Abstract

Minimizing a convex risk function is the main step in many basic learning algorithms. We study protocols for convex optimization which provably leak very little about the individual data points that constitute the loss function. Specifically, we consider differentially private algorithms that operate in the local model, where each data record is stored on a separate user device and randomization is performed locally by those devices. We give new protocols for noninteractive LDP convex optimization—i.e., protocols that require only a single randomized report from each user to an untrusted aggregator.

We study our algorithms’ performance with respect to expected loss—either over the data set at hand (empirical risk) or a larger population from which our data set is assumed to be drawn. Our error bounds depend on the form of individuals’ contribution to the expected loss. For the case of generalized linear losses (such as hinge and logistic losses), we give an LDP algorithm whose sample complexity is only linear in the dimensionality $p$ and quasipolynomial in other terms (the privacy parameters $\epsilon$ and $\delta$, and the desired excess risk $\alpha$). This is the first algorithm for nonsmooth losses with sub-exponential dependence on $p$.

For the Euclidean median problem, where the loss is given by the Euclidean distance to a given data point, we give a protocol whose sample complexity grows quasipolynomially in $p$. This is the first protocol with sub-exponential dependence on $p$ for a loss that is not a generalized linear loss.

Our result for the hinge loss is based on a technique, dubbed polynomial of inner product approximation, which may be applicable to other problems. Our results for generalized linear losses and the Euclidean median are based on new reductions to the case of hinge loss.

Keywords: Differential Privacy, Empirical Risk Minimization, Round Complexity
1. Introduction

In the big data era, a tremendous amount of individual data are generated every day. Such data, if properly used, could greatly improve many aspects of our daily lives. However, due to the sensitive nature of such data, a great deal of care needs to be taken while analyzing them. Private data analysis seeks to enable the benefits of learning from data with the guarantee of privacy-preservation. Differential privacy (Dwork et al., 2006) has emerged as a rigorous notion for privacy which allows accurate data analysis with a guaranteed bound on the increase in harm for each individual to contribute her data. Methods to guarantee differential privacy have been widely studied, and recently adopted in industry (Near, 2018; Erlingsson et al., 2014).

Two main user models have emerged for differential privacy: the central model and the local one. In the central model, data are managed by a trusted central entity which is responsible for collecting them and for deciding which differentially private data analysis to perform and to release. A classical use case for this model is the one of census data (Haney et al., 2017). In the local model instead, each individual manages his/her proper data and discloses them to a server through some differentially private mechanisms. The server collects the (now private) data of each individual and combines them into a resulting data analysis. A classical use case for this model is the one aiming at collecting statistics from user devices like in the case of Google’s Chrome browser (Erlingsson et al., 2014), and Apple’s iOS-10 (Near, 2018; Tang et al., 2017).

In this paper, we study differentially private Empirical Risk Minimization in the non-interactive local model. Before showing our contributions and discussing comparisons with previous work, we first discuss our motivations.

Problem Setting Given a convex, closed and bounded constraint set $C \subseteq \mathbb{R}^p$, a data universe $D$, and a loss function $\ell : C \times D \mapsto \mathbb{R}$, a dataset $D = \{(x_1, y_1), (x_2, y_2), \ldots, (x_n, y_n)\} \in D^n$ with data records $\{x_i\}^n_{i=1} \subset \mathbb{R}^p$ and labels (responses) $\{y_i\}^n_{i=1} \subset \mathbb{R}$ defines an empirical risk function: $L(w; D) = \frac{1}{n} \sum_{i=1}^{n} \ell(w; x_i, y_i)$ (note that in some settings, such as mean estimation, there may not be separate labels). When the inputs are drawn i.i.d from an unknown underlying distribution $P$ on $D$, we can also define the population risk function: $L_P(w) = \mathbb{E}_{D \sim P^n} [\ell(w; D)]$.

Thus, we have the following two types of excess risk measured at a particular output $w_{\text{priv}}$: The empirical risk,

$$\text{Err}_D(w_{\text{priv}}) = L(w_{\text{priv}}; D) - \min_{w \in C} L(w; D),$$

and the population risk,

$$\text{Err}_P(w_{\text{priv}}) = L_P(w_{\text{priv}}) - \min_{w \in C} L_P(w).$$

The problem considered in this paper is to design noninterative LDP protocols that minimize the empirical and/or population excess risks. Alternatively, we can express our goal this problem
in terms of sample complexity: find the smallest $n$ for which we can design protocols that achieve error at most $\alpha$ (in the worst case over data sets, or over generating distributions, depending on how we measure risk).

Duchi, Jordan, and Wainwright (2013) first considered worst-case error bounds for LDP convex optimization. For 1-Lipchitz convex losses over a bounded constraint set, they gave a highly interactive SGD-based protocol with sample complexity $n = O(p/e^2\alpha^2)$; moreover, they showed that no LDP protocol which interacts with each player only once can achieve asymptotically better sample complexity, even for linear losses.

Smith, Thakurta, and Upadhyay (2017) considered the round complexity of LDP protocols for convex optimization. They observed that known methods perform poorly when constrained to be run noninteractively. They gave new protocols that improved on the state of the art but nevertheless required sample complexity exponential in $p$. Specifically, they showed:

**Theorem 1 (Smith et al. (2017))** Under the assumptions above, there is a noninteractive $\epsilon$-LDP algorithm that for all distribution $P$ on $D$, with probability $1 - \beta$, returns a solution with population error at most $\alpha$ as long as $n = \tilde{O}(e^p \log(1/\beta)/e^2\alpha^{p+1})$, where $c$ is an absolute constant. A similar result holds for empirical risk $\text{Err}_D$.

Furthermore, lower bounds on the parallel query complexity of stochastic optimization (e.g., Nemirovski (1994); Woodworth et al. (2018)) mean that, for natural classes of LDP optimization protocols (based on measuring noisy gradients), the exponential dependence of the sample size on the dimension $p$ (in the terms of $\alpha^{-(p+1)}$ and $e^p$) is, in general, unavoidable (Smith et al., 2017).

This situation is challenging: when the dimensionality $p$ is high, the sample complexity (at least $\alpha^{-(p+1)}$) is enormous even for a very modest target error. However, several results have already shown that for some specific loss functions, the exponential dependency on the dimensionality can be avoided. For example, Smith et al. (2017) show that, in the case of linear regression, there is a noninteractive $(\epsilon, \delta)$-LDP algorithm\(^1\) with expected empirical error $\alpha$ and sample complexity $n = \tilde{O}(pe^{-2}\alpha^{-2})$. This indicates that there is a gap between the general case and what is achievable for some specific, commonly used loss functions.

