iterations PROC NLIN performs before it gives up trying to converge. The \(i\) value must be a positive integer. By default, MAXITER=100.

MAXSUBIT=\(i\)

places a limit on the number of step halvings. By default, MAXSUBIT=30. The value of MAXSUBIT must be a positive integer.

METHOD=GAUSS | MARQUARDT | NEWTON | GRADIENT

specifies the iterative method that PROC NLIN uses. The GAUSS, MARQUARDT and NEWTON methods are more robust than the GRADIENT method. If you omit the METHOD= option, METHOD=GAUSS is used. See the “Computational Methods” section beginning on page 3024 for more information.
NOITPRINT suppresses the display of the results of each iteration.

NOHALVE removes the restriction that the objective value must decrease at every iteration. Step halving is still used to satisfy BOUNDS and to ensure that the number of observations that can be evaluated does not decrease. NOHALVE is useful for iteratively reweighted least squares problems.

NOPRINT suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see Chapter 14, “Using the Output Delivery System.”

OUTEST=SAS-data-set specifies an output data set to contain the parameter estimates produced at each iteration. See the “Output Data Sets” section on page 3028 for details. If you want to create a permanent SAS data set, you must specify a two-level name. See the chapter “SAS Files,” in SAS Language Reference: Concepts for more information on permanent SAS data sets.

PRINT displays the result of each statement in the program as it is executed. This option produces large amounts of output.

RHO=value specifies a value to use in controlling the step-size search. By default, RHO=0.1 except when METHOD=MARQUARDT, in which case RHO=10. See the section “Computational Methods” beginning on page 3024 for more details.

SAVE specifies that, when the iteration limit is exceeded, the parameter estimates from the final iteration are output to the OUTEST= data set. These parameter estimates are located in the observation with _TYPE_=FINAL. If you omit the SAVE option, the parameter estimates from the final iteration are not output to the data set unless convergence is attained.

SIGSQ=value specifies a value to replace the mean square error for computing the standard errors of the estimates. The SIGSQ= option is used with maximum-likelihood estimation.

SINGULAR=s specifies the singularity criterion, s, which is the absolute magnitude of the smallest pivot value allowed when inverting the Hessian or approximation to the Hessian. The default value is 1E-8.

SMETHOD=HALVE | GOLDEN | CUBIC specifies the step-size search method that PROC NLIN uses. The default is SMETHOD=HALVE. See the section “Computational Methods” beginning on page 3024 for details.
TAU=value
specifies a value to use in controlling the step-size search. By default, TAU=1 except when METHOD=MARQUARDT, in which case TAU=0.01. See the section “Computational Methods” beginning on page 3024 for details.

TRACE
displays the result of each operation in each statement in the model program as it is executed, in addition to the information displayed by the FLOW and PRINT options. This debugging option is needed very rarely, and it produces even more output than the FLOW and PRINT options.

XREF
displays a cross-reference of the variables in the model program showing where each variable is referenced or given a value. The XREF listing does not include derivative variables.

UNCORRECTEDDF
specifies that no degrees of freedom are lost when a bound is active. When the UNCORRECTEDDF option is not specified, an active bound is treated as if a restriction was applied to the set of parameters so one parameter degree of freedom is deducted.

**BOUNDS Statement**

BOUNDS inequality <, . . . , inequality > ;

The BOUNDS statement restrains the parameter estimates within specified bounds. In each BOUNDS statement, you can specify a series of bounds separated by commas. The series of bounds is applied simultaneously. Each bound contains a list of parameters, an inequality comparison operator, and a value. In a single-bounded expression, these three elements follow one another in the order described. The following are examples of valid single-bounded expressions:

```
bounds a1-a10<=20;
bounds c>30;
bounds a b c > 0;
```

Multiple-bounded expressions are also permitted. For example,

```
bounds 0<=B<=10;
bounds 15<x1<=30;
bounds r <= s <= p < q;
```

If you need to restrict an expression involving several parameters (for example, \(A + B < 1\)), you can reparameterize the model so that the expression becomes a parameter.

For SAS versions 7.01 and later, lagrange multipliers are reported for all bounds that are enforced (active) when the estimation terminates. In the estimates table the Lagrange multiplier estimates are identified with names Bound1, Bound2 ... . An
active bound is treated as if a restriction was applied to the set of parameters so one parameter degree of freedom is deducted. The option UNCORRECTEDDDF specifies that no degrees of freedom are lost when a bound is active.

**BY Statement**

```
BY  variables ;
```

You can specify a BY statement with PROC NLIN to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLIN procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

**CONTROL Statement**

```
CONTROL  variable <=values> < . . . variable <=values>> ;
```

The CONTROL statement declares control variables and specifies their values. A control variable is like a retained variable (see the section “RETAIN Statement” on page 3016) except that it is retained across iterations and the derivative of the model with respect to a control variable is always zero.

**DER Statements**

```
DER.  parameter=expression ;
DER.  parameter.parameter=expression ;
```

The DER statement specifies first or second partial derivatives. By default, analytical derivatives are automatically computed. However, you can specify the derivatives yourself by using the DER.parm syntax. Use the first form shown to specify first partial derivatives, and use the second form to specify second partial derivatives. Note that the DER.parm syntax is retained for backward compatibility. The automatic analytical derivatives are, in general, a better choice. For additional information on automatic analytical derivatives, see the section “Automatic Derivatives” beginning on page 3017.
For most of the computational methods, you need only specify the first partial derivative for each parameter to be estimated. For the NEWTON method, specify both the first and the second derivatives. If any needed derivatives are not specified, they are automatically computed.

If you use the _LOSS_ variable, you can specify the derivative of _LOSS_ with respect to the parameters using the DER. syntax. For more information, see the “Special Variable Used to Determine Convergence Criteria” section on page 3021.

The expression can be an algebraic representation of the partial derivative of the expression in the MODEL statement with respect to the parameter or parameters that appear in the left-hand side of the DER statement. Numerical derivatives can also be used. The expression in the DER statement must conform to the rules for a valid SAS expression, and it can include any quantities that the MODEL statement expression contains.

### ID Statement

```
ID variables ;
```

The ID statement specifies additional variables to place in the output data set created by the OUTPUT statement. Any variable on the left-hand side of any assignment statement is eligible. Also, the special variables created by the procedure can be specified. Variables in the input data set do not need to be specified in the ID statement since they are automatically included in the output data set.

### MODEL Statement

```
MODEL dependent=expression ;
```

The MODEL statement defines the prediction equation by declaring the dependent variable and defining an expression that evaluates predicted values. The expression can be any valid SAS expression yielding a numeric result. The expression can include parameter names, variables in the data set, and variables created by program statements in the NLIN procedure. Any operators or functions that can be used in a DATA step can also be used in the MODEL statement.

A statement such as

```
   model y=expression;
```

is translated into the form

```
   model.y=expression;
```

using the compound variable name `model.y` to hold the predicted value. You can use this assignment as an alternative to the MODEL statement. Either a MODEL statement or an assignment to a compound variable such as `model.y` must appear.
OUTPUT Statement

OUTPUT OUT= SAS-data-set keyword=names <, . . . , keyword=names >;

The OUTPUT statement specifies an output data set to contain statistics calculated for each observation. For each statistic, specify the keyword, an equal sign, and a variable name for the statistic in the output data set. All of the names appearing in the OUTPUT statement must be valid SAS names, and none of the new variable names can match a variable already existing in the data set to which PROC NLIN is applied.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, all the values of all the variables named in the OUTPUT statement are missing values.

You can specify the following options in the OUTPUT statement. For a description of computational formulas, see Chapter 2, “Introduction to Regression Procedures.”

OUT=SAS-data-set

specifies the SAS data set to be created by PROC NLIN when an OUTPUT statement is included. The new data set includes all the variables in the data set to which PROC NLIN is applied. Also included are any ID variables specified in the ID statement, plus new variables with names that are specified in the OUTPUT statement.

The following values can be calculated and output to the new data set.

H=name

specifies a variable to contain the leverage, $x_i(X'X)^{-1}x_i '$, where $X = \partial F / \partial \beta$ and $x_i$ is the $i$th row of $X$. If you specify the special variable _WEIGHT_, the leverage is $w_i x_i(X'WX)^{-1} x_i '$.

L95M=name

specifies a variable to contain the lower bound of an approximate 95% confidence interval for the expected value (mean). See also the description for the U95M= option, which follows.

L95=name

specifies a variable to contain the lower bound of an approximate 95% confidence interval for an individual prediction. This includes the variance of the error as well as the variance of the parameter estimates. See also the description for the U95= option, which follows.

PARMS=names

specifies variables in the output data set to contain parameter estimates. These can be the same variable names as listed in the PARAMETERS statement; however, you can choose new names for the parameters identified in the sequence from the parameter estimates table. A note log indicates which variable in the output data set is associated with each parameter name. Note that, for each of these new variables, the values are the same for every observation in the new data set.
**PARAMETERS Statement**

PARAMETERS parameter=values . . . ;

PARMS parameter=values . . . ;

A PARAMETERS (or PARMS) statement must come before the RUN statement. Several parameter names and values can appear. The parameter names must all be valid SAS names and must not duplicate the names of any variables in the data set to which the NLIN procedure is applied. Any parameters specified but not used in the MODEL statement are dropped from the estimation.
In each `parameter=values` specification, the parameter name identifies a parameter to be estimated, both in subsequent procedure statements and in the output. `Values` specify the possible starting values of the parameter.

Usually, only one value is specified for each parameter. If you specify several values for each parameter, PROC NLIN evaluates the model at each point on the grid. The value specifications can take any of several forms:

- `m` a single value
- `m1, m2, ..., mn` several values
- `m TO n` a sequence where `m` equals the starting value, `n` equals the ending value, and the increment equals 1
- `m TO n BY i` a sequence where `m` equals the starting value, `n` equals the ending value, and the increment is `i`
- `m1, m2 TO m3` mixed values and sequences

This PARMS statement specifies five parameters and sets their possible starting values as shown:

```plaintext
parms b0=0
   b1=4 to 8
   b2=0 to .6 by .2
   b3=1, 10, 100
   b4=0, .5, 1 to 4;
```

<table>
<thead>
<tr>
<th>Possible starting values</th>
</tr>
</thead>
<tbody>
<tr>
<td>B0 B1 B2 B3 B4</td>
</tr>
<tr>
<td>0  4  0.0  1  0.0</td>
</tr>
<tr>
<td>5  0.2 10  0.5</td>
</tr>
<tr>
<td>6  0.4 100  1.0</td>
</tr>
<tr>
<td>7  0.6 2.0</td>
</tr>
<tr>
<td>8  3.0</td>
</tr>
<tr>
<td>4.0</td>
</tr>
</tbody>
</table>

Residual sums of squares are calculated for each of the $1 \times 5 \times 4 \times 3 \times 6 = 360$ combinations of possible starting values. (This can take a long time.) See the “Special Variables” section beginning on page 3020 for information on programming parameter starting values.
Chapter 50. The NLIN Procedure

RETAIN Statement

```
RETAIN variable <=values> < . . . variable <=values>>;
```

The RETAIN statement declares retained variables and specifies their values. A retained variable is like a control variable (see the section “CONTROL Statement” on page 3011) except that it is retained only within iterations. An iteration involves a single pass through the data set.

Other Program Statements with PROC NLIN

PROC NLIN supports many statements that are similar to SAS programming statements used in a DATA step. However, there are some differences in capabilities; for additional information, see the section “Incompatibilities with 6.11 and Earlier Versions of PROC NLIN” beginning on page 3031.

Several SAS program statements can be used after the PROC NLIN statement. These statements can appear anywhere in the PROC NLIN statement, but new variables must be created before they appear in other statements. For example, the following statements are valid since they create the variable `temp` before they use it in the MODEL statement:

```
proc nlin;
  parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
  temp=exp(-b1*x);
  model y=b0*(1-temp);
```

The following statements result in missing values for `y` because the variable `temp` is undefined before it is used:

```
proc nlin;
  parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
  model y=b0*(1-temp);
  temp=exp(-b1*x);
```

PROC NLIN can process assignment statements, explicitly or implicitly subscripted ARRAY statements, explicitly or implicitly subscripted array references, IF statements, SAS functions, and program control statements. You can use program statements to create new SAS variables for the duration of the procedure. These variables are not permanently included in the data set to which PROC NLIN is applied. Program statements can include variables in the DATA= data set, parameter names, variables created by preceding program statements within PROC NLIN, and special variables used by PROC NLIN. All of the following SAS program statements can be used in PROC NLIN:

- ARRAY
- assignment (`y = a*x + b;`)
- CALL
• DO
• iterative DO
• DO UNTIL
• DO WHILE
• END
• FILE
• GO TO
• IF-THEN/ELSE
• LINK-RETURN
• PUT (defaults to the list)
• RETURN
• SELECT
• sum (y + 1;)

These statements can use the special variables created by PROC NLIN. Consult the section “Special Variables” beginning on page 3020 for more information on special variables.

Details

Automatic Derivatives

Depending on the optimization method you select, analytical first- and second-order derivatives are computed automatically. Derivatives can still be supplied using the DER.parm syntax. These DER.parm derivatives are not verified by the differentiator. If any needed derivatives are not supplied, they are computed and added to the program statements. To view the computed derivatives, use the LISTDER or LIST option.