**Our Contributions** The results above motivate the following basic question:

*Are there natural conditions on the loss function which allow for noninteractive $\epsilon$-LDP algorithms with sample complexity growing sub-exponentially (ideally, polynomially or even linearly) on the dimensionality $p$?*

To answer this question, we first consider the case of hinge loss functions, which are “plus functions” of an inner product: \(\ell(w; x, y) = [y\langle w, x \rangle]_+\) where $[a]_+ = \max\{0, a\}$. Hinge loss arises, for example, when fitting support vector machines. We construct our noninteractive LDP algorithm by using Chebyshev polynomials to approximate the loss’s derivative after smoothing. Players randomize their inputs by randomizing the coefficients of a polynomial approximation. The aggregator uses the noisy reports to provide biased gradient estimates when running Stochastic Inexact Gradient Descent (Dvurechensky and Gasnikov, 2016).

\(^1\) Note that these two results are for noninteractive $(\epsilon, \delta)$-LDP, a variant of $\epsilon$-LDP. We omit quasipolynomial terms related to $\log(1/\delta)$ in this paper.
We show that a variant of the same algorithm can be applied to convex, 1-Lipschitz generalized linear loss function, any loss function where each records’s contribution has the form \( \ell(w; x, y) = f(y_i \langle w, x_i \rangle) \) for some 1-Lipschitz convex function \( f \).

Our algorithm has sample complexity that depends only linearly, instead of exponentially, on the dimensionality \( p \) and quasipolynomially on \( \alpha, \epsilon \) and \( \log(1/\delta) \). The protocol exploits the fact that any 1-dimensional 1-Lipschitz convex function can be expressed as a convex combination of linear functions and hinge loss functions.

We also apply our method to other loss functions. In particular, we show that in the Euclidean median problem, where the loss function is the \( \ell_2 \) norm \( L(w; D) = \frac{1}{2n} \sum_{i=1}^{n} \|w - x_i\|_2 \), the sample complexity is only quasipolynomial in \( p, \alpha, \delta, \epsilon \). This is the first noninteractive LDP protocol with sub-exponential dependence on \( p \) for a natural loss function that is not a generalized linear loss. Our result is based on the observation that the \( \ell_2 \) norm function can be approximated by a convex combination of appropriately-scaled hinge losses.

2. Related Work

Differentially private convex optimization, first formulated by Chaudhuri and Monteleoni (2009) and Chaudhuri, Monteleoni, and Sarwate (2011), has been the focus of an active line of work for the past decade, such as (Wang et al., 2017; Bassily et al., 2014; Kifer et al., 2012; Chaudhuri et al., 2011; Talwar et al., 2015; Wang and Xu, 2019). We discuss here only those results which are related to the local model.

Kasiviswanathan et al. (2011) initiated the study of learning under local differential privacy. Specifically, they showed a general equivalence between learning in the local model and learning in the statistical query model. Beimel et al. (2008) gave the first lower bounds for the accuracy of LDP protocols, for the special case of counting queries (equivalently, binomial parameter estimation). The general problem of LDP convex risk minimization was first studied by Duchi et al. (2013), which provided tight upper and lower bounds for a range of settings. Subsequent work considered a range of statistical problems in the LDP setting, providing upper and lower bounds—we omit a complete list here.

Smith et al. (2017) initiated the study of the round complexity of LDP convex optimization, connecting it to the parallel complexity of (nonprivate) stochastic optimization.

Convex risk minimization in the noninteractive LDP received considerable recent attention (Zheng et al., 2017; Smith et al., 2017; Wang et al., 2018) (see Table 1 for details). Smith et al. (2017) first studied the problem with general convex loss functions and showed that the exponential dependence on the dimensionality is unavoidable for a class of noninteractive algorithms. Wang et al. (2018) demonstrated that such an exponential dependence in the term of \( \alpha \) is avoidable if the loss function is smooth enough (i.e., \( (\infty, T) \)-smooth). Their result even holds for non-convex loss functions. However, there is still another term \( c^p \) in the sample complexity. In this paper, we investigate the conditions which allow us to avoid this issue and obtain sample complexity which is linear or quasipolynomial in \( p \).

The work most related to ours is that of (Zheng et al., 2017), which also considered some specific loss functions in high dimensions, such as sparse linear regression and kernel ridge regression. They first propose a method based on Chebyshev polynomial approximation to the gradient function. Their idea is a key ingredient in our algorithms. There are still several differences. First, their analysis requires additional assumptions on the loss function, such as smoothness and boundedness.
of higher order derivatives, which are not satisfied by the hinge loss. In contrast, our approach applies to any convex, 1-Lipschitz generalized linear loss. Second, we introduce a novel argument to "lift" our hinge loss algorithms to more general linear losses and the Euclidean median.

3. Preliminaries

**Assumption 1** We assume that \(\|x_i\|_2 \leq 1\) and \(|y_i| \leq 1\) for each \(i \in [n]\) and the constraint set \(\|C\|_2 \leq 1\). Asymptotic statements assume \(\epsilon, \delta, \alpha \in (0, \frac{1}{2})\) and ignore quasipolynomial dependencies on \(\log(1/\delta)\).

**Differential privacy in the local model.** In LDP, we have a data universe \(D\), \(n\) players with each holding a private data record \(x_i \in D\), and a server coordinating the protocol. An LDP protocol executes a total of \(T\) rounds. In each round, the server sends a message, which is also called a query, to a subset of the players requesting them to run a particular algorithm. Based on the query, each player \(i\) in the subset selects an algorithm \(Q_i\), runs it on her own data, and sends the output back to the server.
**Definition 2** (Evfimievski et al., 2003; Dwork et al., 2006) An algorithm $Q$ is $\epsilon$-locally differentially private (LDP) if for all pairs $x, x' \in D$, and for all events $E$ in the output space of $Q$, we have

$$\Pr[Q(x) \in E] \leq e^{\epsilon} \Pr[Q(x') \in E].$$

A multi-player protocol is $\epsilon$-LDP if for all possible inputs and runs of the protocol, the transcript of player $i$’s interaction with the server is $\epsilon$-LDP. If $T = 1$, we say that the protocol is $\epsilon$ non-interactive LDP.

Kasiviswanathan et al. (2011) gave a separation between interactive and noninteractive protocols. Specifically, they showed that there is a concept class, similarity to parity, which can be efficiently learned by interactive algorithms but which requires sample size exponential in the dimension to be learned by noninteractive local algorithms.

In the following, we will rephrase some basic definitions and lemmas on Chebyshev polynomial approximation.

**Definition 3** The Chebyshev polynomials $\{T_n(x)\}_{n \geq 0}$ are recursively defined as follows

$$T_0(x) \equiv 1, T_1(x) \equiv x \text{ and } T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x).$$

It satisfies that for any $n \geq 0$

$$T_n(x) = \begin{cases} 
\cos(n \arccos(x)), & \text{if } |x| \leq 1 \\
\cosh(n \arccosh(x)), & \text{if } x \geq 1 \\
(-1)^n \cosh(n \arccosh(-x)), & \text{if } x \leq -1 
\end{cases}$$

**Definition 4** For every $\rho > 0$, let $\Gamma_\rho$ be the ellipse $\Gamma$ of foci $\pm 1$ with major radius $1 + \rho$.

**Definition 5** For a function $f$ with a domain containing in $[-1, 1]$, its degree-$n$ Chebyshev truncated series is denoted by $P_n(x) = \sum_{k=0}^{n} a_k T_k(x)$, where the coefficient $a_k = \frac{2-1[k=0]}{\pi} \int_{-1}^{1} f(x)T_k(x) dx$.

**Lemma 6 (Chebyshev Approximation Theorem (Trefethen, 2013))** Let $f(z)$ be a function that is analytic on $\Gamma_\rho$ and has $|f(z)| \leq M$ on $\Gamma_\rho$. Let $P_n(x)$ be the degree-$n$ Chebyshev truncated series of $f(x)$ on $[-1, 1]$. Then, we have

$$\max_{x \in [-1, 1]} |f(x) - P_n(x)| \leq \frac{2M}{\rho + \sqrt{2\rho + \rho^2}}(1 + \sqrt{2\rho + \rho^2})^{-n},$$

$|a_0| \leq M$, and $|a_k| \leq 2M(1 + \rho + \sqrt{2\rho + \rho^2})^{-k}$.

The following theorem shows the convergence rate of the Stochastic Inexact Gradient Method (Dvurechensky and Gasnikov, 2016), which will be used in our algorithm. We first give the definition of inexact oracle.

**Definition 7** For an objective function, a $(\gamma, \beta, \sigma)$ stochastic oracle returns a tuple $(F_{\gamma, \beta, \sigma}(w; \xi), G_{\gamma, \beta, \sigma}(w; \xi))$ such that

$$\mathbb{E}_{\xi}[F_{\gamma, \beta, \sigma}(w; \xi)] = f_{\gamma, \beta, \sigma}(w),$$

$$\mathbb{E}_{\xi}[G_{\gamma, \beta, \sigma}(w; \xi)] = g_{\gamma, \beta, \sigma}(w),$$

$$\mathbb{E}_{\xi}[|G_{\gamma, \beta, \sigma}(w; \xi) - g_{\gamma, \beta, \sigma}(w)|^2] \leq \sigma^2,$$

$$0 \leq f(v) - f_{\gamma, \beta, \sigma}(w) - \langle g_{\gamma, \beta, \sigma}(w), v - w \rangle \leq \frac{\beta}{2} \|v - w\|^2 + \gamma, \forall v, w \in C.$$
Polynomials. Let $P$ iteration, and then run the SIGM step of (Dvurechensky and Gasnikov, 2016). By Lemma 9, we plus function $E[f(w_k)] - \min_{w \in C} f(w) \leq \Theta(\frac{\beta \sigma \|C\|^2}{\sqrt{k}} + \gamma)$.

4. Main Results

In this section, we present our main results for LDP-ERM.

4.1. Sample Complexity for Hinge Loss Function

We first consider LDP-ERM with hinge loss function and then extend the obtained result to general convex linear functions.

The hinge loss function is defined as $\ell(w; x_i, y_i) = f(y_i \langle w, x_i \rangle) = \left[\frac{1}{2} - y_i \langle w, x_i \rangle\right]_+$, where the plus function $[x]_+ = \max\{0, x\}$, i.e., $f(x) = \max\{0, \frac{1}{2} - x\}$ for $x \in [-1, 1]$. Note that to avoid the scenario that $1 - y_i \langle w, x_i \rangle$ is always greater than or equal to 0, we use $\frac{1}{2}$, instead of 1 as in the classical setting.

Before showing our idea, we first smoothen the function $f(x)$. The following lemma shows one of the smooth functions that is close to $f$ in the domain of $[-1, 1]$ (note that there are other ways to smoothen $f$; see (Chen and Mangasarian, 1996) for details).

**Lemma 9** Let $f_\beta(x) = \frac{\frac{1}{2} - x + \sqrt{(\frac{1}{2} - x)^2 + \beta^2}}{2}$ be a function with parameter $\beta > 0$. Then, we have

1. $f_\beta(x)$ is analytic on $x \in \mathbb{R}$.
2. $|f_\beta(x) - f(x)|_\infty \leq \frac{\beta}{2}, \forall x \in \mathbb{R}$.
3. $f_\beta(x)$ is $1$-Lipschitz, that is, $f'(x)$ is bounded by 1 for $x \in \mathbb{R}$.
4. $f_\beta$ is $\frac{1}{2\beta}$-smooth and convex.

The above lemma indicates that $f_\beta(x)$ is a smooth and convex function which well approximates $f(x)$. This suggests that we can focus on $f_\beta(y_i \langle w, x_i \rangle)$, instead of $f$. Our idea is to construct a locally private $(\gamma, \beta, \sigma)$ stochastic oracle for some $\gamma, \beta, \sigma$ to approximate $f'_\beta(y_i \langle w, x_i \rangle)$ in each iteration, and then run the SIGM step of (Dvurechensky and Gasnikov, 2016). By Lemma 9, we know that $f'_\beta$ is bounded and analytic; thus, we can use Lemma 6 to approximate $f'_\beta$ via Chebyshev polynomials. Let $P_d(x) = \sum_{i=0}^{d} a_i T_i(x) = \sum_{i=0}^{d} c_i x^i$, where $\max_{x \in [-1, 1]} |P_d(x) - f'(x)| \leq \frac{\alpha}{4}$ (i.e., $d = c \log(4/\alpha)$ for some constant $c > 0$) and $\sum_{i=0}^{d} c_i x^i$ is the polynomial expansion of $\sum_{i=0}^{d} a_i T_i(x)$. Then, we have $\nabla_w \ell(w; x, y) = f'(y \langle w, x \rangle) y x^T$, which can be approximated by $[\sum_{i=0}^{d} c_i (y \langle w, x \rangle)^i] y x^T$. The idea is that if $(y \langle w, x \rangle)^i$ and $y x^T$ can be approximated locally differentially privately by directly adding $i + 1$ numbers of independent Gaussian noises, which means it is possible to form an unbiased estimator of the term $[\sum_{i=0}^{d} c_i (y \langle w, x \rangle)^i] y x^T$. The error of this procedure can be estimated by Lemma 8. Details of the algorithm are given in Algorithm 1.
Algorithm 1 Hinge Loss-LDP

1: **Input:** Player \( i \in [n] \) holds data \((x_i, y_i) \in D\), where \(||x_i||_2 \leq 1, ||y_i||_2 \leq 1\); privacy parameters \( \epsilon, \delta; d \) is the degree of Chebyshev truncated series of \( f'_\beta \) to achieve the approximation error of \( \frac{\alpha}{2} \) and \( P_d(x) = \sum_{i=0}^{d} a_i T_i(x) = \sum_{i=0}^{d} c_i x^i \) is its Chebyshev polynomial approximation.