The following model is solved using Newton’s method. Analytical first- and second-order derivatives are automatically computed.

```proc nlin data=Enzyme method=newton list;
  parms x1=4 x2=2 ;
  model Velocity = x1 * exp (x2 * Concentration);
run;```
### Figure 50.5. Model and Derivative Code Output

Note that all the derivatives require the evaluation of \( \exp(x2 \times \text{Concentration}) \). If you specify the LISTCODE option in the PROC NLIN statement, the actual machine level code produced is as follows.

### Figure 50.6. LISTCODE Output
Note that, in the generated code, only one exponentiation is performed. The generated code reuses previous operations to be more efficient.

### Hougaard’s Measure of Skewness

A “close-to-linear” nonlinear regression model, first described by Ratkowsky (1990), is a model that produces parameters having properties similar to those produced by a linear regression model. That is, the least squares estimates of the parameters are close to being unbiased, normally distributed, minimum variance estimators.

A nonlinear regression model sometimes fails to be close to linear due to the properties of a single parameter. When this occurs, bias in the parameters can render inferences using the reported standard errors and confidence limits invalid. You can often fix the problem with reparameterization, replacing the offending parameter by one with better estimation properties.

You can use Hougaard’s measure of skewness, $g_{i1}$, to assess whether a parameter is close to linear or whether it contains considerable nonlinearity. Specify the HOUGAARD option in the PROC NLIN statement to compute Hougaard’s measure of skewness.

According to Ratkowsky (1990), if $|g_{i1}| < 0.1$, the estimator $\hat{\theta}_i$ of parameter $\theta_i$ is very close-to-linear in behavior and, if $0.1 < |g_{i1}| < .25$, the estimator is reasonably close-to-linear. If $|g_{i1}| > .25$, the skewness is very apparent. For $|g_{i1}| > 1$, the nonlinear behavior is considerable.

Hougaard’s measure is computed as follows

$$E[\hat{\theta}_i - E(\hat{\theta}_i)]^3 = -(mse)^2 \sum_{jkl}^{np} L_{ij} L_{ik} L_{il} (W_{jkl} + W_{kjl} + W_{ljk})$$

where the sum is a triple sum over the number of parameters and

$$L = (X'X)^{-1}$$

$$W_{jkl} = \sum_{m=1}^{n} J_m^j H_m^{kl}$$

In the preceding equation, $J_m$ is the Jacobian vector and $H_m$ is the Hessian matrix evaluated at observation $m$. This third moment is normalized using the standard error as

$$g_{i1} = E[\hat{\theta}_i - E(\hat{\theta}_i)]^3 / (mse \ast L_{ii})^{3/2}$$
Missing Values

If the value of any one of the SAS variables involved in the model is missing from an observation, that observation is omitted from the analysis. If only the value of the dependent variable is missing, that observation has a predicted value calculated for it when you use an OUTPUT statement and specify the PREDICTED= option.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, all the values of all the variables named in the OUTPUT statement are missing values.

Special Variables

Several special variables are created automatically and can be used in PROC NLIN program statements.

Special Variables with Values that are Set by PROC NLIN

The values of the following six special variables are set by PROC NLIN and should not be reset to a different value by programming statements:

- **_ERROR_**
  is set to 1 if a numerical error or invalid argument to a function occurs during the current execution of the program. It is reset to 0 before each new execution.

- **_ITER_**
  represents the current iteration number. The variable _ITER_ is set to −1 during the grid search phase.

- **_MODEL_**
  is set to 1 for passes through the data when only the predicted values are needed, not the derivatives. It is 0 when both predicted values and derivatives are needed. If your derivative calculations consume a lot of time, you can save resources by coding

  ```
  if _model_ then return;
  ```

  after your MODEL statement but before your derivative calculations. The derivatives generated by PROC NLIN do this automatically.

- **_N_**
  indicates the number of times the PROC NLIN step has been executed. It is never reset for successive passes through the data set.

- **_OBS_**
  indicates the observation number in the data set for the current program execution. It is reset to 1 to start each pass through the data set (unlike the _N_ variable).

- **_SSE_**
  has the error sum of squares of the last iteration. During the grid search phase, the _SSE_ variable is set to 0. For iteration 0, the _SSE_ variable is set to the SSE associated with the point chosen from the grid search.
**Special Variable Used to Determine Convergence Criteria**

The special variable `_LOSS_` can be used to determine convergence criteria:

- `_LOSS_` is used to determine the criterion function for convergence and step shortening. PROC NLIN looks for the variable `_LOSS_` in the program statements and, if it is defined, uses the (weighted) sum of this value instead of the residual sum of squares to determine the criterion function for convergence and step shortening. This feature is useful in certain types of maximum-likelihood estimation where the residual sum of squares is not the basic criterion.

**Weighted Regression with the Special Variable `_WEIGHT_`**

To get weighted least squares estimates of parameters, the `_WEIGHT_` variable can be given a value in an assignment statement:

```
_weight_ = expression;
```

When this statement is included, the expression on the right-hand side of the assignment statement is evaluated for each observation in the data set to be analyzed. The values obtained are taken as inverse elements of the diagonal variance-covariance matrix of the dependent variable.

When a variable name is given after the equal sign, the values of the variable are taken as the inverse elements of the variance-covariance matrix. The larger the `_WEIGHT_` value, the more importance the observation is given.

The `_WEIGHT_` variable can be a function of the estimated parameters. For estimation purposes the derivative of the `_WEIGHT_` variable with-respect-to the parameters is not included in the gradient and the Hessian of the loss function. This is normally the desired approach for iteratively reweighted least squares estimation. With the `_WEIGHT_` variable a function of parameters, the gradient and the Hessian used may lead to poor convergence or non-convergence of the requested estimation. To have the derivative of the `_WEIGHT_` variable with-respect-to the parameters included in the gradient and the Hessian of the loss function, do not use the `_WEIGHT_` variable. Instead, redefine the model as

\[(y - f(x, \beta))/\sqrt{wgt(\beta)}\]

where \(y\) is the original dependent variable, \(f(x, \beta)\) is the nonlinear model, and \(wgt(\beta)\) is the weight that is a function of the parameters.

If the `_WEIGHT_` = statement is not used, the default value of 1 is used, and regular least squares estimates are obtained.
Troubleshooting

This section describes a number of problems that can occur in your analysis with PROC NLIN.

Excessive Time

If you specify a grid of starting values that contains many points, the analysis may take excessive time since the procedure must go through the entire data set for each point on the grid.

The analysis may also take excessive time if your problem takes many iterations to converge since each iteration requires as much time as a linear regression with predicted values and residuals calculated.

Dependencies

The matrix of partial derivatives may be singular, possibly indicating an over-parameterized model. For example, if \( b_0 \) starts at zero in the following model, the derivatives for \( b_1 \) are all zero for the first iteration.

```plaintext
parms b0=0 b1=.022;
model pop=b0*exp(b1*(year-1790));
der.b0=exp(b1*(year-1790));
der.b1=(year-1790)*b0*exp(b1*(year-1790));
```

The first iteration changes a subset of the parameters; then the procedure can make progress in succeeding iterations. This singularity problem is local. The next example displays a global problem.

You may have a term \( b_2 \) in the exponent that is nonidentifiable since it trades roles with \( b_0 \).

```plaintext
parms b0=3.9 b1=.022 b2=0;
model pop=b0*exp(b1*(year-1790)+b2);
der.b0=exp(b1*(year-1790)+b2);
der.b1=(year-1790)*b0*exp(b1*(year-1790)+b2);
der.b2=b0*exp(b1*(year-1790)+b2);
```

Unable to Improve

The method may lead to steps that do not improve the estimates even after a series of step halvings. If this happens, the procedure issues a message stating that it is unable to make further progress, but it then displays the warning message

```
PROC NLIN failed to converge
```

and displays the results. This often means that the procedure has not converged at all. If you provided the derivatives, check them very closely and then check the sum-of-squares error surface before proceeding. If PROC NLIN has not converged, try a different set of starting values, a different METHOD= specification, the G4 option, or a different model.
Divergence

The iterative process may diverge, resulting in overflows in computations. It is also possible that parameters enter a space where arguments to such functions as LOG and SQRT become illegal. For example, consider the following model:

```
parms b=0;
model y=x / b;
```

Suppose that \( y \) happens to be all zero and \( x \) is nonzero. There is no least squares estimate for \( b \) since the SSE declines as \( b \) approaches infinity or minus infinity. The same model could be parameterized with no problem into \( y = a*x \).

If you have divergence problems, try reparameterizing, selecting different starting values, increasing the maximum allowed number of iterations (the MAXITER= option), specifying an alternative METHOD= option, or including a BOUNDS statement.

Local Minimum

The program may converge to a local rather than a global minimum. For example, consider the following model.

```
parms a=1 b=-1;
model y=(1-a*x)*(1-b*x);
```

Once a solution is found, an equivalent solution with the same SSE can be obtained by swapping the values of \( a \) and \( b \).

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not true, the method does not work. For example, the following models do not work:

```
model y=a+int(b*x);
model y=a+b*x+4*(z>c);
```

Responding to Trouble

PROC NLIN does not necessarily produce a good solution the first time. Much depends on specifying good initial values for the parameters. You can specify a grid of values in the PARMS statement to search for good starting values. While most practical models should give you no trouble, other models may require switching to a different iteration method or an inverse computation method. Specifying the option METHOD=MARQUARDT sometimes works when the default method (Gauss-Newton) does not work.
Computational Methods

For the system of equations represented by the nonlinear model

\[ Y = F(\beta_0, \beta_1, \ldots, \beta_r, Z_1, Z_2, \ldots, Z_n) + \epsilon = F(\beta^*) + \epsilon \]

where \( Z \) is a matrix of the independent variables, \( \beta^* \) is a vector of the parameters, \( \epsilon \) is the error vector, and \( F \) is a function of the independent variables and the parameters, there are two approaches to solving for the minimum. The first method is to minimize

\[ L(\beta) = 0.5(e'e) \]

where \( e = Y - F(\beta) \) and \( \beta \) is an estimate of \( \beta^* \).

The second method is to solve the nonlinear “normal” equations

\[ X'F(\beta) = X'Y \]

where

\[ X = \frac{\partial F}{\partial \beta} \]

In the nonlinear situation, both \( X \) and \( F(\beta) \) are functions of \( \beta \) and a closed-form solution generally does not exist. Thus, PROC NLIN uses an iterative process: a starting value for \( \beta \) is chosen and continually improved until the error sum of squares \( e'e \) is minimized.

The iterative techniques that PROC NLIN uses are similar to a series of linear regressions involving the matrix \( X \) evaluated for the current values of \( \beta \) and \( e = Y - F(\beta) \), the residuals evaluated for the current values of \( \beta \).

The iterative process begins at some point \( \beta_0 \). Then \( X \) and \( Y \) are used to compute a \( \Delta \) such that

\[ SSE(\beta_0 + k\Delta) < SSE(\beta_0) \]

The four methods differ in how \( \Delta \) is computed to change the vector of parameters.

Steepest descent: \( \Delta = X'e \)
Gauss-Newton: \( \Delta = (X'X)^{-1}X'e \)
Newton: \( \Delta = (G^{-})X'e \)
Marquardt: \( \Delta = (X'X + \lambda \text{diag}(X'X))^{-1}X'e \)
The default method used to compute \((X'X)^{-}\) is the sweep operator producing a reflexive generalized \((g_2)\) inverse. In some cases it would be preferable to use a Moore-Penrose \((g_4)\) inverse. If the G4 option is specified in the PROC NLIN statement, a \(g_4\) inverse is used to calculate \(\Delta\) on each iteration.

The Gauss-Newton and Marquardt iterative methods regress the residuals onto the partial derivatives of the model with respect to the parameters until the estimates converge. The Newton iterative method regresses the residuals onto a function of the first and second derivatives of the model with respect to the parameters until the estimates converge. Analytical first- and second-order derivatives are automatically computed.

**Steepest Descent (Gradient)**

The steepest descent method is based on the gradient of \(\epsilon'\epsilon\):

\[
\frac{1}{2} \frac{\partial L(\beta)}{\partial \beta} = -XY + XF(\beta) = -X'e
\]

The quantity \(-X'e\) is the gradient along which \(\epsilon'\epsilon\) increases. Thus \(\Delta = X'e\) is the direction of steepest descent.

If the automatic variables _WEIGHT_ and _RESID_ are used, then

\[
\Delta = X'W^{SSE}r
\]

is the direction, where

\(W^{SSE}\) is an \(n \times n\) diagonal matrix with elements \(w_{i}^{SSE}\) of weights from the _WEIGHT_ variable. Each element \(w_{i}^{SSE}\) contains the value of _WEIGHT_ for the \(i\)th observation.

\(r\) is a vector with elements \(r_{i}\) from _RESID_. Each element \(r_{i}\) contains the value of _RESID_ evaluated for the \(i\)th observation.

Using the method of steepest descent, let

\[
\beta_{k+1} = \beta_{k} + \alpha \Delta
\]

where the scalar \(\alpha\) is chosen such that

\[
SSE(\beta_{i} + \alpha \Delta) < SSE(\beta_{i})
\]

Note: The steepest descent method may converge very slowly and is therefore not generally recommended. It is sometimes useful when the initial values are poor.
Newton

The Newton method uses the second derivatives and solves the equation

\[ \Delta = G^{-1}X'e \]

where

\[ G = (X'X) + \sum_{i=1}^{n} H_i(\beta)e_i \]

and \( H_i(\beta) \) is the Hessian of \( e \):

\[ [H_i]_{jk} = \left[ \frac{\partial^2 e_i}{\partial \beta_j \partial \beta_k} \right]_{jk} \]

If the automatic variables _WEIGHT_, _WGTJPJ_, and _RESID_ are used, then

\[ \Delta = G^{-1}X'W^\text{SSE}r \]

is the direction, where

\[ G = X'W^{XPX}X + \sum_{i=1}^{n} H_i(\beta)w_i^{XPX}r_i \]

and

\( W^\text{SSE} \) is an \( n \times n \) diagonal matrix with elements \( w_i^{SSE} \) of weights from the _WEIGHT_ variable. Each element \( w_i^{SSE} \) contains the value of _WEIGHT_ for the \( i \)th observation.

\( W^{XPX} \) is an \( n \times n \) diagonal matrix with elements \( w_i^{XPX} \) of weights from the _WGTJPJ_ variable.

Each element \( w_i^{XPX} \) contains the value of _WGTJPJ_ for the \( i \)th observation.

\( r \) is a vector with elements \( r_i \) from the _RESID_ variable. Each element \( r_i \) contains the value of _RESID_ evaluated for the \( i \)th observation.
Gauss-Newton

The Gauss-Newton method uses the Taylor series

\[ F(\beta) = F(\beta_0) + X(\beta - \beta_0) + \cdots \]

where \( X = \partial F / \partial \beta \) is evaluated at \( \beta = \beta_0 \).

Substituting the first two terms of this series into the normal equations

\[
\begin{align*}
X'F(\beta) &= X'Y \\
X'(F(\beta_0) + X(\beta - \beta_0)) &= X'Y \\
(X'X)(\beta - \beta_0) &= X'Y - X'F(\beta_0) \\
(X'X)\Delta &= X'e
\end{align*}
\]

and therefore

\[ \Delta = (X'X)^{-1}X'e \]

Caution: If \( X'X \) is singular or becomes singular, PROC NLIN computes \( \Delta \) using a generalized inverse for the iterations after singularity occurs. If \( X'X \) is still singular for the last iteration, the solution should be examined.

Marquardt

The Marquardt updating formula is as follows:

\[ \Delta = (X'X + \lambda\text{diag}(X'X))^{-1}X'e \]

The Marquardt method is a compromise between the Gauss-Newton and steepest descent methods (Marquardt 1963). As \( \lambda \to 0 \), the direction approaches Gauss-Newton. As \( \lambda \to \infty \), the direction approaches steepest descent.

Marquardt’s studies indicate that the average angle between Gauss-Newton and steepest descent directions is about 90°. A choice of \( \lambda \) between 0 and infinity produces a compromise direction.

By default, PROC NLIN chooses \( \lambda = 10^{-7} \) to start and computes a \( \Delta \). If \( \text{SSE}(\beta_0 + \Delta) < \text{SSE}(\beta_0) \), then \( \lambda = \lambda/10 \) for the next iteration. Each time \( \text{SSE}(\beta_0 + \Delta) > \text{SSE}(\beta_0) \), then \( \lambda = 10\lambda \).

Note: If the SSE decreases on each iteration, then \( \lambda \to 0 \), and you are essentially using the Gauss-Newton method. If SSE does not improve, then \( \lambda \) is increased until you are moving in the steepest descent direction.

Marquardt’s method is equivalent to performing a series of ridge regressions and is useful when the parameter estimates are highly correlated or the objective function is not well approximated by a quadratic.
Step-Size Search

The default method of finding the step size \( k \) is step halving using SMETHOD=HALVE. If \( \text{SSE}(\beta_0 + \Delta) > \text{SSE}(\beta_0) \), compute \( \text{SSE}(\beta_0 + 0.5\Delta) \), \( \text{SSE}(\beta_0 + 0.25\Delta) \), \ldots, until a smaller \( \text{SSE} \) is found.

If you specify SMETHOD=GOLDEN, the step size \( k \) is determined by a golden section search. The parameter TAU determines the length of the initial interval to be searched, with the interval having length TAU or \( 2 \times \text{TAU} \), depending on \( \text{SSE}(\beta_0 + \Delta) \). The RHO parameter specifies how fine the search is to be. The \( \text{SSE} \) at each endpoint of the interval is evaluated, and a new subinterval is chosen. The size of the interval is reduced until its length is less than RHO. One pass through the data is required each time the interval is reduced. Hence, if RHO is very small relative to TAU, a large amount of time can be spent determining a step size. For more information on the GOLDEN search, refer to Kennedy and Gentle (1980).

If you specify SMETHOD=CUBIC, the NLIN procedure performs a cubic interpolation to estimate the step size. If the estimated step size does not result in a decrease in \( \text{SSE} \), step halving is used.

Output Data Sets

The data set produced by the OUTEST= option in the PROC NLIN statement contains the parameter estimates on each iteration including the grid search.

The variable _ITER_ contains the iteration number. The variable _TYPE_ denotes whether the observation contains iteration parameter estimates ('ITER'), final parameter estimates ('FINAL'), or covariance estimates ('COVB'). The variable _NAME_ contains the parameter name for covariances, and the variable _SSE_ contains the objective function value for the parameter estimates. The variable _STATUS_ indicates whether the estimates have converged.

The data set produced by the OUTPUT statement contains statistics calculated for each observation. In addition, the data set contains all the variables in the input data set and any ID variables that are specified in the ID statement.

Confidence Intervals

Parameter Confidence Intervals

The parameter confidence intervals are computed using the Wald based formula:

\[
\hat{\beta}_i \pm \text{stderr}_i \times t(N - P, 0.05/2)
\]

where \( \text{stderr}_i \) is the standard error of the \( i^{th} \) parameter \( \hat{\beta}_i \) and \( t(N - P, 0.05/2) \) is a \( t \) statistic with \( N - P \) degrees of freedom, \( N \) is the number of observations, and \( P \) is the number of parameters. The confidence intervals are only asymptotically valid.
**Model Confidence Intervals**

Model confidence intervals are output when an OUT= data set is specified and one or more of the options L95M=, L95=, U95M=, or U95= is specified. The values of these terms are

\[
H = w_i x_i (X' W X)^{-1} x_i'
\]

\[
L95M = f(\beta, z_i) - \sqrt{MSE \times H / w_i} \times t(N - P, 0.975/2)
\]

\[
U95M = f(\beta, z_i) + \sqrt{MSE \times H / w_i} \times t(N - P, 0.975/2)
\]

\[
L95 = f(\beta, z_i) - \sqrt{MSE(H + 1/w_i)} \times t(N - P, 0.975/2)
\]

\[
U95 = f(\beta, z_i) + \sqrt{MSE(H + 1/w_i)} \times t(N - P, 0.975/2)
\]

where \(X = \partial f / \partial \beta\) and \(x_i\) is the \(i\)th row of \(X\). These results are derived for linear systems. The intervals are approximate for nonlinear models.

**Parameter Covariance Matrix**

For unconstrained estimates (no active bounds), the parameter covariance matrix is

\[
(X' X)^{-1} \times mse
\]

for the gradient, Marquardt, and Gauss methods and

\[
H^{-1} \times mse
\]

for Newton method. The \(mse\) is computed as

\[
r' r / (nused - np)
\]

where \(nused\) is the number of non-missing observations and \(np\) is the number of estimable parameters. The standard error reported for the parameters is the sqrt of the corresponding diagonal element of this matrix.

Equality restrictions can be written as a vector function

\[
h(\theta) = 0
\]

Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction.

For the following, assume the vector \(h(\theta)\) contains all the current active restrictions. The constraint matrix \(A\) is

\[
A(\hat{\theta}) = \frac{\partial h(\hat{\theta})}{\partial \theta}
\]
The covariance matrix for the restricted parameter estimates is computed as

\[ Z (Z' H Z)^{-1} Z' \]

where \( H \) is Hessian or approximation to the Hessian, and \( Z \) is the last \( (np - nc) \) columns of \( Q \). \( Q \) is from an LQ factorization of the constraint matrix, \( nc \) is the number of active constraints, and \( np \) is the number of parameters. Refer to Gill, Murray, and Wright (1981) for more details on LQ factorization.

The covariance matrix for the Lagrange multipliers is computed as

\[ (AH^{-1} A')^{-1} \]

### Reported Convergence Measures

NLIN computes and reports four convergence measures labeled R, PPC, RPC, and OBJECT.

**R**

is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. R is defined as

\[ \sqrt{\frac{r' X (X'X)^{-1} X' r}{\text{LOSS}^2}} \]

**PPC**

is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the \( k \)th iteration, PPC is the maximum over the parameters

\[ \frac{|\theta_i^{k+1} - \theta_i^k|}{|\theta_i^k + 1E - 6|} \]

where \( \theta_i^k \) is the current value of the \( i \)th parameter and \( \theta_i^{k+1} \) is the prospective value of this parameter after adding the change vector computed for the next iteration. These changes are measured before steplength adjustments are made. The parameter with the maximum prospective relative change is displayed with the value of PPC, unless the PPC is nearly 0.

**RPC**

is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the \( k \)th iteration, RPC is the maximum over \( i \) of

\[ \frac{|\theta_i^k - \theta_i^{k-1}|}{|\theta_i^{k-1} + 1E - 6|} \]
where $\theta_k^i$ is the current value of the $i$th parameter and $\theta_k^{i-1}$ is the previous value of this parameter. These changes are measured before steplength adjustments are made. The name of the parameter with the maximum retrospective relative change is displayed with the value of RPC, unless the RPC is nearly 0.

**OBJECT** measures the relative change in the objective function value between iterations:

\[
\frac{|O^k - O^{k-1}|}{|O^{k-1} + 1E - 6|}
\]

where $O^{k-1}$ is the value of the objective function ($O^k$) from the previous iteration. This is the old CONVERGEOBJ= criterion.

### Displayed Output

In addition to the output data sets, PROC NLIN also produces the following items:

- the estimates of the parameters and the residual Sums of Squares determined in each iteration
- a list of the residual Sums of Squares associated with all or some of the combinations of possible starting values of parameters
- an analysis-of-variance table including as sources of variation Regression, Residual, Uncorrected Total, Corrected Total, and $F$ test

If the convergence criterion is met, PROC NLIN produces

- Estimation Summary Table
- Parameter Estimates
- an asymptotically valid standard error of the estimate, Asymptotic Standard Error.
- an Asymptotic 95% Confidence Interval for the estimate of the parameter
- an Asymptotic Correlation Matrix of the parameters

### Incompatibilities with 6.11 and Earlier Versions of PROC NLIN

The NLIN procedure now uses a compiler that is different from the DATA step compiler. The compiler was changed so that analytical derivatives could be computed automatically. For the most part, the syntax accepted by the old NLIN procedure can be used in the new NLIN procedure. However, there are several differences that should be noted.
You cannot specify a character index variable in the DO statement, and you cannot specify a character test in the IF statement. Thus DO I=1,2,3; is supported, but DO I='ONE','TWO','THREE'; is not supported. And IF 'THIS' < 'THAT' THEN ...; is supported, but "IF 'THIS' THEN ...;" is not supported.

The PUT statement, which is used mostly for program debugging in PROC NLIN, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.

- The PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the `_INFILE_` option, the `:` format modifier, or the symbol `$`.
- The PUT statement does support expressions inside of parentheses. For example, PUT (SQRT(X)); produces the square root of X.
- The PUT statement also supports the option `_PDV_` to display a formatted listing of all the variables in the program. The statement PUT `_PDV_`; prints a much more readable listing of the variables than PUT `_ALL_`; does.

You cannot use the `'*'` subscript, but you can specify an array name in a PUT statement without subscripts. Thus, ARRAY A ...; PUT A; is acceptable, but PUT A[*] ; is not. The statement PUT A; displays all the elements of the array A. The PUT A=; statement displays all the elements of A with each value labeled by the name of the element variable.

You cannot specify any arguments in the ABORT statement.

You can specify more than one target statement in the WHEN and OTHERWISE statements. That is, DO/END groups are not necessary for multiple WHEN statements, for example, SELECT; WHEN(exp1); stmt1; stmt2; WHEN(exp2); stmt3; stmt4; END;.

You can specify only the options LOG, PRINT, and LIST in the FILE statement.

The RETAIN statement retains only values across one pass through the data set. If you need to retain values across iterations, use the CONTROL statement to make a control variable.

The ARRAY statement in PROC NLIN is similar to, but not the same as, the ARRAY statement in the SAS DATA step. The ARRAY statement is used to associate a name (of no more than 8 characters) with a list of variables and constants. The array name can then be used with subscripts in the program to refer to the items in the list.

The ARRAY statement supported by PROC NLIN does not support all the features of the DATA step ARRAY statement. You cannot specify implicit indexing variables; all array references must have explicit subscript expressions. You can specify simple array dimensions; lower bound specifications are not supported. A maximum of six dimensions are accepted.

On the other hand, the ARRAY statement supported by PROC NLIN does accept both variables and constants as array elements. (Constant array elements cannot be changed with assignment statements.)
Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified, or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

If the array is used as a pure array in the program rather than a list of symbols (the individual symbols of the array are not referenced in the code), the array is converted to a numerical array. A pure array is literally a vector of numbers that are accessed only by index. Using these types of arrays results in faster derivatives and compiled code.

PROC NLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

**Convergence Status Table**

The ConvergenceStatus table can be used to programmatically check on the status of an estimation. The ConvergenceStatus table contains the variable STATUS that takes on one of the values, 0, 1, or 3. If STATUS equals 0, then the convergence criterion were met. If STATUS equals 1, then the convergence criterion were met but notes were added to the log that may indicate a problem with the model. If STATUS equals 3, then the convergence criterion were not met.

The following sample program demonstrates how the ConvergenceStatus table can be used.

```plaintext
/* Save the ConvergenceStatus table to the dataset "status" */
ods output ConvergenceStatus=status;
proc nlin data=a ;
    parameters a=1 b=1 c=1;
    model wgt=a+x/(b*y+c*z);
run;

data _NULL_; set status;
    if status > 0 then put "A problem Occurred";
run;
```

**Examples**

**Example 50.1. Segmented Model**

From theoretical considerations, you can hypothesize that

\[
y = a + b x + c x^2 \quad \text{if } x < x_0 \\
y = p \quad \text{if } x \geq x_0
\]

That is, for values of \( x \) less than \( x_0 \), the equation relating \( y \) and \( x \) is quadratic (a parabola); and, for values of \( x \) greater than \( x_0 \), the equation is constant (a horizontal line). PROC NLIN can fit such a segmented model even when the joint point, \( x_0 \), is unknown.

The curve must be continuous (the two sections must meet at \( x_0 \)), and the curve must be smooth (the first derivatives with respect to \( x \) are the same at \( x_0 \)).

These conditions imply that
The segmented equation includes only three parameters; however, the equation is nonlinear with respect to these parameters.

You can write program statements with PROC NLIN to conditionally execute different sections of code for the two parts of the model, depending on whether $x$ is less than $x_0$.

A PUT statement is used to print the constrained parameters every time the program is executed for the first observation (where $x = 1$). The following statements perform the analysis.

```plaintext

Output 50.1.1 indicates that the join point is 12.75 and the plateau value is 0.78. As displayed in the following plot of the predicted values (YP) and the actual values, the selected join point and plateau value is reasonable. The predicted values for the estimation are written to the data set b with the OUTPUT statement.
Example 50.2. Iteratively Reweighted Least Squares

The NLIN procedure is suited to methods that make the weight a function of the parameters in each iteration since the \_WEIGHT\_ variable can be computed with program statements.

The NOHALVE option is used because the SSE definition is modified at each iteration and the step-shortening criteria is thus circumvented.

Iteratively reweighted least squares (IRLS) can produce estimates for many of the robust regression criteria suggested in the literature. These methods act like automatic outlier rejectors since large residual values lead to very small weights. Holland and Welsch (1977) outline several of these robust methods. For example, the biweight criterion suggested by Beaton and Tukey (1974) tries to minimize

\[ S_{\text{biweight}} = \Sigma \rho(r) \]

where

\[ \rho(r) = \frac{B^2}{2} \left( 1 - \left( \frac{r}{B} \right)^2 \right)^2 \quad \text{if } |r| \leq B \]

or

\[ \rho(r) = \frac{B^2}{2} \quad \text{otherwise} \]
where $r$ is $|\text{residual}|/\sigma$, $\sigma$ is a measure of scale of the error, and $B$ is a tuning constant.

The weighting function for the biweight is

$$w_i = (1 - (r_i/B)^2)^2 \quad \text{if } |r_i| \leq B$$

or

$$w_i = 0 \quad \text{if } |r_i| > B$$

The biweight estimator depends on both a measure of scale (like the standard deviation) and a tuning constant; results vary if these values are changed.

The data are the population of the United States (in millions), recorded at ten-year intervals starting in 1790 and ending in 1990.

Output 50.2.2 displays the computed weights. The observations for 1940 and 1950 are highly discounted because of their large residuals.