2: **for** Each Player \( i \in [n] \) **do**
3: \( x_{i,0} = x_i + \sigma_{i,0} \) and \( y_{i,0} = y_i + z_{i,0} \), where \( \sigma_{i,0} \sim \mathcal{N}(0, \frac{32 \log(1.25/\delta)}{\epsilon^2} I_p) \) and \( z_{i,0} \sim \mathcal{N}(0, \frac{32 \log(1.25/\delta)}{\epsilon^2} I_p) \).
4: **for** \( j = 1, \ldots, \frac{d(d+1)}{2} \) **do**
5: \( x_{i,j} = x_i + \sigma_{i,j} \), where \( \sigma_{i,j} \sim \mathcal{N}(0, \frac{8 \log(1.25/\delta)d^2(d+1)^2}{\epsilon^2} I_p) \)
6: \( y_{i,j} = y_i + z_{i,j} \), where \( z_{i,j} \sim \mathcal{N}(0, \frac{8 \log(1.25/\delta)d^2(d+1)^2}{\epsilon^2}) \)
7: **end for**
8: Send \{ \( x_{i,j} \) \}_{j=0}^{d(d+1)} \) and \{ \( y_{i,j} \) \}_{j=0}^{d(d+1)} \) to the server.
9: **end for**
10: **for** the Server side **do**
11: **for** \( t = 1, 2, \ldots, n \) **do**
12: Randomly sample \( i \in [n] \) uniformly.
13: Set \( t_{i,0} = 1 \)
14: **for** \( j = 1, \ldots, d \) **do**
15: \( t_{i,j} = \Pi_{k=j(j-1)/2+1}^{j+1/2} y_{i,k} < w_t, x_{i,k} \)
16: **end for**
17: Denote \( G(w_t, i) = (\sum_{j=0}^{d} c_j t_{i,j}) y_{i,0} x_{i,0}^T \).
18: Update SIGM in (Dvurechensky and Gasnikov, 2016) by \( G(w_t, i) \)
19: **end for**
20: **end for**

**return** \( w_n \)

**Theorem 10** For each \( i \in [n] \), the term \( G(w_t, i) \) generated by Algorithm 1 is an \((\frac{\alpha}{2}, \frac{1}{\beta}, O(\frac{d^{2d+2}4^d}{\epsilon^2^d+\alpha+1}))\) stochastic oracle for function \( L_\beta(w; D) = \frac{1}{n} \sum_{i=1}^{n} f_\beta(y_i(x_i, w)) \), where \( f_\beta \) is the function in Lemma 9.

From Lemmas 8, 9 and Theorem 10, we have the following sample complexity bound for the hinge loss function under the non-interactive local model.

**Theorem 11** For any \( \epsilon > 0 \) and \( 0 < \delta < 1 \), Algorithm 1 is \((\epsilon, \delta)\) non-interactively locally differentially private\(^2\). Furthermore, for the target error \( \alpha \), if choosing sample size \( n = O(\frac{d^{d^2+1}16^d}{\epsilon^d+\alpha^d}) \) and setting \( \beta = \Theta(\frac{d^{d+1}d^2}{\epsilon^d+\alpha^d}) \), the output \( w_n \) satisfies the following inequality

\[
\mathbb{E} L(w_n, D) - \min_{w \in C} L(w, D) \leq \alpha,
\]

where \( d = c \log(4/\alpha) \) for some universal constant \( c > 0 \).

\(^2\) Note that in the non-interactive local model, \((\epsilon, \delta)\)-LDP is equivalent to \(\epsilon\)-LDP by using some protocol given in Bun et al. (2018); this allows us to omit the term of \( \delta \). The full sample complexity of \( n \) is quasi-polynomial in \( \ln(1/\delta) \).
Remark 12 Note that the sample complexity bound in Theorem 11 is quite loose for parameters other than $p$. This is mainly due to the fact that we use only the basic composition theorem to ensure local differential privacy. It is possible to obtain a tighter bound by using Advanced Composition Theorem (Dwork et al., 2010) (same for other algorithms in this paper). Details of the improvement are omitted from this version. We can also extend to the population risk by the same algorithm, the Theorem (Dwork et al., 2010) (same for other algorithms in this paper). Details of the improvement is non-interactively differentially private. Moreover, given the target error $\alpha$, if choosing $n$ and $\beta$ such that $n = O(\frac{\epsilon^2 + \delta^2}{\epsilon\alpha + \delta\alpha})$

4.2. Extension to Generalized Linear Convex Loss Functions

In this section, we extend our results for the hinge loss function to generalized linear convex loss functions $L(w, D) = \frac{1}{n} \sum_{i=1}^{n} f(y_i(x_i, w))$ for any 1-Lipschitz convex function $f$.

One possible way (for the extension) is to follow the same approach used in previous section. That is, we first smoothen the function $f$ by some function $f_\beta$. Then, we use Chebyshev polynomials to approximate the derivative function $f_\beta'$, and apply an algorithm similar to Algorithm 1. One of the main issues of this approach is that we do not know whether Chebyshev polynomials (i.e., Lemma 6) can be directly used for every smooth convex function. Instead, we will use some ideas in Approximation Theory, which says that every smooth convex function can be expressed by a linear combination of the absolute functions and some linear functions.

To implement this approach, we first note that for the plus function $f(x) \equiv \max\{0, x\}$, by using Algorithm 1 we can get the same result as in Theorem 11. Since the absolute function $|x| = 2 \max\{0, x\} - x$, Theorem 11 clearly also holds for the absolute function. The following key lemma shows that every 1-dimensional 1-Lipschitz convex function $f : [-1, 1] \mapsto [-1, 1]$ is contained in the convex hull of the set of absolute and identity functions. We need to point out that Smith et al. (2017) gave a similar lemma. Their proof is, however, somewhat incomplete and thus we give a complete one in this paper.

Lemma 13 Let $f : [-1, 1] \mapsto [-1, 1]$ be a 1-Lipschitz convex function. If we define the distribution $Q$ which is supported on $[-1, 1]$ as the output of the following algorithm:

1. first sample $u \in [f'(1), f'(1)]$ uniformly,
2. then output $s$ such that $u \in \partial f(s)$ (note that such an $s$ always exists due to the fact that $f$ is convex and thus $f'$ is non-decreasing); if multiple number of such as $s$ exist, return the maximal one,

then, there exists a constant $c$ such that

$$\forall \theta \in [-1, 1], f(\theta) = \frac{f'(1) - f'(1)}{2} E_{s \sim Q}[\theta - s] + \frac{f'(1) + f'(1)}{2} \theta + c.$$

Using Lemma 13 and the ideas discussed in the previous section, we can now show that the sample complexity in Theorem 11 also holds for any general linear convex function. See Algorithm 2 for the details.