Example 50.3. Probit Model with Likelihood function

The data, taken from Lee (1974), consist of patient characteristics and a variable indicating whether cancer remission occurred. This example demonstrates how to use PROC NLIN with a likelihood function. In this case, the likelihood function to minimize is
Example 50.3. Probit Model with Likelihood function

\[ -2 \log L = -2 \sum_{i=1}^{N} wght_i \log(\hat{p}_i(y_i, x_i)) \]

where

\[ \hat{p}_i(y_i, x_i) = \begin{cases} \Phi(\alpha + \beta'x_i) & y_i = 0 \\ 1 - \Phi(\alpha + \beta'x_i) & y_i = 1 \end{cases} \]

and \( \Phi \) is the normal probability function. This is the likelihood function for a binary probit model. This likelihood is strictly positive so that you can take a square root of \( \log(\hat{p}_i(y_i, x_i)) \) and use this as your residual in PROC NLIN. The DATA step also creates a zero-valued dummy variable, like, that is used as the dependent variable.

```

1 1 .6 .6 1.7 .964 .99
1 1 .69 .69 .9 .398 .986
0 1 .73 .73 .7 .398 .986
; run;
```
proc nlin data=remiss method=newton sigsq=1;
  parms a -2 b -1 c 6 int -10;
  /* Linear portion of model ------*/
  eql = a*cell + b*li + c*temp +int;
  /* probit */
  p = probnorm(eql);
  if ( remiss = 1 ) then p = 1-p;
  model.like = sqrt(- 2 * log( p));
  output out=p p=predict;
run;

Note that the asymptotic standard errors of the parameters are computed under
the least squares assumptions. The SIGSQ=1 option on the PROC NLIN state-
ment forces PROC NLIN to replace the usual mean square error with 1. Also,
METHOD=NEWTON is selected so the true Hessian of the likelihood function is
used to calculate parameter standard errors rather than the crossproducts approxima-
tion to the Hessian.

Chapter 51
The NLMIXED Procedure
Overview

Introduction

The NLMIXED procedure fits nonlinear mixed models, that is, models in which both fixed and random effects enter nonlinearly. These models have a wide variety of applications, two of the most common being pharmacokinetics and overdispersed binomial data. PROC NLMIXED enables you to specify a conditional distribution for your data (given the random effects) having either a standard form (normal, binomial, Poisson) or a general distribution that you code using SAS programming statements.

PROC NLMIXED fits nonlinear mixed models by maximizing an approximation to the likelihood integrated over the random effects. Different integral approximations are available, the principal ones being adaptive Gaussian quadrature and a first-order Taylor series approximation. A variety of alternative optimization techniques are available to carry out the maximization; the default is a dual quasi-Newton algorithm.

Successful convergence of the optimization problem results in parameter estimates along with their approximate standard errors based on the second derivative matrix of the likelihood function. PROC NLMIXED enables you to use the estimated model to construct predictions of arbitrary functions using empirical Bayes estimates of the random effects. You can also estimate arbitrary functions of the nonrandom parameters, and PROC NLMIXED computes their approximate standard errors using the delta method.

Literature on Nonlinear Mixed Models

Davidian and Giltinan (1995) and Vonesh and Chinchilli (1997) provide good overviews as well as general theoretical developments and examples of nonlinear mixed models. Pinheiro and Bates (1995) is a primary reference for the theory and computational techniques of PROC NLMIXED. They describe and compare several different integrated likelihood approximations and provide evidence that adaptive Gaussian quadrature is one of the best methods. Davidian and Gallant (1993) also use Gaussian quadrature for nonlinear mixed models, although the smooth nonparametric density they advocate for the random effects is currently not available in PROC NLMIXED.

Traditional approaches to fitting nonlinear mixed models involve Taylor series expansions, expanding around either zero or the empirical best linear unbiased predictions of the random effects. The former is the basis for the well-known first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985), and it is optionally available in PROC NLMIXED. The latter is the basis for the estimation method of Lindstrom and Bates (1990), and it is not available in PROC NLMIXED. However, the closely related Laplacian approximation is an option; it is equivalent to adaptive

A parallel literature exists in the area of generalized linear mixed models, in which random effects appear as a part of the linear predictor inside of a link function. Taylor-series methods similar to those just described are discussed in articles such as Harville and Mee (1984), Stiratelli, Laird, and Ware (1984), Gilmour, Anderson, and Rae (1985), Goldstein (1991), Schall (1991), Engel and Keen (1992), Breslow and Clayton (1993), Wolfinger and O’Connell (1993), and McGilchrist (1994), but such methods have not been implemented in PROC NLMIXED because they can produce biased results in certain binary data situations (Rodriguez and Goldman 1995, Lin and Breslow 1996). Instead, a numerical quadrature approach is available in PROC NLMIXED, as discussed in Pierce and Sands (1975), Anderson and Aitkin (1985), Crouch and Spiegelman (1990), Hedeker and Gibbons (1994), Longford (1994), McCulloch (1994), Liu and Pierce (1994), and Diggle, Liang, and Zeger (1994).

Nonlinear mixed models have important applications in pharmacokinetics, and Roe (1997) provides a wide-ranging comparison of many popular techniques. Yuh et al. (1994) provide an extensive bibliography on nonlinear mixed models and their use in pharmacokinetics.

**PROC NLMIXED Compared with Other SAS Procedures and Macros**

The models fit by PROC NLMIXED can be viewed as generalizations of the random coefficient models fit by the MIXED procedure. This generalization allows the random coefficients to enter the model nonlinearly, whereas in PROC MIXED they enter linearly. With PROC MIXED you can perform both maximum likelihood and restricted maximum likelihood (REML) estimation, whereas PROC NLMIXED only implements maximum likelihood. This is because the analog to the REML method in PROC NLMIXED would involve a high dimensional integral over all of the fixed-effects parameters, and this integral is typically not available in closed form. Finally, PROC MIXED assumes the data to be normally distributed, whereas PROC NLMIXED enables you to analyze data that are normal, binomial, or Poisson or that have any likelihood programmable with SAS statements.

PROC NLMIXED does not implement the same estimation techniques available with the NLINMIX and GLIMMIX macros. These macros are based on the estimation methods of Lindstrom and Bates (1990), Breslow and Clayton (1993), and Wolfinger and O’Connell (1993), and they iteratively fit a set of generalized estimating equations (refer to Chapters 11 and 12 of Littell et al. 1996 and to Wolfinger 1997). In contrast, PROC NLMIXED directly maximizes an approximate integrated likelihood.

This remark also applies to the SAS/IML macros MIXNLIN (Vonesh and Chinchilli 1997) and NLMEM (Galecki 1998).
PROC NLMIXED has close ties with the NLP procedure in SAS/OR software. PROC NLMIXED uses a subset of the optimization code underlying PROC NLP and has many of the same optimization-based options. Also, the programming statement functionality used by PROC NLMIXED is the same as that used by PROC NLP and the MODEL procedure in SAS/ETS software.

Getting Started

Nonlinear Growth Curves with Gaussian Data

As an introductory example, consider the orange tree data of Draper and Smith (1981). These data consist of seven measurements of the trunk circumference (in millimeters) on each of five orange trees. You can input these data into a SAS data set as follows:

```sas
data tree;
  input tree day y;
datalines;
1  118  30
1  484  58
1  664  87
1 1004 115
1 1231 120
1 1372 142
1 1582 145
2  118  33
2  484  69
2  664 111
2 1004 156
2 1231 172
2 1372 203
2 1582 203
3  118  30
3  484  51
3  664  75
3 1004 108
3 1231 115
3 1372 139
3 1582 140
4  118  32
4  484  62
4  664 112
4 1004 167
4 1231 179
4 1372 209
4 1582 214
```
Lindstrom and Bates (1990) and Pinheiro and Bates (1995) propose the following logistic nonlinear mixed model for these data:

\[
y_{ij} = \frac{b_1 + u_{i1}}{1 + \exp[-(d_{ij} - b_2)/b_3]} + e_{ij}
\]

Here, \(y_{ij}\) represents the \(j\)th measurement on the \(i\)th tree \((i = 1, \ldots, 5; j = 1, \ldots, 7)\), \(d_{ij}\) is the corresponding day, \(b_1, b_2, b_3\) are the fixed-effects parameters, \(u_{i1}\) are the random-effect parameters assumed to be iid \(N(0, \sigma_u^2)\), and \(e_{ij}\) are the residual errors assumed to be iid \(N(0, \sigma_e^2)\) and independent of the \(u_{i1}\). This model has a logistic form, and the random-effect parameters \(u_{i1}\) enter the model linearly.

The statements to fit this nonlinear mixed model are as follows:

```sas
proc nlmixed data=tree;
  parms b1=190 b2=700 b3=350 s2u=1000 s2e=60;
  num = b1+u1;
  ex = exp(-(day-b2)/b3);
  den = 1 + ex;
  model y ~ normal(num/den,s2e);
  random u1 ~ normal(0,s2u) subject=tree;
run;
```

The PROC NLMIXED statement invokes the procedure and inputs the TREE data set. The PARMS statement identifies the unknown parameters and their starting values. Here there are three fixed-effects parameters (\(B1, B2, B3\)) and two variance components (\(S2U, S2E\)).

The next three statements are SAS programming statements specifying the logistic mixed model. A new variable U1 is included to identify the random effect. These statements are evaluated for every observation in the data set when PROC NLMIXED computes the log likelihood function and its derivatives.

The MODEL statement defines the dependent variable and its conditional distribution given the random effects. Here a normal (Gaussian) conditional distribution is specified with mean NUM/DEN and variance S2E.

The RANDOM statement defines the single random effect to be U1, and specifies that it follows a normal distribution with mean 0 and variance S2U. The SUBJECT= argument defines a variable indicating when the random effect obtains new realizations; in this case, it changes according to the values of the TREE variable. PROC NLMIXED assumes that the input data set is clustered according to the levels of the
TREE variable; that is, all observations from the same tree occur sequentially in the input data set.

The output from this analysis is as follows.

<table>
<thead>
<tr>

</tbody>
</table>

NOTE: GCONV convergence criterion satisfied.

The “Iterations” table records the history of the minimization of the negative log likelihood. For each iteration of the quasi-Newton optimization, values are listed for the number of function calls, the value of the negative log likelihood, the difference from the previous iteration, the absolute value of the largest gradient, and the slope of the search direction. The note at the bottom of the table indicates that the algorithm has converged successfully according to the GCONV convergence criterion, a standard criterion computed using a quadratic form in the gradient and inverse Hessian.

The “Fitting Information” table lists the final maximized value of the log likelihood as well as the information criteria of Akaike and Schwarz in two different forms. These statistics can be used to compare different nonlinear mixed models.
The NLMIXED Procedure

Parameter Estimates

| Parameter | Estimate | Standard Error | DF | t Value | Pr > |t| | Alpha | Lower |

The “Parameter Estimates” table lists the maximum likelihood estimates of the five parameters and their approximate standard errors computed using the final Hessian matrix. Approximate t-values and Wald-type confidence limits are also provided, with degrees of freedom equal to the number of subjects minus the number of random effects. You should interpret these statistics cautiously for variance parameters like S2U and S2E. The final column in the output is the gradient vector at the optimization solution. Each element appears to be sufficiently small to indicate a stationary point.

Since the random-effect parameters $u_{i1}$ enter the model linearly, you can obtain equivalent results by using the first-order method (specify METHOD=FIRO in the PROC NLMIXED statement).

Logistic-Normal Model with Binomial Data

This example analyzes the data from Beitler and Landis (1985), which represent results from a multi-center clinical trial investigating the effectiveness of two topical cream treatments (active drug, control) in curing an infection. For each of eight clinics, the number of trials and favorable cures are recorded for each treatment. The SAS data set is as follows.

```sas
data infection;
  input clinic t x n;
datalines;
1 1 11 36
1 0 10 37
2 1 16 20
2 0 22 32
3 1 14 19
3 0 7 19
4 1 2 16
```

Logistic-Normal Model with Binomial Data ♦ 3053
Suppose $n_{ij}$ denotes the number of trials for the $i$th clinic and the $j$th treatment ($i = 1, \ldots, 8$ $j = 0, 1$), and $x_{ij}$ denotes the corresponding number of favorable cures. Then a reasonable model for the preceding data is the following logistic model with random effects:

$$x_{ij} | u_i \sim \text{Binomial}(n_{ij}, p_{ij})$$

and

$$\eta_{ij} = \log \left( \frac{p_{ij}}{1 - p_{ij}} \right) = \beta_0 + \beta_1 t_j + u_i$$

The notation $t_j$ indicates the $j$th treatment, and the $u_i$ are assumed to be iid $N(0, \sigma_u^2)$.

The PROC NLMIXED statements to fit this model are as follows:

```sas
proc nlmixed data=infection;
   parms beta0=-1 beta1=1 s2u=2;
   eta = beta0 + beta1*t + u;
   expeta = exp(eta);
   p = expeta/(1+expeta);
   model x ~ binomial(n,p);
   random u ~ normal(0,s2u) subject=clinic;
   predict eta out=eta;
   estimate '1/beta1' 1/beta1;
run;
```

The PROC NLMIXED statement invokes the procedure, and the PARMS statement defines the parameters and their starting values. The next three statements define $p_{ij}$, and the MODEL statement defines the conditional distribution of $x_{ij}$ to be binomial. The RANDOM statement defines $U$ to be the random effect with subjects defined by the CLINIC variable.

The PREDICT statement constructs predictions for each observation in the input data set. For this example, predictions of $\eta_{ij}$ and approximate standard errors of prediction are output to a SAS data set named ETA. These predictions include empirical Bayes estimates of the random effects $u_i$.

The ESTIMATE statement requests an estimate of the reciprocal of $\beta_1$.

The output for this model is as follows.
The “Specifications” table provides basic information about the nonlinear mixed model.

The “Dimensions” table provides counts of various variables. You should check this table to make sure the data set and model have been entered properly. PROC NLMIXED selects five quadrature points to achieve the default accuracy in the likelihood calculations.

The “Parameters” table lists the starting point of the optimization.

</tbody>
</table>

The “Parameter Estimates” table indicates marginal significance of the two fixed-effects parameters. The positive value of the estimate of $\beta_1$ indicates that the treatment significantly increases the chance of a favorable cure.
The “Additional Estimates” table displays results from the ESTIMATE statement. The estimate of $1/\beta_1$ equals $1/0.7385 = 1.3541$ and its standard error equals $0.3004/0.7385^2 = 0.5509$ by the delta method (Billingsley 1986, Cox 1998). Note this particular approximation produces a $t$-statistic identical to that for the estimate of $\beta_1$.

Not shown is the ETA data set, which contains the original 16 observations and predictions of the $\eta_{ij}$.

Syntax

The following statements can be used with the NLMIXED procedure:

```plaintext
PROC NLMIXED options ;
    ARRAY array specification ;
    BOUNDS boundary constraints ;
    BY variables ;
    CONTRAST 'label' expression <,expression> ;
    ESTIMATE 'label' expression ;
    ID names ;
    MODEL model specification ;
    PARMS parameters and starting values ;
    PREDICT expression ;
    RANDOM random effects specification ;
    REPLICATE variable ;
    Program statements ;
```

The following sections provide a detailed description of each of these statements.
**PROC NLMIXED Statement**

```
PROC NLMIXED options;
```

This statement invokes the NLMIXED procedure. A large number of options are available in the PROC NLMIXED statement, and the following table categorizes them according to function.