Theorem 14 Under Assumption 1, where the loss function $\ell$ is $\ell(w; x, y) = f(y < w, x >)$ for any 1-Lipschitz convex function $f$, for any $\epsilon, \delta \in (0, 1)$, Algorithm 2 is $(\epsilon, \delta)$ non-interactively differentially private. Moreover, given the target error $\alpha$, if choosing $n$ and $\beta$ such that $n = O(\frac{\epsilon^2 + \delta^2}{\epsilon\alpha + \delta\alpha})$
and $\beta = \Theta\left(\frac{d^{d+1}2^{d}p}{e^{a+1}N}\right)$, the output $w_n$ satisfies the following inequality

$$\mathbb{E}L(w_n, D) - \min_{w \in \mathcal{C}} L(w, D) \leq \alpha,$$

where $d = c \log(4/\alpha)$ for some universal constant $c > 0$ independent of $f$.

**Remark 15** The above theorem suggests that the sample complexity for any generalized linear loss function depends only linearly on $p$. However, there are still some not so desirable issues. Firstly, the dependence on $\alpha$ is quasi-polynomial, while previous work (Wang et al., 2018) has already shown that it is only polynomial (i.e., $\alpha^{-4}$) for sufficiently smooth loss functions. Secondly, the term of $\epsilon$ is not optimal in the sample complexity, since it is $\epsilon^{-\Omega(\ln(1/\alpha))}$, while the optimal one is $\epsilon^{-2}$. We leave it as an open problem to remove the quasi-polynomial dependency. Thirdly, the assumption on
the loss function is that \( \ell(w; x, y) = f(y < w, x >) \), which includes the generalized linear models and SVM. However, as mentioned earlier, there is another slightly more general function class \( \ell(w; x, y) = f(<w, x >, y) \) which does not always satisfy our assumption, e.g., linear regression and \( \ell_1 \) regression. For linear regression, we have already known its optimal bound \( \Theta(p\alpha^{-2}\epsilon^{-2}) \); for \( \ell_1 \) regression, we can use a method similar to Algorithm 1 to achieve a sample complexity which is linear in \( p \). Thus, a natural question is whether the sample complexity is still linear in \( p \) for all loss functions \( \ell(w; x, y) \) that can be written as \( f(< w, x >, y) \).

4.3. Further Extension to Euclidean Median Problem

Last section has showed that using the approximation of hinge loss function and polynomials of inner product functions, we can extend our approach to generalized linear convex loss functions for LDP-ERM. To show the power of this method, we consider in this section the Euclidean median problem, which cannot be written as a function of inner product \( < w, x > \). Euclidean median problem is one of the classic problem in optimization and has been studied for many years (Cohen et al., 2016):

\[
L(w; D) = \frac{1}{2n} \sum_{i=1}^{n} \|w - x_i\|_2.
\]

Note that we need \( 2n \), instead of \( n \), data points to ensure that the loss function \( \|w - x_i\|_2 \) is 1-Lipschitz and the term \( < \frac{w - x_i}{2}, u > \) is bounded by 1 in \( \|C\|_2 \leq 1 \). It is obvious that the \( \ell_2 \)-norm loss function cannot be written as a function of inner product. However, the following key lemma tells us that it can actually be well approximated by a linear combination of the absolute inner product functions.

**Lemma 16** Let \( P \) be the distribution of uniformly sampling from \((p − 1)\)-dimensional unit sphere \( \mathbb{S}^{p−1} \). Then, we have

\[
\|x\|_2 = \frac{\sqrt{\pi p \Gamma(\frac{p−1}{2})}}{2\Gamma(\frac{p}{2})} |\|u\|_P| < u, x > |.
\]

Note that the term \( \frac{\sqrt{\pi p \Gamma(\frac{p−1}{2})}}{2\Gamma(\frac{p}{2})} \) is \( O(\sqrt{p}) \).

With Lemma 16, we have Algorithm 3 and the following theorem for the Euclidean median problem based on the ideas in previous sections.

**Theorem 17** For any \( \epsilon > 0 \) and \( 0 < \delta < 1 \), Algorithm 3 is \((\epsilon, \delta)\) non-interactively locally differentially private. Furthermore, for the target error \( \alpha \), if choosing the sample size \( n \) and \( \beta \) such that

\[
n = O(\frac{d^d + 2d^d p^d}{\epsilon^{2d} \alpha^4}) \quad \text{and} \quad \beta^2 = \Theta(\frac{Cd^{d + 2} \sqrt{d^d}}{\epsilon^{2d} \alpha^4}),
\]

the output \( w_n \) satisfies the following inequality

\[
\mathbb{E}L(w_n; D) - \min_{w \in C} L(w; D) \leq \alpha,
\]

where \( d = c \log(4C/\alpha) \) for some constant \( c > 0 \) and \( C = \frac{\sqrt{\pi p \Gamma(\frac{p−1}{2})}}{2\Gamma(\frac{p}{2} + 1)} = O(\sqrt{p}) \).

From previous sections, we can see that for any convex generalized linear loss function, the sample complexity needs only linearly depending on the dimensionality \( p \). So far, we know that all
loss functions have a sample complexity which is either linear in $p$ \(\text{i.e., all known loss functions can be written as } f(<w, x >, y)\) or exponential in $p$ \(\text{such as the example given in } (\text{Smith et al., 2017})\). Thus, to our best knowledge, the Euclidean median problem (or ERM with loss function \(\ell(w; x) = \frac{1}{2} \|w - x\|_2\)) is the first result which is not generalized linear, but still has a sample complexity sub-exponential in $p$.

Compared with the result for generalized linear loss functions, the quasi-polynomial dependency in the sample complexity of the Euclidean median problem comes from the multiplicative factor \(O(\sqrt{p})\) in Lemma 16, which forces us to use Chebyshev polynomial to achieve the error of \(O(\alpha \sqrt{p})\), instead of \(O(\alpha)\) as in the previous sections. It remains as an open problem to determine whether this dependency is necessary. Also, extending our method to other loss functions is another direction for future research.

5. Discussion

In this paper, we propose a general method for Empirical Risk Minimization in non-interactive differentially private model by using polynomial of inner product approximation. Compared with
the method of directly using polynomial approximation, such as the one in (Wang et al., 2018), which needs exponential (in $p$) number of grids to estimate the function privately, our method avoid this undesirable issue. Using this method, we show that the sample complexity for any 1-Lipschitz generalized linear convex function is only linear in $p$. Moreover, we show that our method can be extended to the Euclidean median problem and achieve a sample complexity that is quasi-polynomial in $p$.