These options are described in alphabetical order. For a description of the mathematical notation used in the following sections, see the section “Modeling Assumptions and Notation.”

ABSConv= \( r \)

ABSTol= \( r \)

specifies an absolute function convergence criterion. For minimization, termination requires \( f(\theta^{(k)}) \leq r \). The default value of \( r \) is the negative square root of the largest double precision value, which serves only as a protection against overflows.

ABSFConv= \( r < [n] > \)

ABSFtol= \( r < [n] > \)

specifies an absolute function convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

\[ |f(\theta^{(k-1)}) - f(\theta^{(k)})| \leq r \]

The same formula is used for the NMSIMP technique, but \( \theta^{(k)} \) is defined as the vertex with the lowest function value, and \( \theta^{(k-1)} \) is defined as the vertex with the highest function value in the simplex. The default value is \( r = 0 \). The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSGConv= \( r < [n] > \)

ABSGtol= \( r < [n] > \)

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

\[ \max_j |g_j(\theta^{(k)})| \leq r \]

This criterion is not used by the NMSIMP technique. The default value is \( r = 1E-5 \). The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSXConv= \( r < [n] > \)

ABSXtol= \( r < [n] > \)

specifies an absolute parameter convergence criterion. For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

\[ \| \theta^{(k)} - \theta^{(k-1)} \|_2 \leq r \]
For the NMSIMP technique, termination requires either a small length \( \alpha^{(k)} \) of the vertices of a restart simplex,
\[
\alpha^{(k)} \leq r
\]
or a small simplex size,
\[
\delta^{(k)} \leq r
\]
where the simplex size \( \delta^{(k)} \) is defined as the L1 distance from the simplex vertex \( \xi^{(k)} \) with the smallest function value to the other \( n \) simplex points \( \theta_l^{(k)} \neq \xi^{(k)} \):
\[
\delta^{(k)} = \sum_{\theta_l \neq \xi} \| \theta_l^{(k)} - \xi^{(k)} \|_1
\]

The default is \( r = 1 \times 10^{-8} \) for the NMSIMP technique and \( r = 0 \) otherwise. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

**ALPHA=** \( \alpha \)
specifies the alpha level to be used in computing confidence limits. The default value is 0.05.

**ASINGULAR=** \( r \)
**ASING=** \( r \)
specifies an absolute singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is the square root of the smallest positive double precision value.

**CFACTOR=** \( f \)
specifies a multiplication factor \( f \) for the estimated covariance matrix of the parameter estimates.

**COV**
requests the approximate covariance matrix for the parameter estimates.

**CORR**
requests the approximate correlation matrix for the parameter estimates.

**COVSING=** \( r > 0 \)
specifies a nonnegative threshold that determines whether the eigenvalues of a singular Hessian matrix are considered to be zero.

**DAMPSTEP=** \( r \geq 0 \)
**DS=** \( r \geq 0 \)
specifies that the initial step-size value \( \alpha^{(0)} \) for each line search (used by the QUANEW, CONGRA, or NEWRAP technique) cannot be larger than \( r \) times the step-size value used in the former iteration. If you specify the DAMPSTEP option without factor \( r \), the default value is \( r = 2 \). The DAMPSTEP=\( r \) option can prevent the line-search algorithm from repeatedly stepping into regions where some objective functions are difficult to compute or where they could lead to floating point overflows during the computation of objective functions and their derivatives. The DAMPSTEP=\( r \) option can save time-costly function calls that result in very small
step sizes $\alpha$. For more details on setting the start values of each line search, see the section “Restricting the Step Length” beginning on page 3096.

**DATA**=`SAS-data-set`

specifies the input data set. Observations in this data set are used to compute the log likelihood function that you specify with PROC NLMIXED statements.

**NOTE:** If you are using a RANDOM statement, the input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you.

**DF**=`d`

specifies the degrees of freedom to be used in computing $p$ values and confidence limits. The default value is the number of subjects minus the number of random effects for random effects models, and the number of observations otherwise.

**DIAHES**

specifies that only the diagonal of the Hessian is used.

**EBOPT**

requests that a more comprehensive optimization be carried out if the default empirical Bayes optimization fails to converge.

**EBSSFRAC**=`r > 0`

specifies the step-shortening fraction to be used while computing empirical Bayes estimates of the random effects. The default value is 0.8.

**EBSSTOL**=`r ≥ 0`

specifies the objective function tolerance for determining the cessation of step-shortening while computing empirical Bayes estimates of the random effects. The default value is $r = 1E - 8$.

**EBSTEPS**=`n ≥ 0`

specifies the maximum number of Newton steps for computing empirical Bayes estimates of random effects. The default value is $n = 50$.

**EBSUBSTEPS**=`n ≥ 0`

specifies the maximum number of step-shortenings for computing empirical Bayes estimates of random effects. The default value is $n = 20$.

**EBTOL**=`r ≥ 0`

specifies the convergence tolerance for empirical Bayes estimation. The default value is $r = \epsilon E4$, where $\epsilon$ is the machine precision. This default value equals approximately $1E - 12$ on most machines.

**EBZSTART**

requests that a zero be used as starting values during empirical Bayes estimation. By default, the starting values are set equal to the estimates from the previous iteration (or zero for the first iteration).
ECOV requests the approximate covariance matrix for all expressions specified in ESTIMATE statements.

ECORR requests the approximate correlation matrix for all expressions specified in ESTIMATE statements.

EDER requests the derivatives of all expressions specified in ESTIMATE statements with respect to each of the model parameters.

FCONV=\( r < [n] > \)
FTOL=\( r < [n] > \)
specifies a relative function convergence criterion. For all techniques except NMSIMP, termination requires a small relative change of the function value in successive iterations,

\[
\frac{|f(\theta(k)) - f(\theta(k-1))|}{\max(|f(\theta(k-1))|, \text{FSIZE})} \leq r
\]

where FSIZE is defined by the FSIZE= option. The same formula is used for the NMSIMP technique, but \( \theta(k) \) is defined as the vertex with the lowest function value, and \( \theta(k-1) \) is defined as the vertex with the highest function value in the simplex. The default is \( r = 10^{-\text{FDIGITS}} \) where FDIGITS is the value of the FDIGITS= option. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

FCONV2=\( r < [n] > \)
FTOL2=\( r < [n] > \)
specifies another function convergence criterion. For all techniques except NMSIMP, termination requires a small predicted reduction of the objective function. The predicted reduction

\[
df(k) \approx f(\theta(k)) - f(\theta(k) + s(k))
\]

of the objective function. The predicted reduction

\[
df(k) = -g(k)^T s(k) - \frac{1}{2} s(k)^T H(k) s(k)
\]

\[
= -\frac{1}{2} s(k)^T g(k)
\]

\[
\leq r
\]

is computed by approximating the objective function \( f \) by the first two terms of the Taylor series and substituting the Newton step.

\[
s(k) = -[H(k)]^{-1} g(k)
\]

For the NMSIMP technique, termination requires a small standard deviation of the function values of the \( n + 1 \) simplex vertices \( \theta_l(k), l = 0, \ldots, n, \)

\[
\sqrt{\frac{1}{n+1} \sum_l \left[ f(\theta_l(k)) - \overline{f}(\theta(k)) \right]^2} \leq r
\]
where \( \bar{f}(\theta^{(k)}) = \frac{1}{n+1} \sum_l f(\theta^{(k)}_l) \). If there are \( n_{act} \) boundary constraints active at \( \theta^{(k)} \), the mean and standard deviation are computed only for the \( n + 1 - n_{act} \) unconstrained vertices. The default value is \( r = 1E - 6 \) for the NMSIMP technique and \( r = 0 \) otherwise. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

**FD**:\(<\) **FORWARD**: | **CENTRAL**: | \( r \) \( >\)**

designates that all derivatives be computed using finite difference approximations. The following specifications are permitted:

- **FD** is equivalent to \( FD=100 \).
- **FD=CENTRAL** uses central differences.
- **FD=FORWARD** uses forward differences.
- **FD=\( r \)** uses central differences for the initial and final evaluations of the gradient, and Hessian. During iteration, start with forward differences and switch to a corresponding central-difference formula during the iteration process when one of the following two criteria is satisfied:

  - The absolute maximum gradient element is less than or equal to \( r \) times the ABSGTOL threshold.
  - The normalized predicted function reduction (see the GTOL option on page 3065) is less than or equal to \( \max(1E - 6, r \times GTOL) \). The \( 1E - 6 \) ensures that the switch is done, even if you set the GTOL threshold to zero.

Note that the FD and FDHESSIAN options cannot apply at the same time. The FDHESSIAN option is ignored when only first-order derivatives are used. See the section “Finite Difference Approximations of Derivatives” beginning on page 3091 for more information.

**FDHESSIAN**:\( <\) **FORWARD**: | **CENTRAL**\( >\)**

**FDHES**:\( <\) **FORWARD**: | **CENTRAL**\( >\)**

**FDH**:\( <\) **FORWARD**: | **CENTRAL**\( >\)**

designates that second-order derivatives be computed using finite difference approximations based on evaluations of the gradients.

- **FDHESSIAN=FORWARD** uses forward differences.
- **FDHESSIAN=CENTRAL** uses central differences.
- **FDHESSIAN** uses forward differences for the Hessian except for the initial and final output.

Note that the FD and FDHESSIAN options cannot apply at the same time. See the section “Finite Difference Approximations of Derivatives” beginning on page 3091 for more information.
FDIGITS=r
specifies the number of accurate digits in evaluations of the objective function. Fractional values such as FDIGITS=4.7 are allowed. The default value is $r = -\log_{10} \epsilon$, where $\epsilon$ is the machine precision. The value of $r$ is used to compute the interval size $h$ for the computation of finite-difference approximations of the derivatives of the objective function and for the default value of the FCONV= option.

FLOW
displays a message for each statement in the model program as it is executed. This debugging option is very rarely needed and produces voluminous output.

FSIZE=r
specifies the FSIZE parameter of the relative function and relative gradient termination criteria. The default value is $r = 0$. For more details, see the FCONV= and GCONV= options.

G4=n > 0
specifies a dimension to determine the type of generalized inverse to use when the approximate covariance matrix of the parameter estimates is singular. The default value of $n$ is 60. See the section “Covariance Matrix” beginning on page 3101 for more information.

GCONV=r < [n] >
GTOLe=r < [n] >
specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction is small,

$$\frac{g(\theta^{(k)})^T [H^{(k)}]^{-1} g(\theta^{(k)})}{\max(|f(\theta^{(k)})|, FSIZE)} \leq r$$

where FSIZE is defined by the FSIZE= option. For the CONGRA technique (where a reliable Hessian estimate $H$ is not available), the following criterion is used:

$$\frac{\| g(\theta^{(k)}) \|_2}{\| g(\theta^{(k)}) - g(\theta^{(k-1)}) \|_2} \frac{\| s(\theta^{(k)}) \|_2}{\max(|f(\theta^{(k)})|, FSIZE)} \leq r$$

This criterion is not used by the NMSIMP technique. The default value is $r = 1E-8$. The optional integer value $n$ specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

HESCAL=0|1|2|3
HS=0|1|2|3
specifies the scaling version of the Hessian matrix used in NRRIDG, TRUREG, NEWRAP, or DBLDOG optimization. If HS is not equal to 0, the first iteration and each restart iteration sets the diagonal scaling matrix $D^{(0)} = \text{diag}(d_i^{(0)})$:

$$d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}$$

where $H_{i,i}^{(0)}$ are the diagonal elements of the Hessian. In every other iteration, the diagonal scaling matrix $D^{(0)} = \text{diag}(d_i^{(0)})$ is updated depending on the HS option:
HS=0 specifies that no scaling is done.

HS=1 specifies the Moré (1978) scaling update:

\[ d_i^{(k+1)} = \max \left[ d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right] \]

HS=2 specifies the Dennis, Gay, & Welsch (1981) scaling update:

\[ d_i^{(k+1)} = \max \left[ 0.6 * d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right] \]

HS=3 specifies that \( d_i \) is reset in each iteration:

\[ d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \]

In each scaling update, \( \epsilon \) is the relative machine precision. The default value is HS=0. Scaling of the Hessian can be time consuming in the case where general linear constraints are active.

**HESS**
requests the display of the final Hessian matrix after optimization. If you also specify the START option, then the Hessian at the starting values is also printed.

**INHESSIAN=**

**INHESS**
specifies how the initial estimate of the approximate Hessian is defined for the quasi-Newton techniques QUANEW and DBLDOG. There are two alternatives:

- If you do not use the \( r \) specification, the initial estimate of the approximate Hessian is set to the Hessian at \( \theta^{(0)} \).
- If you do use the \( r \) specification, the initial estimate of the approximate Hessian is set to the multiple of the identity matrix \( rI \).

By default, if you do not specify the option INHESSIAN=\( r \), the initial estimate of the approximate Hessian is set to the multiple of the identity matrix \( rI \), where the scalar \( r \) is computed from the magnitude of the initial gradient.

**INSTEP=**
reduces the length of the first trial step during the line search of the first iterations. For highly nonlinear objective functions, such as the EXP function, the default initial radius of the trust-region algorithm TRUREG or DBLDOG or the default step length of the line-search algorithms can result in arithmetic overflows. If this occurs, you should specify decreasing values of \( 0 < r < 1 \) such as INSTEP=1E-1, INSTEP=1E-2, INSTEP=1E-4, and so on, until the iteration starts successfully.

- For trust-region algorithms (TRUREG, DBLDOG), the INSTEP= option specifies a factor \( r > 0 \) for the initial radius \( \Delta^{(0)} \) of the trust region. The default initial trust-region radius is the length of the scaled gradient. This step corresponds to the default radius factor of \( r = 1 \).
- For line-search algorithms (NEWRAP, CONGRA, QUANEW), the INSTEP= option specifies an upper bound for the initial step length for the line search during the first five iterations. The default initial step length is $r = 1$.

- For the Nelder-Mead simplex algorithm, using TECH=NMSIMP, the INSTEP= option defines the size of the start simplex.

For more details, see the section “Computational Problems” beginning on page 3098.

**ITDETAILS**

requests a more complete iteration history, including the current values of the parameter estimates, their gradients, and additional optimization statistics. For further details, see the section “Iterations” beginning on page 3104.

**LCDEACT=**

**LCDE=**

specifies a threshold $r$ for the Lagrange multiplier that determines whether an active inequality constraint remains active or can be deactivated. During minimization, an active inequality constraint can be deactivated only if its Lagrange multiplier is less than the threshold value $r < 0$. The default value is

$$r = -\min(0.01, \max(0.1 \times \text{ABSGCONV}, 0.001 \times g_{\text{max}}(k)))$$

where ABSGCONV is the value of the absolute gradient criterion, and $g_{\text{max}}(k)$ is the maximum absolute element of the (projected) gradient $g^{(k)}$ or $Z^T g^{(k)}$. (See the section “Active Set Methods” beginning on page 3093 for a definition of $Z$.)

**LCEPSILON=**

**LCEPS=**

**LCE=**

specifies the range for active and violated boundary constraints. The default value is $r = 1E^{-8}$. During the optimization process, the introduction of rounding errors can force PROC NLMIXED to increase the value of $r$ by a factor of 10, 100, . . .. If this happens, it is indicated by a message displayed in the log.

**LCSINGULAR=**

**LCSING=**

**LCS=**

specifies a criterion $r$, used in the update of the QR decomposition, that determines whether an active constraint is linearly dependent on a set of other active constraints. The default value is $r = 1E^{-8}$. The larger $r$ becomes, the more the active constraints are recognized as being linearly dependent. If the value of $r$ is larger than 0.1, it is reset to 0.1.

**LINESEARCH=**

**LIS=**

specifies the line-search method for the CONGRA, QUANEW, and NEWRAP optimization techniques. Refer to Fletcher (1987) for an introduction to line-search techniques. The value of $i$ can be 1, . . . , 8. For CONGRA, QUANEW and NEWRAP, the default value is $i = 2$. 
LIS=1  specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is similar to one used by the Harwell subroutine library.

LIS=2  specifies a line-search method that needs more function than gradient calls for quadratic and cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.

LIS=3  specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.

LIS=4  specifies a line-search method that needs the same number of function and gradient calls for stepwise extrapolation and cubic interpolation.

LIS=5  specifies a line-search method that is a modified version of LIS=4.

LIS=6  specifies golden section line search (Polak 1971), which uses only function values for linear approximation.

LIS=7  specifies bisection line search (Polak 1971), which uses only function values for linear approximation.

LIS=8  specifies the Armijo line-search technique (Polak 1971), which uses only function values for linear approximation.

LIST  displays the model program and variable lists. The LIST option is a debugging feature and is not normally needed.

LISTCODE  displays the derivative tables and the compiled program code. The LISTCODE option is a debugging feature and is not normally needed.

LOGNOTE< =n >  writes periodic notes to the log describing the current status of computations. It is designed for use with analyses requiring extensive CPU resources. The optional integer value \( n \) specifies the desired level of reporting detail. The default is \( n = 1 \). Choosing \( n = 2 \) adds information about the objective function values at the end of each iteration. The most detail is obtained with \( n = 3 \), which also reports the results of function evaluations within iterations.

LSPRECISION=r  LSP=r  specifies the degree of accuracy that should be obtained by the line-search algorithms LIS=2 and LIS=3. Usually an imprecise line search is inexpensive and successful. For more difficult optimization problems, a more precise and expensive line search may be necessary (Fletcher 1987). The second line-search method (which is the
default for the NEWRAP, QUANEW, and CONGRA techniques) and the third line-
search method approach exact line search for small LSPRECISION= values. If you
have numerical problems, you should try to decrease the LSPRECISION= value to
obtain a more precise line search. The default values are shown in the following table.

<table>
<thead>
<tr>
<th>TECH=</th>
<th>UPDATE=</th>
<th>LSP default</th>
</tr>
</thead>
<tbody>
<tr>
<td>QUANEW</td>
<td>DBFGS, BFGS</td>
<td>$r = 0.4$</td>
</tr>
<tr>
<td>QUANEW</td>
<td>DDFP, DFP</td>
<td>$r = 0.06$</td>
</tr>
<tr>
<td>CONGRA</td>
<td>all</td>
<td>$r = 0.1$</td>
</tr>
<tr>
<td>NEWRAP</td>
<td>no update</td>
<td>$r = 0.9$</td>
</tr>
</tbody>
</table>

For more details, refer to Fletcher (1987).

**MAXFUNC=** $i$

specifies the maximum number $i$ of function calls in the optimization process. The
default values are

- TRUREG, NRRIDG, NEWRAP: 125
- QUANEW, DBLDOG: 500
- CONGRA: 1000
- NMSIMP: 3000

Note that the optimization can terminate only after completing a full iteration. Therefore, the number of function calls that is actually performed can exceed the
number that is specified by the MAXFUNC= option.

**MAXITER=** $i$

specifies the maximum number $i$ of iterations in the optimization process. The default
values are

- TRUREG, NRRIDG, NEWRAP: 50
- QUANEW, DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1000

These default values are also valid when $i$ is specified as a missing value.

**MAXSTEP=** $r < [n]$ >

specifies an upper bound for the step length of the line-search algorithms during the
first $n$ iterations. By default, $r$ is the largest double precision value and $n$ is the largest
integer available. Setting this option can improve the speed of convergence for the
CONGRA, QUANEW, and NEWRAP techniques.
**MAXTIME**=$r$

specifies an upper limit of $r$ seconds of CPU time for the optimization process. The default value is the largest floating point double representation of your computer. Note that the time specified by the MAXTIME= option is checked only once at the end of each iteration. Therefore, the actual running time can be much longer than that specified by the MAXTIME= option. The actual running time includes the rest of the time needed to finish the iteration and the time needed to generate the output of the results.

**METHOD**=$value$

specifies the method for approximating the integral of the likelihood over the random effects. Valid values are as follows.

- **FIRO**
  specifies the first-order method of Beal and Sheiner (1982). When using METHOD=FIRO, you must specify the NORMAL distribution in the MODEL statement and you must also specify a RANDOM statement.

- **GAUSS**
  specifies adaptive Gauss-Hermite quadrature (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. This is the default integration method.

- **HARDY**
  specifies Hardy quadrature based on an adaptive trapezoidal rule. This method is available only for one-dimensional integrals; that is, you must specify only one random effect.

- **ISAMP**
  specifies adaptive importance sampling (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. You can use the SEED= option to specify a starting seed for the random number generation used in the importance sampling. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock.

**MINITER**=$i$

**MINIT**=$i$

specifies the minimum number of iterations. The default value is 0. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations.

**MSINGULAR**=$r > 0$

**MSING**=$r > 0$

specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is $10^{-12}$ if you do not specify the SINGHESS= option; otherwise, the default value is $\max(10^{-1}, (10^{-4} \times \text{SINGHESS})$. See the section “Covariance Matrix” beginning on page 3101 for more information.
NOAD
requests that the Gaussian quadrature be nonadaptive; that is, the quadrature points are centered at zero for each of the random effects and the current random-effects variance matrix is used as the scale matrix.

NOADSCALE
requests nonadaptive scaling for adaptive Gaussian quadrature; that is, the quadrature points are centered at the empirical Bayes estimates for the random effects, but the current random-effects variance matrix is used as the scale matrix. By default, the observed Hessian from the current empirical Bayes estimates is used as the scale matrix.

OPTCHECK\(<r>0</tt>
computes the function values \(f(\theta_l)\) of a grid of points \(\theta_l\) in a ball of radius of \(r\) about \(\theta^\ast\). If you specify the OPTCHECK option without factor \(r\), the default value is \(r = 0.1\) at the starting point and \(r = 0.01\) at the terminating point. If a point \(\theta_l^\ast\) is found with a better function value than \(f(\theta^\ast)\), then optimization is restarted at \(\theta_l^\ast\).

OUTQ=SAS-data-set
specifies an output data set containing the quadrature points used for numerical integration.

QFAC\(=r>0\)
specifies the additive factor used to adaptively search for the number of quadrature points. For METHOD=GAUSS, the search sequence is 1, 3, 5, 7, 9, 11, 11 + \(r\), 11 + 2\(r\), ..., where the default value of \(r\) is 10. For METHOD=ISAMP, the search sequence is 10, 10 + \(r\), 10 + 2\(r\), ..., where the default value of \(r\) is 50.

QMAX\(=r>0\)
specifies the maximum number of quadrature points permitted before the adaptive search is aborted. The default values are 31 for adaptive Gaussian quadrature, 61 for non-adaptive Gaussian quadrature, 160 for adaptive importance sampling, and 310 for non-adaptive importance sampling.

QPOINTS\(=n>0\)
specifies the number of quadrature points to be used during evaluation of integrals. For METHOD=GAUSS, \(n\) equals the number of points used in each dimension of the random effects, resulting in a total of \(n^r\) points, where \(r\) is the number of dimensions. For METHOD=ISAMP, \(n\) specifies the total number of quadrature points regardless of the dimension of the random effects. By default, the number of quadrature points is selected adaptively, and this option disables the adaptive search.

QSCALEFAC\(=r>0\)
specifies a multiplier for the scale matrix used during quadrature calculations. The default value is 1.0.

QTOL\(=r>0\)
specifies the tolerance used to adaptively select the number of quadrature points. When the relative difference between two successive likelihood calculations is less than \(r\), then the search terminates and the lesser number of quadrature points is used during the subsequent optimization process. The default value is \(1E \, - \, 4\).
specifies that the QUANEW or CONGRA algorithm is restarted with a steepest descent/ascent search direction after, at most, \( i \) iterations. Default values are

- **CONGRA**: UPDATE=PB: restart is performed automatically, \( i \) is not used.
- **CONGRA**: UPDATE\( \neq \)PB: \( i = \min(10n, 80) \), where \( n \) is the number of parameters.
- **QUANEW**: \( i \) is the largest integer available.

**SEED=**

specifies the random number seed for METHOD=ISAMP. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. The value must be less than \( 2^{31} - 1 \).

**SINGCHOL=**

specifies the singularity criterion \( r \) for Cholesky roots of the random-effects variance matrix and scale matrix for adaptive Gaussian quadrature. The default value is \( 1 \times 10^4 \times \) the machine epsilon; this product is approximately \( 1 \times 10^{-12} \) on most computers.

**SINGHESS=**

specifies the singularity criterion \( r \) for the inversion of the Hessian matrix. The default value is \( 1 \times 10^{-8} \). See the ASINGULAR, MSINGULAR=, and VSINGULAR= options for more information.

**SINGSWEEP=**

specifies the singularity criterion \( r \) for inverting the variance matrix in the first-order method and the empirical Bayes Hessian matrix. The default value is \( 1 \times 10^4 \times \) the machine epsilon; this product is approximately \( 1 \times 10^{-12} \) on most computers.

**SINGVAR=**

specifies the singularity criterion \( r \) below which statistical variances are considered to equal zero. The default value is \( 1 \times 10^4 \times \) the machine epsilon; this product is approximately \( 1 \times 10^{-12} \) on most computers.

**START**

requests that the gradient of the log likelihood at the starting values be displayed. If you also specify the HESS option, then the starting Hessian is displayed as well.

**TECHNIQUE=value**

specifies the optimization technique. Valid values are

- **CONGRA**
  
  performs a conjugate-gradient optimization, which can be more precisely specified with the UPDATE= option and modified with the LINESEARCH= option. When you specify this option, UPDATE=PB by default.
• **DBLDOG**
  performs a version of double dogleg optimization, which can be more precisely specified with the UPDATE= option. When you specify this option, UPDATE=DBFGS by default.

• **NMSIMP**
  performs a Nelder-Mead simplex optimization.

• **NONE**
  does not perform any optimization. This option can be used
  - to perform a grid search without optimization
  - to compute estimates and predictions that cannot be obtained efficiently with any of the optimization techniques

• **NEWRAP**
  performs a Newton-Raphson optimization combining a line-search algorithm with ridging. The line-search algorithm LIS=2 is the default method.

• **NRRIDG**
  performs a Newton-Raphson optimization with ridging.

• **QUANEW**
  performs a quasi-Newton optimization, which can be defined more precisely with the UPDATE= option and modified with the LINESEARCH= option. This is the default estimation method.

• **TRUREG**
  performs a trust region optimization.

**TRACE**
  displays the result of each operation in each statement in the model program as it is executed. This debugging option is very rarely needed, and it produces voluminous output.

**UPDATE=**<i>method</i>
**UPD=**<i>method</i>
  specifies the update method for the quasi-Newton, double dogleg, or conjugate-gradient optimization technique. Not every update method can be used with each optimizer. See the section “Optimization Algorithms” beginning on page 3086 for more information.

Valid methods are

• **BFGS**
  performs the original Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the inverse Hessian matrix.

• **DBFGS**
  performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default update method.

• **DDFP**
  performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
DFP
performs the original DFP update of the inverse Hessian matrix.

PB
performs the automatic restart update method of Powell (1977) and Beale (1972).

FR
performs the Fletcher-Reeves update (Fletcher 1987).

PR
performs the Polak-Ribiere update (Fletcher 1987).

CD

VSINGULAR=r > 0
VSING=r > 0
specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is \( r = 1E^{-8} \) if the SINGHESS= option is not specified, and it is the value of SINGHESS= option otherwise. See the section “Covariance Matrix” beginning on page 3101 for more information.

XCONV=r < [n] > R
XTOL=r [n]
specifies the relative parameter convergence criterion. For all techniques except NMSIMP, termination requires a small relative parameter change in subsequent iterations.

\[
\max_j |\theta_j^{(k)} - \theta_j^{(k-1)}| \leq r
\]

For the NMSIMP technique, the same formula is used, but \( \theta_j^{(k)} \) is defined as the vertex with the lowest function value and \( \theta_j^{(k-1)} \) is defined as the vertex with the highest function value in the simplex. The default value is \( r = 1E^{-8} \) for the NMSIMP technique and \( r = 0 \) otherwise. The optional integer value \( n \) specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

XSIZE=r > 0
specifies the XSIZE parameter of the relative parameter termination criterion. The default value is \( r = 0 \). For more detail, see the XCONV= option.

ARRAY Statement

ARRAY arrayname [dimensions] [S] [variables and constants] ;

The ARRAY statement is similar to, but not the same as, the ARRAY statement in the SAS DATA step, and it is the same as the ARRAY statements in the NLIN, NLP, and MODEL procedures. The ARRAY statement is used to associate a name (of no more than eight characters) with a list of variables and constants. The array name
is used with subscripts in the program to refer to the array elements. The following statements illustrate this.

```plaintext
array r[8] r1-r8;

do i = 1 to 8;
   r[i] = 0;
end;
```

The ARRAY statement does not support all the features of the ARRAY statement in the DATA step. It cannot be used to assign initial values to array elements. Implicit indexing of variables cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement does allow both variables and constants to be used as array elements. (Constant array elements cannot have values assigned to them.) Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

**BOUNDS Statement**

**BOUNDS**

```plaintext
b_con [ , b_con... ];
```

where

- `b_con := number operator parameter_list operator number`
- `or b_con := number operator parameter_list`
- `or b_con := parameter_list operator number`
- `and operator := <=, <, >=, or >`

Boundary constraints are specified with a BOUNDS statement. One- or two-sided boundary constraints are allowed. The list of boundary constraints are separated by commas. For example,

```plaintext
bounds 0 <= a1-a9 x <= 1, -1 <= c2-c5;
bounds b1-b10 y >= 0;
```

You can specify more than one BOUNDS statement. If you specify more than one lower (upper) bound for the same parameter, the maximum (minimum) of these is taken.