Appendix A. Detailed Proofs

Proof [Proof of Lemma 9] It is easy to see that items 1 and 2 are true. Item 3 is due to the following

$$|f_\beta'(x)| = \left| -1 + \frac{x - \frac{1}{2}}{\sqrt{(x - \frac{1}{2})^2 + \beta^2}} \right| \leq 1.$$  

Item 4 is because of the following

$$0 \leq f_\beta''(x) = \frac{\beta^2}{((x - \frac{1}{2})^2 + \beta^2)^{\frac{3}{2}}} \leq \frac{1}{\beta}.$$

Proof [Proof of Theorem 10] For simplicity, we omit the term of $\delta$, which will not affect the linear dependency. Let

$$\hat{G}(w, i) = \left[ \sum_{j=0}^{d} c_j(y_i(w, x_i))^j \right] y_i x_i^T,$$

$$\mathbb{E}_i \hat{G}(w, i) = \frac{1}{n} \sum_{i=1}^{n} \hat{G}(w, i) = \hat{G}(w).$$

For the term of $G(w, i)$, the randomness comes from sampling the index $i$ and the Gaussian noises added for preserving local privacy.

Note that in total $\mathbb{E}_{\sigma, z, i} G(w, i) = \hat{G}(w)$, where $\sigma = \{\sigma_{i,j}\}_{j=0}^{d(d+1)}$ and $z = \{z_{i,j}\}_{j=0}^{d(d+1)}$.

It is easy to see that $\mathbb{E}_{\sigma, z} G(w, i) = \mathbb{E}[\{\sum_{j=0}^{d} c_j t_{i,j} y_i, 0 x_i^T \} | \hat{i}] = \hat{G}(w, i)$, which is due to the fact that $\mathbb{E} t_{i,j} = (y_i(w, x_i))^i$ and each $t_{i,j}$ is independent. We now calculate the variance for this term with fixed $i$. Firstly, we have $\text{Var}(y_{i,0} x_i^T) = O(\frac{1}{\epsilon^2})$. For each $t_{i,j}$, we get

$$\text{Var}(t_{i,j}) \leq O(\frac{d(d+1)}{\epsilon^2}) \text{Var}(y_{i,0} x_i^T) \text{Var}(\langle w, x_i, k \rangle) + (\mathbb{E}(w_i^T x_i, k))^2) \leq O\left( \left( \frac{d(d+1)}{\epsilon^2} \right)^{2j} \right).$$

Since function $f_\beta'$ is bounded by 1 and analytic, by Lemma 6 we know that $|a_i| \leq 1$ for each $i$. Also note that $c_k = \sum_{m=0}^{d} a_m b_{mk}$, where $|a_m| \leq 1$ is the Chebyshev coefficient of the original function $f_\beta'$ and $b_{mk}$ is the coefficient of order $k$ monomial in Chebyshev basis $\mathcal{T}_m(x)$. By (Qazi and Rahman, 2007), we have

$$|b_{mk}| \leq \max_{\theta \in [0, \frac{1}{2}]} O(\sqrt{m}^{(1 - \theta)^{1 - \frac{\theta}{1 - 2\theta} - \frac{\theta}{1 - 2\theta}}}) \leq O(\sqrt{m}^{2m}).$$

This tells that $|c_k| \leq O(d^{\frac{3}{2}})2^d$ for each $i$. In total, we have

$$\text{Var}(G(w_i, i)) \leq O(d \cdot d^{3} \cdot 4^d \cdot (\frac{d(d+1)}{\epsilon^2})^{2d \cdot \frac{p}{e^4}}) = \tilde{O}(\frac{d^{4d+4} 16^d p}{e^{4d+4}}).$$
Next we consider $\text{Var}(\hat{G}(w, i))$. Since
\[
\|\hat{G}(w, i) - f'_\beta(y_i x_i^T w) y_i x_i^T\|_2^2 = \|\sum_{j=0}^d c_j(y_i  \langle w, x_i \rangle)^j - f'_\beta(w) y_i x_i^T\|_2^2 \leq \left(\frac{\alpha}{4}\right)^2,
\]
we get
\[
\text{Var}(\hat{G}(w, i)) \leq O\left(\mathbb{E}[\|\hat{G}(w, i) - f'_\beta(y_i x_i^T w) y_i x_i^T\|_2^2] + \mathbb{E}[\|\nabla L_\beta(w; D)\|_2^2]\right) + O\left(\|\nabla L_\beta(w; D)\|_2^2\right) \leq O((\alpha + 1)^2).
\]

In total, we have $\mathbb{E}[\|G(w, i) - \hat{G}(w, i)\|_2^2] \leq \mathbb{E}[\|\hat{G}(w, i) - \hat{G}(w)\|_2^2] \leq \mathbb{E}[\|\hat{G}(w, i) - \hat{G}(w)\|_2^2] \leq O\left(\left(\frac{d^{d+2} \sqrt{\beta}}{\epsilon \sqrt{n}} + \alpha + 1\right)\right)$.

Also, we know that
\[
L_\beta(v; D) - L_\beta(w; D) < \hat{G}(w), v - w > = L_\beta(v; D) - L_\beta(w; D) - \nabla L_\beta(w; D), v - w > + \nabla L_\beta(w; D) - G(w), v - w > 
\leq \frac{1}{2\beta}\|v - w\|_2^2 + \frac{\alpha}{2},
\]
since $L_\beta$ is $\frac{1}{\beta}$-smooth and $|\nabla L_\beta(w) - G(w), v - w | \leq \frac{\alpha}{\beta}$.

Thus, $G(w, i)$ is an $\left(\frac{\alpha}{2}, \frac{1}{\beta}, O\left(\frac{d^{d+2} \sqrt{\beta}}{\epsilon \sqrt{n}} + \alpha + 1\right)\right)$ stochastic oracle of $L_\beta$. \hfill \blacksquare

**Proof [Proof of Theorem 11]**

The guarantee of differential privacy is by Gaussian mechanism and composition theorem. By Theorem 10 and Lemma 8, we have
\[
\mathbb{E}L_\beta(w_n, D) - \min_{w \in C} L_\beta(w, D) \leq O\left(\frac{d^{d+2} \sqrt{\beta}}{\epsilon \sqrt{n}} + \alpha + 1\right) + \frac{\alpha}{2} = O\left(\frac{d^{d+2} 4^d \sqrt{\beta}}{\epsilon^{2d+2} \beta \sqrt{n}} + \frac{\alpha}{2}\right).
\]

By Lemma 9, we know that
\[
\mathbb{E}L(w_n, D) - \min_{w \in C} L(w, D) \leq O\left(\beta^d + \frac{d^{d+2} 4^d \sqrt{\beta}}{\epsilon^{2d+2} \beta \sqrt{n}} + \frac{\alpha}{2}\right).
\]