If the maximum $l_j$ of all lower bounds is larger than the minimum of all upper bounds $u_j$ for the same variable $\theta_j$, the boundary constraint is replaced by $\theta_j := l_j := \min(u_j)$ defined by the minimum of all upper bounds specified for $\theta_j$. 
BY Statement

BY variables;

You can use a BY statement with PROC NLMIXED to obtain separate analyses on DATA= data set observations in groups defined by the BY variables. This means that, unless TECH=NONE, an optimization problem is solved for each BY group separately. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Use the SORT procedure with a similar BY statement to sort the data.
- Use the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLMIXED procedure. As a cautionary note, the NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Use the DATASETS procedure (in Base SAS software) to create an index on the BY variables.

For more information on the BY statement, refer to the discussion in SAS Language Reference: Concepts. For more information on the DATASETS procedure, refer to the discussion in the SAS Procedures Guide.

CONTRAST Statement

CONTRAST 'label' expression <, expression> <options>;

The CONTRAST statement enables you to conduct a statistical test that several expressions simultaneously equal zero. The expressions are typically contrasts, that is, differences whose expected values equal zero under the hypothesis of interest.

In the CONTRAST statement you must provide a quoted string to identify the contrast and then a list of valid SAS expressions separated by commas. Multiple CONTRAST statements are permitted, and results from all statements are listed in a common table. PROC NLMIXED constructs approximate $F$ tests for each statement using the delta method (Cox 1998) to approximate the variance-covariance matrix of the constituent expressions.

The following option is available in the CONTRAST statement.

**DF=d**

specifies the denominator degrees of freedom to be used in computing $p$ values for the $F$ statistics. The default value corresponds to the DF= option in the PROC NLMIXED statement.
**ESTIMATE Statement**

The ESTIMATE statement enables you to compute an additional estimate that is a function of the parameter values. You must provide a quoted string to identify the estimate and then a valid SAS expression. Multiple ESTIMATE statements are permitted, and results from all statements are listed in a common table. PROC NLMIXED computes approximate standard errors for the estimates using the delta method (Billingsley 1986). It uses these standard errors to compute corresponding $t$ statistics, $p$-values, and confidence limits.

The ECOV option in the PROC NLMIXED statement produces a table containing the approximate covariance matrix of all of the additional estimates you specify. The ECORR option produces the corresponding correlation matrix. The EDER option produces a table of the derivatives of the additional estimates with respect to each of the model parameters.

The following options are available in the ESTIMATE statement:

- **ALPHA=** $\alpha$
  - specifies the alpha level to be used in computing confidence limits. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

- **DF=** $d$
  - specifies the degrees of freedom to be used in computing $p$-values and confidence limits. The default value corresponds to the DF= option in the PROC NLMIXED statement.

**ID Statement**

The ID statement identifies additional quantities to be included in the OUT= data set of the PREDICT statement. These can be any symbols you have defined with SAS programming statements.

**MODEL Statement**

The MODEL statement is the mechanism for specifying the conditional distribution of the data given the random effects. You must specify a single dependent variable from the input data set, a tilde ($\sim$), and then a distribution with its parameters. Valid distributions are as follows.

- **normal($m,v$)** specifies a normal (Gaussian) distribution with mean $m$ and variance $v$.
- **binary($p$)** specifies a binary (Bernoulli) distribution with probability $p$.
- **binomial($n,p$)** specifies a binomial distribution with count $n$ and probability $p$.
- **gamma($a,b$)** specifies a gamma distribution with shape $a$ and scale $b$. 
• *negbin(n,p)* specifies a negative binomial distribution with count *n* and probability *p*.
• *poisson(m)* specifies a Poisson distribution with mean *m*.
• *general(ll)* specifies a general log likelihood function that you construct using SAS programming statements.

The MODEL statement must follow any SAS programming statements you specify for computing parameters of the preceding distributions.

**PARMS Statement**

```
PARMS <name-list [=numbers] [, name-list [=numbers] ... ]>
   </options> ;
```

The PARMS statement lists names of parameters and specifies initial values, possibly over a grid. You can specify the parameters and values either directly in a list or provide the name of a SAS data set that contains them using the DATA= option.

While the PARMS statement is not required, you are encouraged to use it to provide PROC NLMIXED with accurate starting values. Parameters not listed in the PARMS statement are assigned an initial value of 1. PROC NLMIXED considers all symbols not assigned values to be parameters, so you should specify your modeling statements carefully and check the output from the “Parameters” table to make sure the proper parameters are identified.

A list of parameter names in the PARMS statement is not separated by commas and is followed by an equal sign and a list of numbers. If the number list consists of only one number, this number defines the initial value for all the parameters listed to the left of the equal sign.

If the number list consists of more than one number, these numbers specify the grid locations for each of the parameters listed to the left of the equal sign. You can use the TO and BY keywords to specify a number list for a grid search. If you specify a grid of points in a PARMS statement, PROC NLMIXED computes the objective function value at each grid point and chooses the best (feasible) grid point as an initial point for the optimization process. You can use the BEST= option to save memory for the storing and sorting of all grid point information.

The following options are available in the PARMS statement after a slash (/):

- **BEST=i > 0**
  specifies the maximum number of points displayed in the “Parameters” table, selected as the points with the maximum likelihood values. By default, all grid values are displayed.

- **DATA=SAS-data-set**
  specifies a SAS data set containing parameter names and starting values. The data set should be in one of two forms: narrow or wide. The narrow-form data set contains the variables PARAMETER and ESTIMATE, with parameters and values listed as
distinct observations. The wide-form data set has the parameters themselves as variables, and each observation provides a different set of starting values. BY groups are ignored in this data set, so the same starting grid is evaluated for each BY group.

**PREDICT Statement**

```
PREDICT  expression OUT=SAS-data-set <options> ;
```

The PREDICT statement enables you to construct predictions of an expression across all of the observations in the input data set. Any valid SAS programming expression involving the input data set variables, parameters, and random effects is valid. Predicted values are computed using the parameter estimates and empirical Bayes estimates of the random effects. Standard errors of prediction are computed using the delta method (Billingsley 1986, Cox 1998). Results are placed in an output data set that you specify with the OUT= option. Besides all variables from the input data set, the OUT= data set contains the following variables: Pred, StdErrPred, DF, tValue, Probt, Alpha, Lower, Upper. You can also add other computed quantities to this data set with the ID statement.

The following options are available in the PREDICT statement:

- **ALPHA=α**
  specifies the alpha level to be used in computing t statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

- **DER**
  requests that derivatives of the predicted expression with respect to all parameters be included in the OUT= data set. The variable names for the derivatives are the same as the parameter names with the prefix “Der…” appended. All of the derivatives are evaluated at the final estimates of the parameters and the empirical Bayes estimates of the random effects.

- **DF=d**
  specifies the degrees of freedom to be used in computing t statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NLMIXED statement.

**RANDOM Statement**

```
RANDOM  random-effects ~ distribution SUBJECT=variable <options> ;
```

The RANDOM statement defines the random effects and their distribution. The random effects must be represented by symbols that appear in your SAS programming statements. They typically influence the mean value of the distribution specified in the MODEL statement. The RANDOM statement consists of a list of the random effects (usually just one or two symbols), a tilde (~), the distribution for the random effects, and then a SUBJECT= variable.

**NOTE:** The input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you; rather, it processes the data sequentially and considers an observation to be
The only distribution currently available for the random effects is normal($m,v$) with mean $m$ and variance $v$. This syntax is illustrated as follows for one effect:

```
random u ~ normal(0,s2u) subject=clinic;
```

For multiple effects, you should specify bracketed vectors for $m$ and $v$, the latter consisting of the lower triangle of the random-effects variance matrix listed in row order. This is illustrated for two and three random effects as follows.

```
random b1 b2 ~ normal([0,0],[g11,g21,g22]) subject=person;
random b1 b2 b3 ~ normal([0,0,0],[g11,g21,g22,g31,g32,g33]) subject=person;
```

The SUBJECT= variable determines when new realizations of the random effects are assumed to occur. PROC NLMIXED assumes that a new realization occurs whenever the SUBJECT= variable changes from the previous observation, so your input data set should be clustered according to this variable. One easy way to accomplish this is to run PROC SORT prior to calling PROC NLMIXED using the SUBJECT= variable as the BY variable.

Only one RANDOM statement is permitted, so multilevel nonlinear mixed models are not currently accommodated.

The following options are available in the RANDOM statement:

- \textbf{ALPHA=}$\alpha$
  specifies the alpha level to be used in computing $t$ statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

- \textbf{DF=}$d$
  specifies the degrees of freedom to be used in computing $t$ statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NLMIXED statement.

- \textbf{OUT=}$SAS$-data-set
  requests an output data set containing empirical Bayes estimates of the random effects and their approximate standard errors of prediction.

\textbf{REPLICATE Statement}

```
REPLICATE variable ;
```

The REPLICATE statement provides a way to accommodate models in which different subjects have identical data. This occurs most commonly when the dependent variable is binary. When you specify a REPLICATE variable, PROC NLMIXED assumes that its value indicates the number of subjects having data identical to those for the current value of the SUBJECT= variable (specified in the RANDOM statement). Only the last observation of the REPLICATE variable for each subject is used, and the replicate variable must have only positive integer values.
Programming Statements

This section lists the programming statements used to code the log likelihood function in PROC NLMIXED. It also documents the differences between programming statements in PROC NLMIXED and programming statements in the DATA step. The syntax of programming statements used in PROC NLMIXED is identical to that used in the CALIS and GENMOD procedures (see Chapter 19 and Chapter 31, respectively), and the MODEL procedure (refer to the SAS/ETS User’s Guide). Most of the programming statements that can be used in the SAS DATA step can also be used in the NLMIXED procedure. Refer to SAS Language Reference: Dictionary for a description of SAS programming statements. The following are valid statements:

- **ABORT**;
- **CALL** name [ ( expression [, expression ... ] ) ];
- **DELETE**;
- **DO** [ variable = expression
  [ TO expression ] [ BY expression ]
  [ , expression [ TO expression ] [ BY expression ] ... ]
  [ WHILE expression ] [ UNTIL expression ];
- **END**;
- **GOTO** statement_label;
- **IF** expression;
- **IF** expression THEN program_statement;
  - ELSE program_statement;
- **variable** = expression;
- **variable** + expression;
- **LINK** statement_label;
- **PUT** [ variable ] [= ] [ ... ];
- **RETURN**;
- **SELECT** [( expression )];
- **STOP**;
- **SUBSTR**( variable, index, length ) = expression;
- **WHEN** ( expression ) program_statement;
  - OTHERWISE program_statement;

For the most part, the SAS programming statements work the same as they do in the SAS DATA step, as documented in SAS Language Reference: Concepts; however, there are several differences.

- The ABORT statement does not allow any arguments.
- The DO statement does not allow a character index variable. Thus
  
  ```
  do i = 1,2,3;
  ```

  is supported; however, the following statement is not supported.
  
  ```
  do i = 'A', 'B', 'C';
  ```
- The LAG function does work appropriately with PROC NLMIXED, but you can use the ZLAG function instead.

- The PUT statement, used mostly for program debugging in PROC NLMIXED, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.
  
  - The PROC NLMIXED PUT statement does not support line pointers, factored lists, iteration factors, overprinting, _INFILE_, the colon (:) format modifier, or “$”.
  - The PROC NLMIXED PUT statement does support expressions, but the expression must be enclosed in parentheses. For example, the following statement displays the square root of x:
    ```
    put (sqrt(x));
    ```
  - The PROC NLMIXED PUT statement supports the item _PDV_ to display a formatted listing of all variables in the program. For example, the following statement displays a much more readable listing of the variables than the _ALL_ print item:
    ```
    put _pdv_;
    ```

- The WHEN and OTHERWISE statements enable you to specify more than one target statement. That is, DO/END groups are not necessary for multiple statement WHENs. For example, the following syntax is valid.

  ```
  select;
  when (exp1) stmt1;
    stmt2;
  when (exp2) stmt3;
    stmt4;
  end;
  ```

When coding your programming statements, you should avoid defining variables that begin with an underscore (_), as they may conflict with internal variables created by PROC NLMIXED. The MODEL statement must come after any SAS programming statements you specify for computing parameters of the modeling distribution.
Details

This section contains details about the underlying theory and computations of PROC NLMIXED.

Modeling Assumptions and Notation

PROC NLMIXED operates under the following general framework for nonlinear mixed models. Assume that you have an observed data vector \( y_i \) for each of \( i \) subjects, \( i = 1, \ldots, s \). The \( y_i \) are assumed to be independent across \( i \), but within-subject covariance is likely to exist because each of the elements of \( y_i \) are measured on the same subject. As a statistical mechanism for modeling this within-subject covariance, assume that there exist latent random-effect vectors \( u_i \) of small dimension (typically one or two) that are also independent across \( i \). Assume also that an appropriate model linking \( y_i \) and \( u_i \) exists, leading to the joint probability density function

\[
p(y_i | X_i, \phi, u_i)q(u_i | \xi)
\]

where \( X_i \) is a matrix of observed explanatory variables and \( \phi \) and \( \xi \) are vectors of unknown parameters.

Let \( \theta = (\phi, \xi) \) and assume that it is of dimension \( n \). Then inferences about \( \theta \) are based on the marginal likelihood function

\[
m(\theta) = \prod_{i=1}^{s} \int p(y_i | X_i, \phi, u_i)q(u_i | \xi)du_i
\]

In particular, the function

\[
f(\theta) = -\log m(\theta)
\]

is minimized over \( \theta \) numerically in order to estimate \( \theta \), and the inverse Hessian (second derivative) matrix at the estimates provides an approximate variance-covariance matrix for the estimate of \( \theta \). The function \( f(\theta) \) is referred to both as the negative log likelihood function and as the objective function for optimization.

As an example of the preceding general framework, consider the nonlinear growth curve example in the “Getting Started” section. Here, the conditional distribution \( p(y_i | X_i, \phi, u_i) \) is normal with mean

\[
b_1 + u_{i1}
\]

\[
1 + \exp[-(d_{ij} - b_2)/b_3]
\]

and variance \( \sigma^2_e \), thus \( \phi = (b_1, b_2, b_3, \sigma^2_e) \). Also, \( u_i \) is a scalar and \( q(u_i | \xi) \) is normal with mean 0 and variance \( \sigma^2_u \), thus \( \xi = \sigma^2_u \).

The following additional notation is also found in this chapter. The quantity \( \theta^{(k)} \) refers to the parameter vector at the \( k \)th iteration, the function \( g(\theta) \) refers to the gradient vector \( \nabla f(\theta) \), and the matrix \( H(\theta) \) refers to the Hessian \( \nabla^2 f(\theta) \). Other symbols are used to denote various constants or option values.
Integral Approximations

An important part of the marginal maximum likelihood method described previously is the computation of the integral over the random effects. The default method in PROC NLMIXED for computing this integral is adaptive Gaussian quadrature as described in Pinheiro and Bates (1995). Another approximation method is the first-order method of Beal and Sheiner (1982, 1988). A description of these two methods follows.

Adaptive Gaussian Quadrature

A quadrature method approximates a given integral by a weighted sum over predefined abscissas for the random effects. A good approximation can usually be obtained with an adequate number of quadrature points as well as appropriate centering and scaling of the abscissas. Adaptive Gaussian quadrature for the integral over $u_i$ centers the integral at the empirical Bayes estimate of $u_i$, defined as the vector $\hat{u}_i$ that minimizes

$$-\log \left[ p(y_i|X_i, \phi, u_i)q(u_i|\xi) \right]$$

with $\phi$ and $\xi$ set equal to their current estimates. The final Hessian matrix from this optimization can be used to scale the quadrature abscissas.

Suppose $(z_j, w_j; j = 1, \ldots, p)$ denote the standard Gauss-Hermite abscissas and weights (Golub and Welsch 1969, or Table 25.10 of Abramowitz and Stegun 1972). The adaptive Gaussian quadrature integral approximation is as follows.

$$\int p(y_i|X_i, \phi, u_i)q(u_i|\xi)du_i \approx 2^{r/2} |\Gamma(X_i, \theta)|^{-1/2} \sum_{j_1=1}^{p} \cdots \sum_{j_r=1}^{p} \left[ p(y_i|X_i, \phi, a_{j_1,\ldots,j_r})q(a_{j_1,\ldots,j_r}|\xi) \prod_{k=1}^{r} w_{j_k} \exp z_{j_k}^2 \right]$$

where $r$ is the dimension of $u_i$, $\Gamma(X_i, \theta)$ is the Hessian matrix from the empirical Bayes minimization, $z_{j_1,\ldots,j_r}$ is a vector with elements $(z_{j_1}, \ldots, z_{j_r})$, and

$$a_{j_1,\ldots,j_r} = \hat{u}_i + 2^{1/2} \Gamma(X_i, \theta)^{-1/2} z_{j_1,\ldots,j_r}$$

PROC NLMIXED selects the number of quadrature points adaptively by evaluating the log likelihood function at the starting values of the parameters until two successive evaluations have a relative difference less than the value of the QTOL= option. The specific search sequence is described under the QFAC= option. Using the QPOINTS= option, you can adjust the number of quadrature points $p$ to obtain different levels of accuracy. Setting $p = 1$ results in the Laplacian approximation as described in Beal and Sheiner (1992), Wolfinger (1993), Vonesh (1992, 1996), Vonesh and Chinchilli (1997), and Wolfinger and Lin (1997).

The NOAD option in the PROC NLMIXED statement requests nonadaptive Gaussian quadrature. Here all $\hat{u}_i$ are set equal to zero, and the Cholesky root of the estimated variance matrix of the random effects is substituted for $\Gamma(X_i, \theta)^{-1/2}$ in the preceding
expression for $a_{j_1,\ldots,j_r}$. In this case derivatives are computed using the algorithm of Smith (1995). The NOADSCALE option requests the same scaling substitution but with the empirical Bayes $\hat{u}_i$.

PROC NLMIXED computes the derivatives of the adaptive Gaussian quadrature approximation when carrying out the default dual quasi-Newton optimization.

**First-Order Method**

Another integral approximation available in PROC NLMIXED is the first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985). This approximation is used only in the case where $p(y_i | X_i, \phi, u_i)$ is normal, that is,

$$p(y_i | X_i, \phi, u_i) = (2\pi)^{-n_i/2} |R_i(X_i, \phi)|^{-1/2} \exp \left\{ -(1/2) [y_i - m_i(X_i, \phi, u_i)]^T R_i(X_i, \phi)^{-1} [y_i - m_i(X_i, \phi, u_i)] \right\}$$

where $n_i$ is the dimension of $y_i$, $R_i$ is a diagonal variance matrix, and $m_i$ is the conditional mean vector of $y_i$.

The first-order approximation is obtained by expanding $m(X_i, \phi, u_i)$ with a one-term Taylor series expansion about $u_i = 0$, resulting in the approximation

$$p(y_i | X_i, \phi, u_i) \approx (2\pi)^{-n_i/2} |R_i(X_i, \phi)|^{-1/2} \exp \left\{ -(1/2) [y_i - m_i(X_i, \phi, 0) - Z_i(X_i, \phi)u_i]^T R_i(X_i, \phi)^{-1} [y_i - m_i(X_i, \phi, 0) - Z_i(X_i, \phi)u_i] \right\}$$

where $Z_i(X_i, \phi)$ is the Jacobian matrix $\partial m_i(X_i, \phi, u_i) / \partial u_i$ evaluated at $u_i = 0$.

Assuming that $q(u_i | \xi)$ is normal with mean 0 and variance matrix $G(\xi)$, the first-order integral approximation is computable in closed form after completing the square:

$$\int p(y_i | X_i, \phi, u_i)q(u_i | \xi)du_i \approx (2\pi)^{-n_i/2} |V_i(X_i, \theta)|^{-1/2} \exp \left\{ -(1/2) [y_i - m_i(X_i, \phi, 0)]^T V_i(X_i, \theta)^{-1} [y_i - m_i(X_i, \phi, 0)] \right\}$$

where $V_i(X_i, \theta) = Z_i(X_i, \phi)G(\xi)Z_i(X_i, \phi)^T + R_i(X_i, \phi)$. The resulting approximation for $f(\theta)$ is then minimized over $\theta = (\phi, \xi)$ to obtain the first-order estimates. PROC NLMIXED uses finite-difference derivatives of the first-order integral approximation when carrying out the default dual quasi-Newton optimization.
Optimization Algorithms

There are several optimization techniques available in PROC NLMIXED. You can choose a particular optimizer with the TECH= name option in the PROC NLMIXED statement.

No algorithm for optimizing general nonlinear functions exists that always finds the global optimum for a general nonlinear minimization problem in a reasonable amount of time. Since no single optimization technique is invariably superior to others, PROC NLMIXED provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC NLMIXED can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem.

All optimization techniques in PROC NLMIXED use $O(n^2)$ memory except the conjugate gradient methods, which use only $O(n)$ of memory and are designed to optimize problems with many parameters. Since the techniques are iterative, they require the repeated computation of

- the function value (optimization criterion)
- the gradient vector (first-order partial derivatives)
- for some techniques, the (approximate) Hessian matrix (second-order partial derivatives)

However, since each of the optimizers requires different derivatives, some computational efficiencies can be gained. The following table shows, for each optimization technique, which derivatives are required (FOD: first-order derivatives; SOD: second-order derivatives).

Each optimization method employs one or more convergence criteria that determine when it has converged. The various termination criteria are listed and described in the “PROC NL MIXED Statement” section. An algorithm is considered to have converged when any one of the convergence criterion is satisfied. For example, under the default settings, the QUANEW algorithm will converge if $ABSGCONV < 1E - 5$, $FCONV < 10^{-FDIGITS}$, or $GCONV < 1E - 8$.

**Choosing an Optimization Algorithm**

The factors that go into choosing a particular optimization technique for a particular problem are complex and may involve trial and error.

For many optimization problems, computing the gradient takes more computer time than computing the function value, and computing the Hessian sometimes takes much more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer. Techniques that do not use the Hessian also tend to be less reliable. For example, they can more easily terminate at stationary points rather than at global optima.

A few general remarks about the various optimization techniques are as follows.

- The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems where the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $n(n + 1)/2$ double words; TRUREG and NEWRAP require two such matrices.

- The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems where the objective function and the gradient are much faster to evaluate than the Hessian. The QUANEW and DBLDOG algorithms, in general, require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP (essentially one matrix with $n(n + 1)/2$ double words). QUANEW is the default optimization method.

- The first-derivative method CONGRA is best for large problems where the objective function and the gradient can be computed much faster than the Hessian and where too much memory is required to store the (approximate) Hessian. The CONGRA algorithm, in general, requires more iterations than QUANEW or DBLDOG, but each iteration can be much faster. Since CONGRA requires only a factor of $n$ double-word memory, many large applications of PROC NL MIXED can be solved only by CONGRA.

- The no-derivative method NMSIMP is best for small problems where derivatives are not continuous or are very difficult to compute.
Algorithm Descriptions

Some details about the optimization techniques are as follows.

Trust Region Optimization (TRUREG)

The trust region method uses the gradient $g(\theta(\kappa))$ and the Hessian matrix $H(\theta(\kappa))$; thus, it requires that the objective function $f(\theta)$ have continuous first- and second-order derivatives inside the feasible region.

The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyper-elliptic trust region with radius $\Delta$ that constrains the step size corresponding to the quality of the quadratic approximation. The trust region method is implemented using Dennis, Gay, and Welsch (1981), Gay (1983), and Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms may be more efficient.

Newton-Raphson Optimization with Line Search (NEWRAP)

The NEWRAP technique uses the gradient $g(\theta(\kappa))$ and the Hessian matrix $H(\theta(\kappa))$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method may perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive definite (Eskow and Schnabel 1991).

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation (LIS=2).

Newton-Raphson Ridge Optimization (NRRIDG)

The NRRIDG technique uses the gradient $g(\theta(\kappa))$ and the Hessian matrix $H(\theta(\kappa))$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms may be more efficient.
Since the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with Cholesky decomposition. Usually, however, NRRIDG requires fewer iterations than NEWRAP.

**Quasi-Newton Optimization (QUANEW)**

The (dual) quasi-Newton method uses the gradient $g(\theta_k)$, and it does not need to compute second-order derivatives since they are approximated. It works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian; but, in general, it requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. QUANEW is the default optimization algorithm because it provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique is one of the following, depending upon the value of the UPDATE= option.

- the original quasi-Newton algorithm, which updates an approximation of the inverse Hessian
- the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian (default)

You can specify four update formulas with the UPDATE= option:

- DBFGS performs the dual Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- BFGS performs the original BFGS update of the inverse Hessian matrix.
- DFP performs the original DFP update of the inverse Hessian matrix.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size $\alpha$ satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction. You can specify line-search algorithms other than the default with the LIS= option.

The QUANEW algorithm performs its own line-search technique. All options and parameters (except the INSTEP= option) controlling the line search in the other algorithms do not apply here. In several applications, large steps in the first iterations are troublesome. You can use the INSTEP= option to impose an upper bound for the step size.
size $\alpha$ during the first five iterations. You can also use the INHESSIAN [$=r$] option to specify a different starting approximation for the Hessian. If you specify only the INHESSIAN option, the Cholesky factor of a (possibly ridged) finite difference approximation of the Hessian is used to initialize the quasi-Newton update process. The values of the LCSINGULAR=, LCEPSILON=, and LCDEACT= options, which control the processing of linear and boundary constraints, are valid only for the quadratic programming subroutine used in each iteration of the QUANEW algorithm.

**Double Dogleg Optimization (DBLDOG)**

The double dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double dogleg algorithm computes the step $s^{(k)}$ as the linear combination of the steepest descent or ascent search direction $s_1^{(k)}$ and a quasi-Newton search direction $s_2^{(k)}$.

$$s^{(k)} = \alpha_1 s_1^{(k)} + \alpha_2 s_2^{(k)}$$

The step is requested to remain within a prespecified trust region radius; refer to Fletcher (1987, p. 107). Thus, the DBLDOG subroutine uses the dual quasi-Newton update but does not perform a line search. You can specify two update formulas with the UPDATE= option:

- **DBFGS** performs the dual Broyden, Fletcher, Goldfarb, and Shanno update of the Cholesky factor of the Hessian matrix. This is the default.
- **DDFP** performs the dual Davidon, Fletcher, and Powell update of the Cholesky factor of the Hessian matrix.

The double dogleg optimization technique works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian. The implementation is based on Dennis and Mei (1979) and Gay (1983), but it is extended for dealing with boundary and linear constraints. The DBLDOG technique generally requires more iterations than the TRUREG, NEWRAP, or NRRIDG technique, which requires second-order derivatives; however, each of the DBLDOG iterations is computationally cheap. Furthermore, the DBLDOG technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

**Conjugate Gradient Optimization (CONGRA)**

Second-order derivatives are not required by the CONGRA algorithm and are not even approximated. The CONGRA algorithm can be expensive in function and gradient calls, but it requires only $O(n)$ memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the CONGRA iterations is computationally cheap. You can specify four different update formulas for generating the conjugate directions by using the UPDATE= option:

- **PB** performs the automatic restart update method of Powell (1977) and Beale (1972). This is the default.
FR performs the Fletcher-Reeves update (Fletcher 1987).

PR performs the Polak-Ribiere update (Fletcher 1987).

The default, UPDATE=PB, behaved best in most test examples. You are advised to avoid the option UPDATE=CD, which behaved worst in most test examples.

The CONGRA subroutine should be used for optimization problems with large \( n \). For the unconstrained or boundary constrained case, CONGRA requires only \( O(n) \) bytes of working memory, whereas all other optimization methods require order \( O(n^2) \) bytes of working memory. During \( n \) successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of \( n \) conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size \( \alpha \) satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size. Other line-search algorithms can be specified with the LIS= option.

**Nelder-Mead Simplex Optimization (NMSIMP)**

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it may be unable to generate precise results for \( n \gg 40 \).

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex adapting to the nonlinearities of the objective function, which contributes to an increased speed of convergence. It uses a special termination criteria.

**Finite Difference Approximations of Derivatives**

The FD= and FDHESSIAN= options specify the use of finite difference approximations of the derivatives. The FD= option specifies that all derivatives are approximated using function evaluations, and the FDHESSIAN= option specifies that second-order derivatives are approximated using gradient evaluations.

Computing derivatives by finite difference approximations can be very time consuming, especially for second-order derivatives based only on values of the objective function (FD= option). If analytical derivatives are difficult to obtain (for example, if a function is computed by an iterative process), you might consider one of the optimization techniques that uses first-order derivatives only (QUANEW, DBLDOG, or CONGRA).

**Forward Difference Approximations**

The forward difference derivative approximations consume less computer time, but they are usually not as precise as approximations that use central difference formulas.
For first-order derivatives, \( n \) additional function calls are required:

\[
g_i = \frac{\partial f}{\partial \theta_i} \approx \frac{f(\theta + h_i e_i) - f(\theta)}{h_i}
\]

For second-order derivatives based on function calls only (Dennis and Schnabel 1983, p. 80), \( n + n^2 / 2 \) additional function calls are required for dense Hessian:

\[