Thus, if we take $\beta = \Theta\left(\frac{d^{d+2} \sqrt{\beta}}{\epsilon \sqrt{n}}\right)$ and $n = \Omega\left(\frac{d^{d+2} 4^d \beta}{\epsilon^{2d+2} \alpha^2}\right)$, we have
\[
\mathbb{E}L(w_n, D) - \min_{w \in C} L(w, D) \leq \alpha. \hfill \blacksquare
\]

**Proof [Proof of Lemma 13]** Let $g(\theta) = \mathbb{E}_{s \sim \mathcal{Q}}|s - \theta|$. Then, we have the following for every $\theta$, where $f'(\theta)$ is well defined,
\[
g'(\theta) = \mathbb{E}_{s \sim \mathcal{Q}}[1_{s < \theta}] - \mathbb{E}_{s \sim \mathcal{Q}}[1_{s > \theta}] = [f'(\theta) - f'(-1)] - [f'(1) - f'(\theta)]
\leq f'(1) - f(-1) = \frac{2f'(\theta) - (f'(1) + f'(-1))}{f'(1) - f'(-1)}.
\]
Thus, we get
\[ F'(\theta) = \frac{f'(1) - f'(-1)}{2} g'(\theta) + \frac{f'(1) + f'(-1)}{2} = f'(\theta). \]

Next, we show that if \( F'(\theta) = f'(\theta) \) for every \( \theta \in [0, 1] \), where \( f'(\theta) \) is well defined, there is a constant \( c \) which satisfies the condition of \( F(\theta) = f(\theta) + c \) for all \( \theta \in [0, 1] \).

**Lemma 18** If \( f \) is convex and \( 1 \)-Lipschitz, then \( f \) is differentiable at all but countably many points. That is, \( f' \) has only countably many discontinuous points.

**Proof** [Proof of Lemma 18] Since \( f \) is convex, we have the following for \( 0 \leq s < u \leq v < t \leq 1 \)
\[ \frac{f(u) - f(s)}{u - s} \leq \frac{f(t) - f(v)}{t - v}, \]
This is due to the property of 3-point convexity, where
\[ \frac{f(u) - f(s)}{u - s} \leq \frac{f(t) - f(u)}{t - u} \leq \frac{f(t) - f(v)}{t - v}. \]
Thus, we can obtain the following inequality of one-sided derivation, that is,
\[ f'_-(x) \leq f'_+(x) \leq f'_+(y) \]
for every \( x < y \). For each point where \( f'_-(x) < f'_+(x) \), we pick a rational number \( q(x) \) which satisfies the condition of \( f'_-(x) < q(x) < f'_+(x) \). From the above discussion, we can see that all these \( q(x) \) are different. Thus, there are at most countable many points where \( f \) is non-differentiable.

From the above lemma, we can see that the Lebesgue measure of these discontinuous points is 0. Thus, \( f' \) is Riemann Integrable on \([-1, 1]\). By Newton-Leibniz formula, we have the following for any \( \theta \in [0, 1] \),
\[ \int_{-1}^{\theta} f'(x) dx = f(\theta) - f(-1) = \int_{-1}^{\theta} F'(x) dx = F(\theta) - F(-1). \]
Therefore, we get \( F(\theta) = f(\theta) + c \) and complete the proof.

**Proof [Proof of Theorem 14]**

Let \( h_\beta \) denote the function \( h_\beta(x) = \frac{x + \sqrt{x^2 + \beta^2}}{2} \). By Lemma 13 we have
\[ f(\theta) = (f'(1) - f'(-1)) \mathbb{E}_{s \sim Q} \frac{|s - \theta|}{2} + \frac{f'(1) + f'(-1)}{2} \theta + c. \]
Now, we consider function \( F_\beta(\theta) \), which is
\[ F_\beta(\theta) = (f'(1) - f'(-1)) \mathbb{E}_{s \sim Q}[2h_\beta(\frac{\theta - s}{2}) - \frac{\theta - s}{2}] + \frac{f'(1) + f'(-1)}{2} \theta + c. \]
From this, we have
\[ \nabla F_\beta(\theta) = (f'(1) - f'(-1)) \mathbb{E}_{s \sim Q}[\nabla h_\beta(\frac{\theta - s}{2})] + \frac{f'(1) + f'(-1)}{2} - \frac{f'(1) - f'(-1)}{2}. \]
Thus, we get

\[ F_\beta(w; D) = \frac{1}{n} \sum_{i=1}^{n} F_\beta(y_i < x_i, w >). \]

For each fixed \( i \) and \( s \), we let

\[ \hat{G}(w, i, s) = (f'(1) - f'(-1)) \sum_{j=1}^{d} c_j \Pi_{k=j}^{(j+1)/2+1} \left( \frac{y_i < wT, x_i > -s_k}{2} \right) |y_i x_i^T + f'(-1). \]

Then, we have \( \mathbb{E}_{\sigma,z} \hat{G}(w, i, s) = \hat{G}(w, i, s) \). By using a similar argument given in the proof of Theorem 10, we get

\[ \text{Var}(\hat{G}(w, i, s) | i, s) \leq \tilde{O}(d^{4d+16d^4}p). \]

Thus, for each fixed \( i \) we have

\[ \mathbb{E}_s \hat{G}(w, i, s) = \hat{G}(w, i) = (f'(1) - f'(-1)) \mathbb{E}_{a \sim \rho} \sum_{j=1}^{d} c_j \left( \frac{y_i < w, x_i > -s}{2} \right) |y_i x_i^T + f'(-1). \]

Next, we bound the term of \( \text{Var}(\hat{G}(w, i, s) | i) \leq O(d) \).

Let \( t_j = \Pi_{k=j}^{(j+1)/2+1} \left( \frac{y_i < wT, x_i > -s_k}{2} \right) \). Then, we have

\[ \text{Var}(t_j) \leq \Pi_{k=j}^{(j+1)/2+1} |y_i|^2 \text{Var}(y_i x_i^T > -s_k) \leq O(1). \]

Thus, we get

\[ \text{Var}(\hat{G}(w, i, s) | i) \leq O(d) \sum_{j=1}^{d} c_j^2 \text{Var}(t_j) = O(d \times d^3 \times 4^d = O(d^4d^d). \]

Since \( \mathbb{E}_s \hat{G}(w, i) = \hat{G} = \frac{1}{n} \sum_{i=1}^{n} \hat{G}(w, i) \), we have \( \text{Var}(\hat{G}(w, i)) \leq O((\alpha + 1)^2) \) by a similar argument given in the proof of Theorem 10. Thus, in total we have

\[ \mathbb{E}\|G(w, i, s) - \hat{G}\| \leq \tilde{O}((\frac{d^{2d+2}4^d}{\epsilon^{2d+2}} + \alpha + 1 + d^22^d)^2) = \tilde{O}((\frac{d^{2d+2}4^d}{\epsilon^{2d+2}} \sqrt{p})^2). \]

The other part of the proof is the same as that of Theorem 10.

\[ \text{Proof [Proof of Lemma 16]} \]

Let \( g(x) = \mathbb{E}_{u \sim \rho} < u, x > \). Then, we have the following properties:

- For every \( x, y \) if \( \|x\|_2 = \|y\|_2 \), then \( g(x) = g(y) \). This is due to the rotational symmetry of the \( \ell_2 \)-norm ball.
- For any constant \( \alpha \), we have \( g(\alpha x) = |\alpha| g(x) \).
Thus, for every $x \in \mathbb{R}^p$, we have $g(x) = \|x\|2g(\frac{x}{\|x\|^2}) = \|x\|2g(e_1)$, where $e_1 = (1, 0, \cdots, 0)$.

Next we calculate $g(e_1) = E_{x \sim P}|x_1|$. Let $s_p(r)$ denote the area of a $p - 1$-dimensional sphere with radius $r$. Then, we have $s_p(r) = \frac{\pi^{\frac{p}{2}}}{\Gamma(\frac{p}{2} + 1)}r^{p-1}$. Thus, we get

$$E_{x \sim P}|x_1| = \frac{2}{s_p(1)} \int_0^1 s_{p-1}(\sqrt{1-r^2})rdr.$$  

By changing the coordinate $r = \sin(\theta)$, we then have

$$E_{x \sim P}|x_1| = \frac{2}{s_p(1)} \int_0^{\pi} s_{p-1}(\cos(\theta)) \sin(\theta) \cos(\theta) \cos(\theta) d\theta = \frac{2s_{p-1}(1)}{s_p(1)} \int_0^{\pi} \cos^{p-1}(\theta) \sin(\theta) d\theta.$$  

Also, since $\int_0^{\frac{\pi}{2}} \cos^{p-1}(\theta) \sin(\theta) d\theta = \frac{1}{p}$, we obtain

$$E_{x \sim P}|x_1| = \frac{2s_{p-1}(1)}{s_p(1)p} = \frac{2(p-1)\pi^{\frac{p-1}{2}}\Gamma(\frac{p}{2} + 1)}{p\pi^{\frac{p}{2}}\Gamma(\frac{p-1}{2} + 1)} \cdot \frac{1}{p} = \frac{2\Gamma(\frac{p}{2})}{\sqrt{\pi}p\Gamma(\frac{p-1}{2})} = O\left(\frac{1}{\sqrt{p}}\right),$$

where the last inequality comes from the Stirling’s approximation of the $\Gamma$-function. Hence, we have $\|x\|_2 = \frac{\sqrt{\pi}p\Gamma(\frac{p-1}{2})}{2\Gamma(\frac{p}{2})}g(x)$. 

**Proof (Proof of Theorem 17)**

By Lemma 16, we can see that the optimization problem becomes the following

$$L(w; D) = \frac{C}{n} \sum_{i=1}^n E_{u \sim P}[<u, \frac{w-x_i}{2}>].$$

Let $\tilde{L}_\beta(w; D)$ denote the following function

$$\tilde{L}_\beta(w; D) = \frac{C}{n} \sum_{i=1}^n E_{u \sim P}[2h_\beta(<u, \frac{w-x_i}{2}>) - <u, \frac{w-x_i}{2}>].$$

Then, we have

$$\nabla \tilde{L}_\beta(w; D) = \frac{C}{n} \sum_{i=1}^n E_{u \sim P}[2u^T h_\beta(<u, \frac{w-x_i}{2}>) - u^T \frac{w-x_i}{2}].$$

Thus, we know that $|\tilde{L}_\beta(w; D) - L(w; D)|_\infty \leq O(C\beta)$, and $\tilde{L}(w; D)$ is $O(\frac{C}{\beta})$-smooth and convex.

Now, consider the term $\tilde{G}(w, i, u) = u_0^T \left[ \sum_{j=1}^d c_j t_{i,j} - \frac{1}{2} \right]$.

For each fixed $i, u$, we know that

$$E_0 \tilde{G}(w, i, u) = \tilde{G}(w, i, u) = u_0^T \left[ \sum_{j=1}^d c_j \Pi_{k=j(j-1)/2+1}^{d(j+1)/2} \left( \frac{<u_k, w-x_i>}{2} \right) - \frac{1}{2} \right].$$

17
Thus, by a similar argument given in the proof of Theorem 11 and the fact that $\|u_k\|_2 \leq 1$, we have

$$\text{Var}(\hat{G}(w, i, u)) \leq \tilde{O}(d \times d^3 \times 4^d(d + 1) \frac{d}{e^2}) = \tilde{O}(\frac{8^d d^{d+4}}{e^{2d}}).$$

Next, for each fixed $i$, we have

$$\mathbb{E}_u \hat{G}(w, i, u) = G(w, i) = \mathbb{E}_{u \sim P}[u^T \left( \sum_{j=1}^{d} c_j \left( \frac{<u, w - x_i>^2}{2} - 1 \right) \right)].$$

Thus, we get

$$\text{Var}(\hat{G}(w, i, u)) \leq O(d^4 d^4).$$

For the term $\bar{G}(w, i)$, by a similar argument given in the proof of Theorem 11, we know that

$$\mathbb{E}_i \bar{G}(w, i) = \bar{G}(w) = \frac{1}{n} \sum_{i=1}^{n} \mathbb{E}_{u \sim P}[u^T \left( \sum_{j=1}^{d} c_j \left( \frac{<u, w - x_i>^2}{2} - 1 \right) \right)].$$

Thus, we have

$$\text{Var}(\bar{G}(w, i)) \leq O((\frac{d}{e^2} + 1)^2).$$

In total, we have

$$\text{Var}(G(w, i, u)) \leq \tilde{O}((\frac{C}{\sqrt{e^2}}) + C^2).$$

This means that $G(w, i, u)$ is an $(\frac{d}{e^2}, O(C^{\sqrt{e^2}} + C))$ stochastic oracle of $\hat{L}(w; D)$.

By Lemma 8, we know that after $n$ iterations, the following holds

$$\mathbb{E}[\hat{L}(w_n; D)] - \min_{w \in C} \hat{L}(w; D) \leq \Theta(\frac{C}{\beta} \times \frac{C\sqrt{8^d d^{d+2}}}{\sqrt{ne^d}} + \frac{\alpha}{2}).$$

By the relation between $\hat{L}(w; D)$ and $L(w; D)$, we finally get

$$\mathbb{E}[L(w_n; D)] - \min_{w \in C} L(w; D) \leq \Theta(\frac{C}{\beta} \times \frac{C\sqrt{8^d d^{d+2}}}{\sqrt{ne^d}} + \frac{\alpha}{2} + C\beta).$$

Taking $\beta^2 = \Theta(\frac{C(2\sqrt{2})^{d+2}}{\sqrt{ne^d}})$, we get the proof.
